
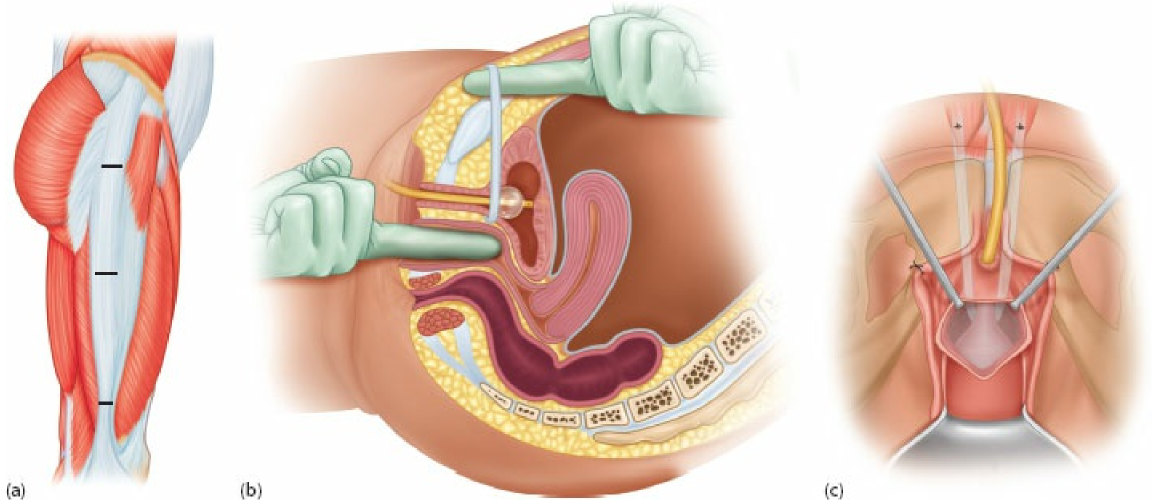

Figure 70.8 Fascia lata sling. (a) Diagram showing the skin markings and incisions required to mobilize a strip of fascia lata from the lateral thigh. (b and c) Original technique described by Govier for placing a fascia lata sling around the urethra and sutured to itself over the rectus sheath.

Some very small RCTs in which the quality of study was considered to be very poor have been left out. Six RCTs comparing rectus fascia to other interventions are reviewed involving 514 women (326 in one trial) [12,14,90–93]. A further 16 studies are reviewed, which present either a case series [94–103] or one arm of a cohort study [104–108] of women receiving autologous RF, involving over 1800 women in total. The single large-scale RCT [12] shows that the efficacy of RF is superior to Burch colposuspension though the risk of adverse events is higher. Guerrero et al. [14] showed that the efficacy and risk of shorter suspended slings equate to full-length slings, and this evidence reflects the changing use of rectus fascial slings in which the use of full lengths has become unusual and shorter lengths the norm.

Rates of urinary retention range from 0% to 18%. Postoperative pain (of any type) ranges from 0% to 25% and de novo urgency from 2% to 30%, the median value being 15% in those studies that reported this outcome.

A Cochrane Review in 2005 of traditional sling surgery [109] failed to draw any conclusions about the relative efficacy or risk of various sling procedures. Complications of autologous sling have included hemorrhage, wound infection, and bladder perforation. Long-term complications include de novo urgency, voiding difficulty, lower abdominal pain, incisional hernia, and erosion. However, a well-funded study reported by Albo establishes the relative efficacy and risk of RF sling and Burch with confidence [12]. Additionally, according to recent AUA guidelines, the estimated cured/dry rates for an autologous sling (rectus fascia or fascia lata) ranged between 90% at 12–23 months and 82% at 48 months or longer [5]. This is supported by the recent Stress Incontinence Surgical Treatment Efficacy Trial was performed, which was a multicenter RCT of 655 women randomized to autologous sling versus Burch. The study showed a higher success rate in the treatment of stress incontinence with the autologous fascial sling (47% vs. 38%, $p = 0.01$) but also a higher complication profile when compared to the traditional Burch repair [12].

Donor Materials

The major disadvantage of all autologous grafts used for sling surgery is that they require significant dissection, and this brings with it potential for morbidity—especially bleeding and pain.

Consequently, the use of donor materials to perform a similar procedure has been extensively explored over the last 15 years. By using preprepared strips of donor tissue, a sling procedure becomes minimally invasive with the need only for a small suburethral incision and one or two small suprapubic incisions. The possibility of local anesthetic procedures carried out in a day case setting, with the commensurately low use of hospital resources, is highly attractive to patients and health commissioners alike, even if the cost of the material used is relatively high.

Knowledge of how biological grafts behave in humans with the passage of time is scant though many animal studies have been done to explore this question. It is known that autologous fascia will become rapidly infiltrated by neovascularization and fibroblasts. Whether the grafted tissue remains intact or is completely replaced by new fibrosis however is not clear. Woodruff et al. biopsied 24 explanted grafts and found that, while host tissue infiltration was greatest with polypropylene meshes, autologous fascia and porcine dermis degraded, with the latter became encapsulated with no sign of tissue infiltration [110]. Lemer studied the mechanical properties of a variety of implantable materials and showed that solvent-dried fascia lata and dermal allografts were as strong as autologous fascia but that freeze-dried fascia lata was substantially weaker [111].

Although Karram (1990) was first to describe fascia lata in 10 patients [112], Beck was probably the first person to use the technique since he wrote up a 22-year series in 1990, having started in 1965 [113]. Beck reported a 100% success rate for his most recent 148 cases—out of 170—stating that failure occurred in 13 of his first 22 patients. However, only 12 patients of this series were followed for more than 5 years, and whether the women themselves were asked if they felt cured is not clear.

ALLOGRAFTS

Allograft (cadaveric) fascial material can be implanted into humans once all cellular and antigenic material has been removed. This is achieved by freeze-drying, by fresh freezing, or by solvent dehydration techniques. All of these have been used in women with stress incontinence. The risk of disease transmission (e.g., hepatitis B and C, HIV, and variant CJD) has always been a fear, but manufacturers offer strong reassurances that this is theoretically impossible. Selection of donors for allograft material involves rigorous screening for disease [114], and there have been no reported cases as yet.

Once implanted, allograft material goes through a similar process of fibroblast invasion and neovascularization to autologous tissue, but the timing of these steps is unpredictable—hence, there may be a period of relative weakness before step 2 when grafts can give way.

One RCT was found, which compared cadaveric fascia lata to intravaginal slingplasty [115], one of the new generations of minimally invasive techniques. The data are limited to short-term follow-up, and no conclusions can be drawn about relative efficacy.

A further 10 case series [116–125] and seven cohort studies [105,106,120,126–130] including over 1000 women who received cadaveric fascia lata are reviewed. Subjective cure ranged from 40% to 98% and objective cure from 17% to 68%. However, the range of follow-up and outcome measures, as usual, varies so much that it is impossible to draw conclusions about the relative merits of freeze-dried versus solvent-dried preparations or how this procedure compared to other autologous or synthetic grafts. One study [124], which used bone anchors, shows progressive deterioration over time, but it is not clear whether the failure is related to the material or the method of anchoring used. Fewer complications were reported for fascia lata than for other types of autologous fascia but not in the context of randomized trials.

The other main allograft material that has been used is lyophilized dura mater. There are data from a case series [131] and one RCT comparing dura mater to Burch [132]. The limited medium-term results suggest a higher efficacy than Burch but with more urgency and voiding problems.

XENOGRAFT

Xenograft (animal) tissues have also been used and are prepared using similar techniques. After going through a stepwise process of cellular destruction and sterilization, these materials essentially provide a framework of collagen, which lends itself to invasion with fibroblasts and new blood vessels. Whether the tissues become completely replaced by host fibrous tissue or remain intact remains unclear.

Of the available xenografts materials, more has been written about porcine dermis. Xenoderm was a dried preparation requiring preliminary soaking before implantation, while Pelvicol is a prewetted dermal graft that handles much like a piece of autologous fascia. One early RCT with 12-month follow-up promised excellent outcomes from Pelvicol when compared to TVT [133]. Case series presenting early outcomes from Pelvicol implantation [133] promised encouraging efficacy, but longer-term studies have shown unacceptable failure rates.

Two case series [134,135] and one RCT [48] reported the use of Xenoderm. The material was awkward to handle and was withdrawn from the market by the manufacturers in the mid-1990s.

Pelvicol has been reported in two case series [136,137] and in three cohort studies [107,129,138], one reporting high failure rates at medium-term follow-up. The two RCTs involving Pelvicol present totally different outcomes, one with 89% subjective cure at 12 months [133] and the other reporting (Guerrero) only a 20% objective cure at 12 months.

Small intestinal submucosa has also been used for urethral support as well as many other uses. There are no data from RCTs, but two case series focus exclusively on women with stress incontinence [76,139]. There have been conflicting reports on the extent of tissue reaction related to the use of this tissue [140,141].

Synthetics

As aforementioned, the long-term durability of these procedures with graft materials has been questioned, with reports of graft failure and declining success rates over time [5]. As such, the midurethral synthetic sling was developed, replacing the pubovaginal sling as the gold standard for stress incontinence, and thus, polypropylene mesh is worth mentioning here as a graft material though it is discussed at length in another chapter [142].

The AUA SUI guideline panel's meta-analysis estimated cured/dry rates in patients without prolapse treatment ranging from 81% to 84% at all time points, which is comparable to the medium-term results for the Burch suspensions and autologous fascial slings, showing comparable efficacy between midurethral slings and autologous slings in the surgical treatment of stress incontinence [5].

However, in 2008, the FDA issued a statement cautioning against the vaginal placement of mesh for both pelvic organ prolapse and urinary incontinence. In 2011, an updated FDA warning stated that most mesh-related complications were associated with the transvaginal placement of mesh for pelvic organ prolapse, and there were insufficient data to recommend against using mesh for SUI [143]. Nonetheless, patients are not necessarily aware of these differences and should be counseled appropriately prior to any surgical intervention, especially when voicing concerns about mesh placement [144]. As such, patients should be informed that synthetic slings are considered a first-line treatment option for stress incontinence. In fact, the American Urogynecologic Society and Society of Urodynamics, Female Pelvic Medicine, and Urogenital Reconstruction issued a joint statement in 2014 strongly supporting the use of polypropylene mesh for the treatment of SUI, stating that the midurethral sling procedure is safe and effective and remains the standard of care for the treatment of SUI [145].

BULKING AGENTS

Coaptation of the urethral mucosa is thought to be an important contributory mechanism in maintaining continence, the effect being apparently conferred through submucosal vascular cushions. Attempts to improve this coaptation effect through minimally invasive injection techniques have challenged clinicians for over 50 years. The mechanics of urethral bulking seem to be that by increasing the passive resistance of the urethra, leakage is diminished. The ideal injection material should be nonimmunogenic, thus causing no localized inflammatory reaction; stable chemically; nondegradable so that its bulking effect remains; and easy to inject to minimize the difficulties of surgery. Since most of these agents consist of particles suspended in a carrier gel or fluid, it is also important that the particles are large enough not to be absorbed and risk migration, and for as little carrier gel as possible to be absorbed, which results in reduction in efficacy.

The first injection techniques to be tried and reported were by Murless in 1938 [146]. He used sclerosing agent, sodium morrhuate, in 20 women and achieved continence in 17 of them, presumably through the effect of scarring and contracture of the vaginal wall. Quakels in 1955 used paraffin to achieve the same effect, but reports of pulmonary embolism stopped the technique [147].

In 1964, Politano and Harper [148] began using polytetrafluoroethylene (PTFE, Teflon, Polytef) paste for injection into the vesicoureteric junction, and numerous reports followed over the next 30 years of its use in the paraurethral tissues [149–151]. The speed of this procedure and its apparent efficacy, even if this was lower than conventional surgery, appeared to offer a truly minimally invasive alternative to surgery for women who wanted to avoid the risk of morbidity. However, reports of serious complications began to emerge including periurethral abscess [152,153] pulmonary granulomata [154,155], and obstructive uropathy [156], and long-term outcomes were observed to deteriorate from 80% initial response to 27% at 3 years [157] and to 33% at 5 years [158]. As a consequence of these reports, PTFE paste lost its licensing for use as a bulking agent from the FDA, and NICE in 2006 recommended that it should not be used for this purpose.

Gonzales de Garibay, in 1989, reported an alternative bulking agent that utilized autologous fat cells obtained by microliposuction and reinjected into the periurethral tissues [159]. This had the major advantage of being autologous tissue with no immunogenicity problems, cheapness, and ease of use. However, the initial results were disappointing with only 23% of women improved at 12 months [160] and none in another study [161] though Palma achieved 64% cure at 12 months by means of repeated injections [162].

The only RCT carried out in this area, before the advent of newer injectable materials, was by Lee et al. in 2001 [163]. Of the 68 women enrolled, 35 received fat and 33 received saline injections of whom 22% and 20%, respectively, were improved at three months. The lack of convincing efficacy together with further reports of pulmonary embolism, in this case leading to death, have resulted in the use of autologous fat also being officially discouraged both by NICE (2006) [2] and by ICI [4].

Much further research and clinical development has continued into the modern era using a variety of injectable materials. In brief, recently developed injectables such as silicon particles and calcium hydroxylapatite can result in an improvement in incontinence, but patients may not necessarily achieve dryness. According to the 2012 Cochrane Review on injection therapy for urinary incontinence, there is insufficient evidence in the use of bulking agents to guide clinical practice, and this is discussed in detail in another chapter [164].

CONCLUSIONS

This chapter has described some obsolete operations and others that marked a turning point in surgical practice. Nevertheless, understanding these procedures is paramount as our current surgical treatment options are based on these fundamental surgical principles.

The continued use of what some would regard as archaic may be defensible in experienced hands, where the outcomes are well monitored and known to surgeon and patient alike. Historically, objective data in stress incontinence surgery are sparse, but as new advances emerge, researchers understand the importance of RCTs. Thus, scrutiny of surgical technique and materials is becoming commonplace, ultimately providing better patient care, which is the ultimate goal.

Retropubic Urethropexy

Dudley Robinson and Linda Cardozo

INTRODUCTION

The term stress urinary incontinence may be used to describe the symptom or sign of urinary leakage on coughing or exertion but should not be regarded as a diagnosis. A diagnosis of urodynamic stress incontinence can only be made after urodynamic investigation, and this is defined as the involuntary leakage of urine during increased abdominal pressure in the absence of a detrusor contraction [1].

Stress incontinence is the most commonly reported type of urinary incontinence in women. In a large epidemiological study of 27,936 women from Norway [2], overall, 25% of women reported urinary incontinence, of whom 7% considered it to be significant, and the prevalence of incontinence increased with age. When considering the type of incontinence, 50% of women complained of stress, 11% urge, and 36% mixed incontinence. The prevalence of urinary incontinence among nulliparous women ranged from 8% to 32% and increased with age. In general, parity was associated with incontinence, and the first delivery was the most significant. In the age group 20–34 years, the relative risk of stress incontinence was 2.7 (95% CI: 2.0–3.5) for primiparous women and 4.0 (95% CI: 2.5–6.4) for multiparous women. There was a similar association for mixed incontinence although not for urge incontinence [3].

PATHOPHYSIOLOGY

There are various different underlying causes that result in weakness of one or more of the components of the urethral sphincter mechanism (Table 71.1).

The bladder neck and proximal urethra are normally situated in an intra-abdominal position above the pelvic floor and are supported by the pubourethral ligaments. Damage to either the pelvic floor musculature (levator ani) or pubourethral ligaments may result in descent of the proximal urethra such that it is no longer an intra-abdominal organ, and this results in leakage of urine per urethram during stress.

This theory has given rise to the concept of the “hammock hypothesis,” which suggests that the posterior position of the vagina provides a backboard against which increasing intra-abdominal forces compress the urethra [4]. This is supported by the fact that continent women experience an increase in intraurethral closure pressure during coughing [5]. This pressure rise is lost in women with stress incontinence although it may be restored following successful continence surgery [6].

In addition to pelvic floor damage, there is also evidence to suggest that stress incontinence may be caused by primary urethral sphincter weakness or intrinsic sphincter deficiency (ISD). In order to distinguish this type of stress incontinence from that caused by descent and rotation of the bladder neck during straining, the Blaivas Classification has been described based on videocystourethrographic observations [7]. This proposes that type I and type II stress incontinence are caused principally by urethral hypermobility, whereas type III, or ISD, is caused by a primary weakness in the urethral sphincter. Factors associated with ISD are pudendal innervation [8], integrity of the striated urethral sphincter [9], urethral smooth muscle, the urethral mucosa, and submucosal urethral cushions.

More recently, the “midurethral theory” or “integral theory” has been described by Petros and Ulmsten [10]. This concept is based on earlier studies suggesting that the distal and midurethra play an important role in the continence mechanism [11] and that the maximal urethral closure pressure is at the mid-urethral point [12]. This theory proposes that damage to the pubourethral ligaments supporting the urethra, impaired support of the anterior vaginal wall to the mid-urethra, and weakened function of part of the pubococcygeal muscles, that insert adjacent to the urethra, are responsible for causing stress incontinence.

RETROPUBIC URETHROPEXY

History

In 1923, Victor Bonney observed that “incontinence depends in some way upon a sudden and abnormal displacement of the urethra and urethrovesical junction immediately behind the symphysis” [13]. This association of urethral hypermobility and stress urinary incontinence was also noted by Watson in 1924 [14] although it was not until 1949 that the first retropubic procedure for stress incontinence was described by Marshall et al. [15]. This early example of cooperation between two urologists and a gynecologist described “the correction of stress incontinence by simple vesicourethral suspension” in a series of 50 patients including 12 men with postprostatectomy stress incontinence. They reported an initial 82% success and 7% improvement rate, and the procedure became popular in the management of women with stress urinary incontinence.

In 1961, John Burch described his modification of the Marshall–Marchetti–Krantz procedure when he encountered difficulty in suture placement. Rather than placing the sutures in the periosteum of the pubic symphysis, he described the attachment of the anterolateral vagina to the pectineal ligament using three sutures on each side [16]. He initially reported a series of 53 patients with 100% success rate and subsequently published a 9-year series of results in 1968 with a 93% success rate and an 8% incidence of enterocele [17].

Over the last 50 years, the Burch colposuspension has remained an efficacious and durable procedure in the surgical management of stress urinary incontinence and has undergone several modifications. In 1976, Tanagho recommended avoiding dissection of the midline neurovascular supply to the urethra to reduce the risk of causing ISD [18] and also observed that overcorrection at the level of the bladder neck did not improve success rates but led to a higher incidence of voiding difficulties [19]. This observation led to the widely adopted technique of providing support to the bladder neck without overelevation.

Table 71.1 Causes of Urodynamic Stress Incontinence

- Urethral hypermobility
  - Urogenital prolapse
- Pelvic floor damage or denervation
  - Parturition
  - Pelvic surgery
  - Menopause
- Urethral scarring
  - Vaginal (urethral) surgery
  - Incontinence surgery
  - Urethral dilatation or urethrotomy
  - Recurrent urinary tract infections
  - Radiotherapy
- Raised intra-abdominal pressure
  - Pregnancy
  - Chronic cough (bronchitis)
  - Abdominal/pelvic mass
  - Fecal impaction
  - Ascites
  - Obesity

With the increasing trend to minimal access techniques, the laparoscopic colposuspension was first reported in 1991 [20]. Although many authors have reported excellent short-term subjective results from laparoscopic colposuspension [21], early studies showed inferior results to the open procedure [22,23].

More recently, the description of the “integral theory” has revolutionized the concept behind the traditional approach to retropubic surgery and has led to the introduction of the mid-urethral tapes using a retropubic [24,25] and transobturator approach [26]. While these procedures have largely replaced retropubic urethropexies in clinical practice, the colposuspension still has an important role in the management of women with stress urinary incontinence.

Marshall–Marchetti–Krantz

Operative Technique

The patient is placed in the modified lithotomy position and a Foley catheter inserted. A low transverse suprapubic incision is made and the retropubic space entered. The bladder neck and proximal urethra are then mobilized from the vagina with the assistance of the index and middle fingers of the surgeon's left hand placed within the vagina. Between one and three sutures are inserted on each side. Each suture should include the paraurethral tissue, lateral wall of the urethra, and the vaginal wall. The sutures are then fixed to the periosteum of the superior pubic ramus or the perichondrium of the symphysis pubis. Further sutures may then be placed between the anterior surface of the bladder and rectus abdominis to provide additional elevation and support (Figure 71.1). At the end of the procedure, a Redivac drain should be placed in the retropubic space and a suprapubic catheter used for postoperative urinary drainage. When the urinary residuals are less than 100 mL, the catheter may be removed.

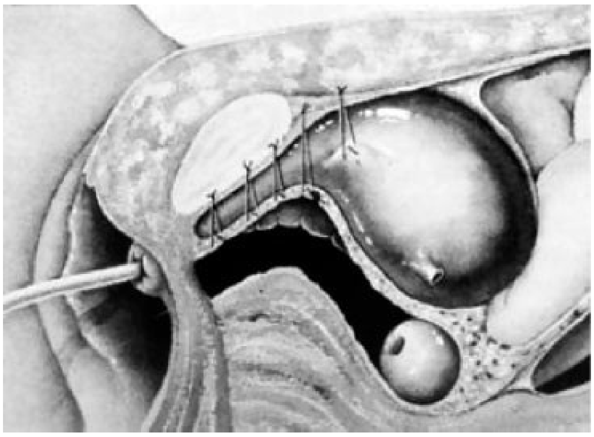

Figure 71.1 Marshall–Marchetti–Krantz.

Results

Overall, there have been 58 published papers between 1951 and 1998 that have included 3238 patients, although many of these studies were retrospective case series. Overall cure rates were approximately 88% with results of 92% and 84% in primary surgery and redo surgery, respectively [27].

While there has been no formal Cochrane Review of the procedure, there has been a review of comparative trials with colposuspension [28–30]. Although the early results of MMK are not significantly different to colposuspension, both subjective and objective cures were found to be significantly better following colposuspension than after MMK at 1–5 years (RR 0.44; 95% CI: 0.25–0.77) [31].

In addition, two further studies comparing MMK with colposuspension were identified by the National Collaborating Centre for Women's and Children's Health (NCCWCH) in the United Kingdom. While one study showed significantly better objective outcome based on negative stress test in the MMK group (93% vs. 53%; $p = 0.02$) [32], the other showed significantly better subjective outcomes in the colposuspension group at 2-year follow-up (59% vs. 49%; $p = 0.02$) [33]. More recently, a case series comparing MMK with tension-free vaginal tape (TVT) has been published in 228 women with a 10-year follow-up. The short-term success in the MMK was 89%, although this fell to 68.2% at 5 years and only 32% at 10 years. Conversely, the cure rate for TVT was 90.0% initially and 84.3% at 5 years [34].

Data regarding the long-term success of MMK are more limited, although six studies have been reported with a mean cure rate of 58% reported between 4 and 15 years [35–40]. Two of these long-term studies have shown the efficacy rates to reduce over time with reported success rates being 90% and 77% at 1 year, 86% and 57% at 5 years, and 72% and 28% at 10 years [34,36].

Complications

The major complication associated with the MMK procedure is osteitis pubis, which has been reported to occur in 2.5%–7% of cases [41,42]. Patients present with a history of severe suprapubic pain radiating into the groins and perineum, and a bone scan shows increased uptake in the suprapubic region. Long-term antibiotic treatment over several months is generally required, and occasionally, a retropubic abscess may require drainage.

Colposuspension

Operative Technique

The patient is positioned on the operating table in the modified lithotomy position using Lloyd–Davies stirrups. The abdomen and vagina are then prepared as a sterile operating field in order to allow the manipulation of the vaginal fornices and bladder neck by the surgeon. An indwelling Foley catheter is then inserted and the balloon inflated with 6 mL of water to allow the identification of the bladder neck.

A low transverse suprapubic incision approximately 1 cm above the pubic symphysis is made and the rectus fascia incised taking care not to open the peritoneal cavity unless a concomitant intra-abdominal procedure is being performed. A Turner–Warwick self-retaining retractor may then be inserted (Figure 71.2a), and the retropubic space (cave of Retzius) is opened using both sharp and blunt dissections (Figure 71.2b) until the white paravaginal tissue lateral to the bladder neck and urethra is identified (Figure 71.2c). Vaginal manipulation is also used to further assist in the elevation of the lateral vaginal fornices while the bladder is swept medially. Two to four delayed absorbable sutures are inserted into the paravaginal fascia on each side and each tied down onto the vaginal tissue ensuring hemostasis. The first suture is at the level of the bladder neck and 1 cm lateral (Figure 71.2d). The suture is then passed vertically through the ipsilateral iliopectineal ligament, taking care not to pull the bladder neck open, and left untied. Each subsequent suture is then placed 1 cm lateral and 1 cm cephalad (Figure 71.2e) and all left untied before the sutures are placed on the opposite side (Figure 71.2f). Once all the sutures are positioned correctly, each lateral fornix is elevated by an assistant allowing the sutures to be tied easily without tension (Figure 71.2g). After checking for adequate hemostasis, the retropubic space is drained with a Redivac suction drain and the abdomen closed (Figure 71.2h and i). The bladder is left on free drainage using a suprapubic catheter for 48 hours prior to starting a clamping regimen. When the urinary residuals are less than 100 mL, the suprapubic catheter may be removed.

Results

The 4th International Consultation on Incontinence (ICI) [27] on 33 published randomized trials of colposuspension in addition to the following:

- Seven trials comparing colposuspension with anterior colporrhaphy
- Four trials comparing colposuspension with Marshall–Marchetti–Krantz
- Nine trials comparing colposuspension with needle suspension
- One trial comparing colposuspension with abdominal paravaginal repair
- Seven trials comparing colposuspension with traditional sling procedures
- Five trials comparing colposuspension with TVT
- One trial comparing colposuspension with transobturator tape (TOT)
- Seven trials comparing open colposuspension with laparoscopic colposuspension

In total, these studies included 4161 women of whom 1900 were randomized to colposuspension. Additionally, there have been two recent meta-analyses performed by the Cochrane group [31] and also by the NCCWCH within the United Kingdom. Since the 4th report from the ICI, a further two additional studies have been published comparing retropubic mid-urethral slings to open colposuspension in the updated 5th report [43].

When considering all studies of colposuspension, objective cure rates varied between 59% and 100% (median 80%) and subjective cure rates between 71% and 100% (median 88%). Based on these results, colposuspension would appear to have comparable objective and subjective outcomes to traditional sling procedures and to both retropubic and transobturator mid-urethral tapes. The evidence would also appear to suggest that outcomes with colposuspension are significantly better than those achieved with anterior colporrhaphy, needle suspension procedures, paravaginal repair, and the Marshall–Marchetti–Krantz procedure.

Outcome: Colposuspension

Historically, there have been many prospective case series and cohort studies assessing the efficacy of colposuspension with some studies providing long-term follow-up data up to 20 years (Table 71.2).

In addition, there have also been three reported meta-analyses. The first of these was reported by Jarvis in 1994 [41] who reviewed 1726 women with a follow-up of at least 1 year and a mean objective success rate of 84.3%. Very similar results were reported from a meta-analysis of 2196 women reported by the American Urological Association in 1997. Overall mean objective cure rates were 84% at 48 months (CI: 79%–88%) with a follow-up to at least 4 years [44]. More recently, the Cochrane group has published a meta-analysis of 39 randomized controlled trials involving 2403 women with a mean follow-up of 1 year. Objective cure rates were found to be 85%–90%, and there was a slow decline in cure rates to 70% over 5 years [31].

Table 71.2 Subjective and Objective Outcome of Colposuspension: Case Series and Cohort Studies

Study	No.	Objective outcome (%)	Subjective outcome (%)	Follow-up (months)

Burch [17]	143	—	93	10–60
Stanton et al. [45]	32	80	—	6–30
Milani et al. [46]	44	79	—	>12
Cardozo and Cutner [47]	100	80	—	6–12
Herbetsson and Iosif [48]	72	90	—	84–144
Feyereisl et al. [49]	87	82	—	60–120
Alcalay et al. [50]	109	90	—	120–240
Langer [51]	127	94	—	120–180

Outcome: Redo Colposuspension

There have been several case series reporting the outcome of colposuspension following failed previous surgery (Table 71.3). While success rates tend to be slightly lower following failed previous continence surgery, continence rates between 65% and 86% are generally reported indicating the efficacy of colposuspension as a secondary procedure.

Outcome: Colposuspension versus Anterior Colporrhaphy

There have been seven trials comparing colposuspension with anterior colporrhaphy (Table 71.4) and one meta-analysis. In general, success rates tend to be lower in the group of patients having anterior colporrhaphy as compared to colposuspension. Consequently, the 4th ICI [27] recommended that anterior colporrhaphy should not be used alone in the management of stress urinary incontinence.

Outcome: Colposuspension versus Marshall–Marchetti–Krantz

There have been four trials comparing colposuspension with the Marshall–Marchetti–Krantz procedure (Table 71.5). While some studies indicate comparable success rates in the short term, the longer-term studies would suggest that efficacy is less good when compared to colposuspension. Consequently, the 4th ICI concluded that there is no evidence to support the use of the Marshall–Marchetti–Krantz procedure over colposuspension [27].

[33]

Outcome: Colposuspension versus Needle Suspension Procedures

There have been nine trials comparing colposuspension with needle suspension procedures (Table 71.6). The majority of reported studies suggest that needle suspension operations are less effective than colposuspension both in the long and short term, and the 4th ICI has concluded that their use should not be recommended [27].

Outcome: Colposuspension versus Paravaginal Repair

There has been only one randomized controlled trial comparing colposuspension with paravaginal repair in 72 women with a follow-up at 24 months [65]. There was a significantly higher success rate in the colposuspension arm compared to the paravaginal repair arm (100% vs. 61%; $p = 0.004$), and consequently, the trial was discontinued early for ethical reasons. The 4th ICI has concluded that the evidence would suggest that abdominal paravaginal repair is less effective than colposuspension [27].

Outcome: Colposuspension versus Traditional Sling Procedures

Seven trials have compared colposuspension with traditional sling procedures (Table 71.7). The evidence suggests that traditional sling procedures have similar efficacy to colposuspension although it may be associated with a higher incidence of voiding difficulties [27]. While there is considerable evidence to support the use of autologous fascial slings, adverse events may be more common following the use of synthetic sling materials.

Outcome: Colposuspension versus Tension-Free Vaginal Tape

There have been seven reported trials comparing colposuspension with the TVT (Table 71.8). While efficacy rates are similar for both procedures, operation time, hospital stay, and time to resume normal activities were significantly shorter with the TVT [76,79,81]. However, the number of bladder injuries was found to be higher in those women having a TVT when compared to colposuspension [76,79]. Conversely, significantly, more patients were found to have voiding difficulties following colposuspension [76] and subsequently were taught self-catheterization. In addition, significantly more women required surgery for urogenital prolapse following colposuspension [78]. The 4th ICI has suggested, based on the available evidence, that TVT is more effective than colposuspension and equally effective as the more traditional sling procedures [27]. These findings are also supported by the more recently published 5th report [43].

Outcome: Colposuspension versus Transobturator Tape

To date, there has been only one randomized controlled trial comparing colposuspension to a TOT procedure [85] in 100 women followed up at 12 and 24 months. Success rates at 12 months were 80% and 86% in the colposuspension and TOT, respectively, and were no different at 24 months (84% and 88%, respectively).

Outcome: Colposuspension versus Laparoscopic Colposuspension

There have been seven reported studies comparing open and laparoscopic colposuspension (Table 71.9). In addition to the published studies, the Cochrane group has also reported a meta-analysis of 22 studies including laparoscopic colposuspension [86]. In comparison to open colposuspension, they found subjective cure rates from 58% to 96% in the open group compared to 62% to 100% in the laparoscopic group at 18-month follow-up. This resulted in a nonsignificant 5% lower relative subjective cure rate for the laparoscopic procedure (RR 0.95; 95% CI: 0.90–1.00). Objective cure rates, using cough test or pad test, were found to be lower in the laparoscopic group when compared to the open colposuspension group (RR 0.91; 95% CI: 0.86–0.96) at 18 months although not at 5 years (RR 1.01; 95% CI: 0.88–1.16). However, when objective cure was assessed using repeat urodynamic studies, there was a significantly higher success rate following the open procedure (RR 0.91; 95% CI: 0.85–0.89).

Table 71.9 Comparative Studies: Colposuspension (Open) versus Laparoscopic Colposuspension (Lap)

Study	**Type of study**	**Success rate (obj/subj) open vs. lap (%)**	**Follow-up (months)**
Su et al. [92]	RCT	96 vs. 80	6
Fatthy et al. [93]	RCT	85 vs. 88	18
Cheon et al. [94]	RCT	86 vs. 85	12
Ankardal et al. [95]	RCT	92 vs. 90	12
Usten et al. [96]	RCT	81 vs. 81	3–24
Kitchener et al. [97]	RCT	70 vs. 80	24
Carey et al. [98]	RCT	80 vs. 69	24

There are only two small trials providing long-term data at 5 years comparing laparoscopic and open colposuspension, one favoring the open procedure [87] and the other the laparoscopic [88].

In light of the available evidence, the 5th ICI concluded that laparoscopic colposuspension has comparable subjective and objective outcomes when compared with open colposuspension in the short to medium term, although longer-term outcomes are unknown. Laparoscopic colposuspension has similar subjective outcome to TVT, although the objective outcome is less good [43].

COMPLICATIONS

Perioperative Complications

Common perioperative complications encountered during colposuspension include hemorrhage and lower urinary tract injury.

While major hemorrhage is rare [55], one series of 151 patients reported blood loss of over 1000 mL in 2% of cases [89] and transfusion rates have been reported to be approximately 5% (CI: 3%–8%) [43].

Bladder and urethral trauma may occur during dissection in the retropubic space, and the reported incidence of bladder injury is 1.2% [90] to 2.0% [55]. In addition, the ureters may be injured or kinked at the level of the most cephalad suture with one series of 60 cases reporting an incidence of 6.7% [91].

Postoperative Complications

Overactive Bladder

“De novo” urgency and urge incontinence may be reported, although whether this really represents new pathology or simply symptoms that were not adequately diagnosed preoperatively remains open to debate. While the exact cause may be multifactorial and partially explained by increased outflow resistance, postoperatively, there is some evidence to suggest that damage to the autonomic innervation may occur following dissection and mobilization of the bladder neck [99].

Overall, the incidence of “de novo” symptoms suggestive of overactive bladder (OAB) has been reported as 11% (CI: 8–16) [43]. These findings support the findings of earlier studies that reported an incidence of detrusor overactivity between 12% and 18.5% [49,96,100,101].

Unfortunately, there are no reliable predictors of outcome with regard to OAB, although there is some evidence to suggest that increased bladder wall thickness may be associated with a higher risk of “de novo” detrusor overactivity postoperatively [102]. Conversely, there is also evidence from some series to suggest that OAB symptoms may improve in 20% [49] to 60% [55] of women following colposuspension.

Voiding Difficulties

Voiding difficulty may occur early or late in the postoperative period. While the former may be caused by overelevation of the bladder neck at the time of the procedure [103], the latter may be related to gradual detrusor muscle compensation secondary to prolonged outflow obstruction. In addition, many women also notice that their urinary stream is slower and may need to change position to empty their bladder completely. Overall, the incidence of voiding difficulties lasting over 1 month is reported as 5% (CI: 3–5) [43], although other series have reported rates as high as 21% [76].

Urogenital Prolapse

While elevation of the anterior vaginal wall during colposuspension is effective in correcting a mild to moderate cystocele, it also results in alteration of the vaginal angle and hence a change in pressure transmission down the vaginal axis. This may exacerbate posterior vaginal wall defects and leads to an increased incidence of posterior vaginal compartment prolapse. In addition, although colposuspension offers effective support of the bladder, neck prolapse of the upper third of the anterior vaginal wall may result in a “high” cystocele.

To date, several large retrospective studies have been performed examining the outcome of colposuspension, which, as well as giving valuable outcome data in terms of cure, also provides information regarding complications. In a retrospective study of 131 women undergoing colposuspension between 1977 and 1986, 35 women (26.7%) required a total of 40 procedures to correct urogenital prolapse [104]. There was no association between age, weight, parity, menopausal status, and prior pelvic surgery, although a large cystocele preoperatively was a significant risk factor.

These findings are supported by a further follow-up study of 186 women in Finland 1 year following colposuspension in which 12% of women were found to have a rectocele or enterocele requiring surgical repair [105].

In a similar 6-month follow-up study of 74 women following colposuspension in Mexico, the site of urogenital prolapse was assessed [106]. The prevalence of urethrocele was 2.7%, cystocele 50.6%, uterine prolapse 21.3%, vault prolapse 9.3%, and enterocele 41.9%. The authors concluded that while posterior vaginal repair was effective in posterior compartment defects, a Moschcowitz procedure was not.

More recently, a 10–15-year follow-up study of 127 women undergoing Burch colposuspension has been reported [50]. The mean length of follow up was 12.4 years, and objective cure rate was 93.7%. While 18.7% of women complained of anatomical defects, the majority of these were not detected until more than 5 years following surgery implying that long-term follow-up should be mandatory. A further study of 220 women with a mean follow-up of 18 months again gives similar results: 18 (8.2%) women complained of cystocele, 32 (14.5%) rectocele, and 35 (15.9%) enterocele [107].

From these studies, it is clear that the incidence of urogenital prolapse, and in particular posterior compartment defects, increases following colposuspension. In view of these findings, it is important to counsel women regarding outcome not only in terms of cure but also in respect to the need for further pelvic floor surgery.

Sexual Dysfunction

By elevating the bladder neck and anterior vaginal wall, a colposuspension may lead to the posterior vaginal being pulled forward and upward leading to a change in the vaginal angle causing dyspareunia [108]. Postoperative sexual dysfunction has been described in 2%–8% of women following continence surgery although there were no significant differences between procedures [43].

ECONOMIC ANALYSIS

Two studies have been reported comparing a cost analysis of colposuspension in comparison to both TVT and laparoscopic colposuspension.

As part of the UK colposuspension study, a cost utility analysis was also performed. At 6-month follow-up, TVT resulted in a mean cost saving of £243 when compared to colposuspension. Differential mean quality-adjusted life year (QALY) per patient (TVT—colposuspension) was 0.01 (95% CI: −0.01–0.03). The probability of TVT being less costly than colposuspension was 100%, while the probability of TVT being more cost-effective was 94.6% if the willingness-to-pay threshold was £30,000 per additional QALY gain [109].

A cost analysis comparing laparoscopic to open colposuspension was also performed alongside the UK laparoscopic colposuspension study [110]. While laparoscopic surgery produced QALY gain, there was an additional cost when compared to open colposuspension. Healthcare resource use over the first 6-month follow-up period translated into costs of £1805 for the laparoscopic group versus £1433 for the open group. At 6 months, QALYs were slightly higher in the laparoscopic group relative to the open group. Therefore, the cost of each extra QALY (incremental cost-effectiveness ratio [ICER]) was £74,000 at 6 months. At 24 months, the laparoscopic arm also had a higher mean QALY score compared to the open group. Consequently, the ICER was effectively reduced to £9300 at 24 months.

CONCLUSIONS

Retropubic urethropexy remains a durable and efficacious surgical treatment for stress urinary incontinence in women. The description of Burch colposuspension in 1961 revolutionized the surgical approach to stress incontinence and rapidly replaced the Marshall–Marchetti–Krantz procedure.

Almost 50 years later, the available evidence demonstrates that open retropubic suspension is an effective treatment for the treatment of stress incontinence in both long- and short-term trials. Comparative studies have demonstrated that colposuspension is superior to anterior colporrhaphy and needle suspension procedures and is comparable to traditional sling procedures and laparoscopic colposuspension. The evidence from individual trials suggests that colposuspension is as effective as both retropubic and transobturator mid-urethral tape procedures, although a more recent meta-analysis has shown that overall cure rates (OR 0.61; 95% CI: 0.46–0.82; $p = 0.00009$) and objective cure rates

(OR 0.38; 95% CI: 0.25–0.57; $p < 0.0001$) are lower for colposuspension when compared to mid-urethral tapes [111]. These findings are also supported by the most recent Cochrane analysis, which has also shown a higher cure rate with mid-urethral slings when compared to colposuspension (RR 0.75; 95% CI: 0.62–0.90) [112].

Colposuspension has also been shown to be a durable and long-lasting procedure. A recent long-term study has reported outcome in 155 458 women over 10 years following surgery for stress urinary incontinence. The 9-year cumulative incidence of repeat surgery after all procedures was 14.5% (95% CI: 13.4–15.5), after sling procedures 13.0% (95% CI: 11.7–14.3), and colposuspension 10.8% (95% CI: 9.3–12.3). Overall, the rate of repeat surgery was 28% higher for sling procedures when compared to colposuspension (adjusted HR 1.28; 95% CI: 1.19–1.37) [113].

In the 5th report of the ICI, colposuspension continues to be recommended as an effective treatment for primary stress incontinence, and, while superseded by the less invasive mid-urethral tapes, it should still be considered for those women who are having a concomitant abdominal procedure [43]. Consequently, colposuspension still has a role in women having concomitant surgery such as abdominal hysterectomy, oophorectomy, and open abdominal sacrocolpopexy. In addition, colposuspension may offer an alternative to a mid-urethral tape procedure following urethral diverticulectomy or repair of a urethra–vaginal fistula, where it may be preferable to avoid the interposition of a synthetic mesh.

72 Fascial Slings

Aaron Brothers, David James Osborn, Melissa R. Kaufman, W. Stuart Reynolds, and Roger R. Dmochowski

INTRODUCTION

Early in their inception, pubovaginal bladder neck slings (PVSs) were primarily reserved for the treatment of refractory stress urinary incontinence (SUI). However, owing to an improved understanding of SUI pathophysiology and the introduction of several technological advancements, the PVS has become the surgical gold standard for women who suffer from uncomplicated or complicated SUI. The ideal material for the construction of a pubovaginal sling is sterile, biocompatible, noncarcinogenic, and consistent in quality. In the literature, several allograft, xenograft, and synthetic materials meeting these criteria have been studied. Allograft and xenograft materials are not commonly used for pubovaginal slings because of questions about their durability and cost. Most synthetic materials are made out of polypropylene mesh. In addition, while synthetic meshes are certainly durable, they do carry the potential drawbacks of higher rates of graft infection, urinary tract perforation, and vaginal exposure. Outcomes data have shown that synthetic pubovaginal slings are 15 times more likely to perforate into the urethra (0.02%) and are exposed 14 times more often in the vagina (0.007%) compared to autologous slings [1,2]. For these reasons and others, autologous fascial slings remain the material of choice. Their use and outcomes will be the focus of this chapter.

PATHOPHYSIOLOGY OF STRESS URINARY INCONTINENCE

Female continence depends on a complex interaction between urethral and bladder neck support, intrinsic urethral properties, the urethral sphincter mechanism, and the pelvic floor musculature. In 1990, Petros and Ulmsten proposed a unifying concept called the integral theory [3]. This theory stated that the most important factors for preserving continence were adequate function of the pubourethral ligaments, the suburethral vaginal hammock, and the pubococcygeus muscle. The authors postulated that injury to any of these three components from surgery, parturition, aging, or hormonal deprivation could lead to impaired midurethral function and subsequently urinary incontinence. Dynamic ultrasound studies have shown that stress maneuvers can cause the posterior wall of the urethra to slide away from the anterior urethral wall and allow for opening of the bladder neck and proximal urethra (funneling), resulting in the loss of urine [4]. The goal of a PVS is to provide adequate urethral coaptation (without causing obstruction, ischemia, and erosion from unnecessary tension) and to increase urethral responsiveness to abdominal pressure such that leakage is avoided during stress maneuvers.

PUBOVAGINAL SLING OPERATIVE PROCEDURE

Preoperative Considerations

A comprehensive history and a physical examination including a focused neurourologic exam and pelvic exam should be performed on all patients to properly characterize the nature of their incontinence and to identify all aspects of pelvic support. While not all elements of vaginal prolapse require repair, consideration must be given to addressing prolapse at or distal to the hymenal ring, or symptomatic prolapse of a lesser degree. Doing so may minimize the possibility of postoperative SUI, urinary retention, or worsening prolapse in the future. An in-office cough stress test should also be performed on all patients and confirming the diagnosis in this manner is helpful. According to the AUA Guideline for the surgical management of SUI, additional testing should also include a postvoid residual (PVR) measurement and a urinalysis [5]. Some clinicians may also find quantitative measurement of urethral hypermobility and a voiding diary helpful. A cystoscopy or upper tract imaging for women is not part of the routine assessment of SUI. In addition, urodynamics are not required for the evaluation of primary SUI; however, they may be helpful in cases of mixed urinary incontinence, concomitant pelvic prolapse, incomplete emptying, neurogenic dysfunction, prior surgical failures, and when the diagnosis of SUI is in doubt.

A preoperative bowel preparation is not needed unless a concomitant hysterectomy, vaginal vault suspension, or posterior compartment surgery is planned. Preemptive perioperative clean intermittent catheterization (CIC) training may decrease trips to the emergency room and the need for indwelling catheters postoperatively.

As with any surgical intervention, a thorough discussion of the risks, benefits, and alternative therapies needs to be undertaken. Intraoperative risks include bleeding (with potential for transfusion); injury to the bladder, urethra, or bowel; and hematoma formation. Postoperative risks include transient or permanent voiding dysfunction (possibly requiring urethrolysis or sling incision), worsening or de novo storage or emptying symptoms, urinary tract infections (UTIs), or even sling exposure in the case of synthetic slings. For autologous slings, harvest site complications include seroma formation, wound infection, and incisional hernia formation. As with all surgical procedures, preoperative discussion should also include mention of the rare but serious risks of cardiovascular, pulmonary, and thromboembolic events. In the authors' opinion, sequential compression devices should be placed on the bilateral lower extremities prior to the induction of anesthesia. According to the AUA Best Practice Policy Statement for the Prevention of Deep Venous Thrombosis in Patients Undergoing Urologic Surgery, consideration for the use of low-dose unfractionated heparin or low-molecular-weight heparin should be based on individual patient and procedural risk factors [6].

Patient Positioning and Preparation

PVS surgery can be performed under spinal or general anesthesia. Prior to the start of the procedure, patients should receive a single dose of one of the following: a first- or second-generation cephalosporin, aztreonam (in cases of renal insufficiency), an aminoglycoside plus metronidazole, or clindamycin [7]. The patient is then positioned in a slightly exaggerated dorsal lithotomy position. The abdomen just above the umbilicus and the vagina are prepped with povidone-iodine or chlorhexidine gluconate solutions. The thigh is also widely prepped if autologous fascia lata (FL) is to be used. After draping, a weighted speculum is placed in the vagina and an 18 F Foley catheter is inserted into the urethra and placed to continuous gravity drainage.

Fascial Harvest

A Pfannenstiel incision is made approximately 2 cm above the pubic symphysis, providing excellent exposure and cosmesis. In women with a history of prior pelvic surgery, a preexisting skin incision can also be used. Electrocautery is used to carry the incision down to the rectus fascia (RF). A strip of RF measuring approximately 1.5 by 7 cm is then excised at least 2 cm from the pubic symphysis to help ensure a tension-free fascial closure. This is illustrated in Figure 72.1. The graft is then soaked in a 0.9% normal saline solution and the overlying fat and perifascial tissue is cleaned off. A No. 1 polydioxanone (PDS) or 1–0 polypropylene suture is secured to each end of the graft and left long. The fascial defect is closed with continuous or interrupted #1 PDS. The skin and Scarpa's layer are left open for passage of sling sutures later in the procedure.

In cases where FL is being harvested, an initial 3 cm longitudinal incision is made above the patella over the iliotibial band. This dissection is carried down to the level of the FL, where two parallel, longitudinal incisions are made, approximately 2 cm apart. The graft is then bluntly separated from the underlying muscle and transected as far distally as possible. This free end is then secured with a No. 1 PDS suture as described for the RF graft. This distal FL is then completely freed from any adipose tissue and muscle fibers before a Crawford fascial stripper is used to extend the fascial incision proximally up to 20 cm. The proximal flap is transected and another No. 1 PDS is secured to the free end. The flap is then stored in 0.9% normal saline until needed. Immediate compression should be applied to the thigh to constrict perforating vessels. Once hemostasis is ensured, the thigh wound is closed in three layers without closing the FL. A compressive wrap is then placed for 8 hours postoperatively and early ambulation is encouraged [8].

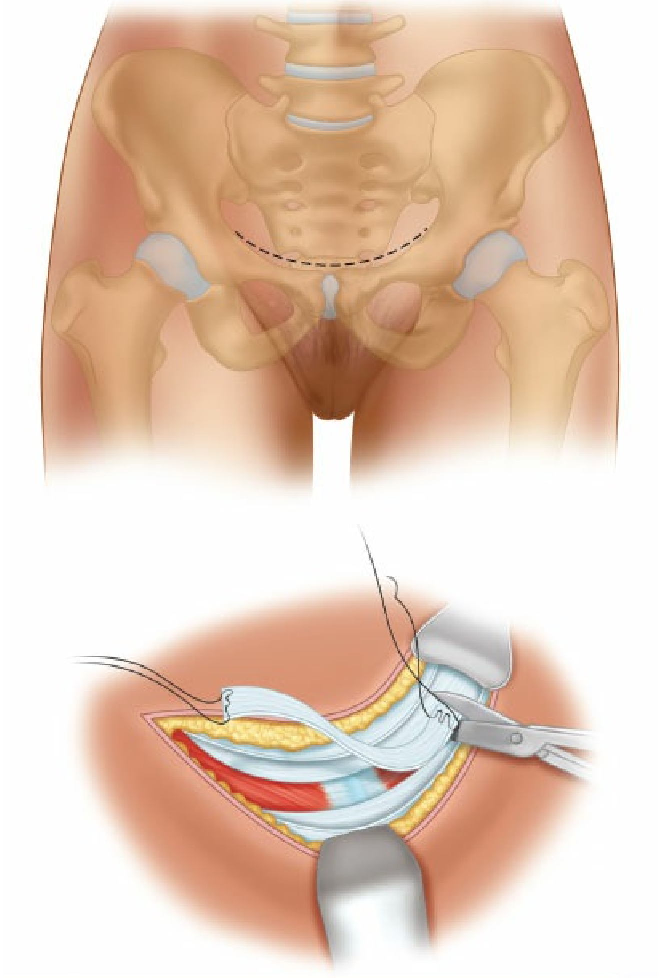

Figure 72.1 The rectus fascia graft is harvested and attached to 2-0 polypropylene sutures. The rent in the rectus fascia is closed while the skin and Scarpa's fascia are left open. (Reproduced from Blaivas JG and Chaikin D, Pubovaginal fascial sling for the treatment of all types of stress urinary incontinence: surgical treatment and long-term outcome, in Cardozo L and Staskin D, eds., *Textbook of Female Urology and Urogynecology*, Informa, London, U.K., 2006. With permission.)

Vaginal Dissection

If no concomitant surgery is planned, an inverted U-shaped incision is made in the vaginal epithelium after injection of 0.9% sterile normal saline with the apex of the U based at the mid-urethra and the widely spaced legs of the U extending just proximal to the bladder neck. Alternatively, a vertical midline incision can be made if concomitant anterior or apical compartment surgery is planned. The vaginal mucosa is then dissected sharply off the underlying surface of the pubocervical and periurethral fascia, with lateral dissection proceeding up to the inferior edge of the pubic symphysis. The vaginal flaps are retracted with help of a vaginal ring retractor.

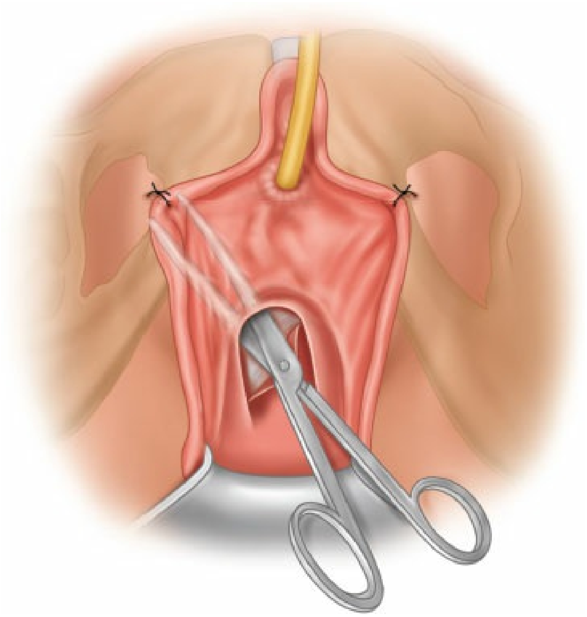

Figure 72.2 After incising the vaginal mucosa in a midline or inverted-U incision, the endopelvic fascia is perforated with Metzenbaum scissors aimed at the ipsilateral shoulder. The retropubic space is entered. (Reproduced from Blaivas JG and Chaikin D, Pubovaginal fascial sling for the treatment of all types of stress urinary incontinence: surgical treatment and long-term outcome, in Cardozo L and Staskin D, eds., *Textbook of Female Urology and Urogynecology*, Informa, London, U.K., 2006. With permission.)

To prevent inadvertent bladder injury, bladder drainage is ensured prior to perforation of the endopelvic fascia with Metzenbaum scissors. The space of Retzius is then entered. The scissors should be aimed at the ipsilateral shoulder and remain just inferior to the pubic symphysis. This is illustrated in Figure 72.2. Once the endopelvic fascia is perforated, periurethral adhesions in the retropubic space are released manually with an index finger (Figure 72.3). With this dissection, the infrapubic and retropubic dissection planes are now connected. During this step, it is important to ensure that the retropubic space is fully opened. The posterior surface of the pubic symphysis should be easily palpable with very little intervening tissue.

Sling Placement and Fixation

If not already done, bladder drainage is again ensured. A finger in the retropubic space is then used to carefully guide Stamey needles from the abdominal incision into the vaginal incision on either side of the urethra (Figure 72.4). The needles should pass directly behind the pubic symphysis. Cystoscopy with a 70° lens is then performed to diagnose inadvertent bladder perforation. Indigo carmine is given intravenously to document ureteral integrity via efflux of blue urine bilaterally. If bladder perforation is identified, the needle can be repositioned until it is outside the bladder and the surgery can proceed.

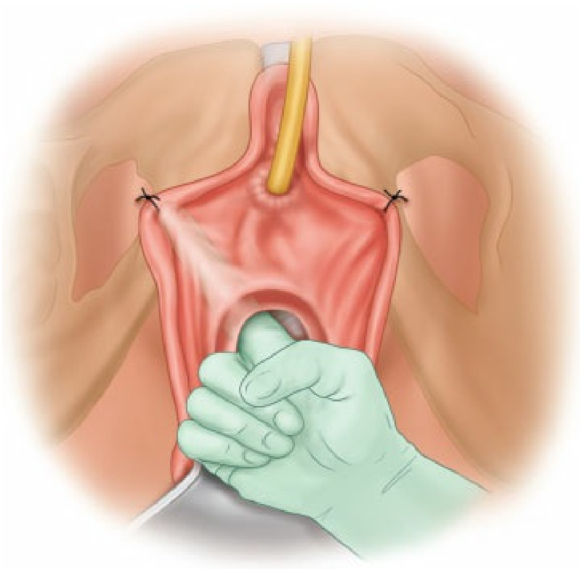

Figure 72.3 Once the endopelvic fascia is perforated sharply, manual dissection with the index finger is performed to release any adhesions and develop the retropubic space. (Reproduced from Blaivas JG and Chaikin D, Pubovaginal fascial sling for the treatment of all types of stress urinary incontinence: surgical treatment and long-term outcome, in Cardozo L and Staskin D, eds., *Textbook of Female Urology and Urogynecology*, Informa, London, U.K., 2006. With permission.)

The graft sutures are then passed into the Stamey needle eyelets and brought out through the abdominal incision and tagged with clamps. The midportion of the sling is positioned over the bladder neck and the distal aspect is sutured to the periurethral tissue with two simple 4-0 polyglactin 910 sutures. The vaginal incision is then closed with running 2-0 polyglactin 910 sutures.

Adjusting Sling Tension and Abdominal Wound Closure

Sling tension is then set from the abdominal incision. The sling PDS sutures are tied above the RF to their contralateral partner while cystoscopy with a 30° lens is performed to visualize adequate coaptation of the proximal urethra. Typically, the sling is tensioned with a two-fingerbreadth width distance between the RF and the PDS knot (Figure 72.5). Before tying a 3rd knot, a cystoscope sheath is passed into the bladder to ensure that there is no *hitch*. If significant resistance is encountered, the two knots can be undone and the tension adjusted until the sheath passes without a hitch.

Once the sling is correctly tensioned, Scarpa’s fascia is reapproximated with an interrupted 3-0 absorbable suture. The skin is closed with a subcuticular 4-0 absorbable suture and the vagina is carefully packed with gauze impregnated with conjugated estrogen cream (or saline or povidone-iodine-soaked gauze in premenopausal women). The urethral catheter is left to gravity drainage.

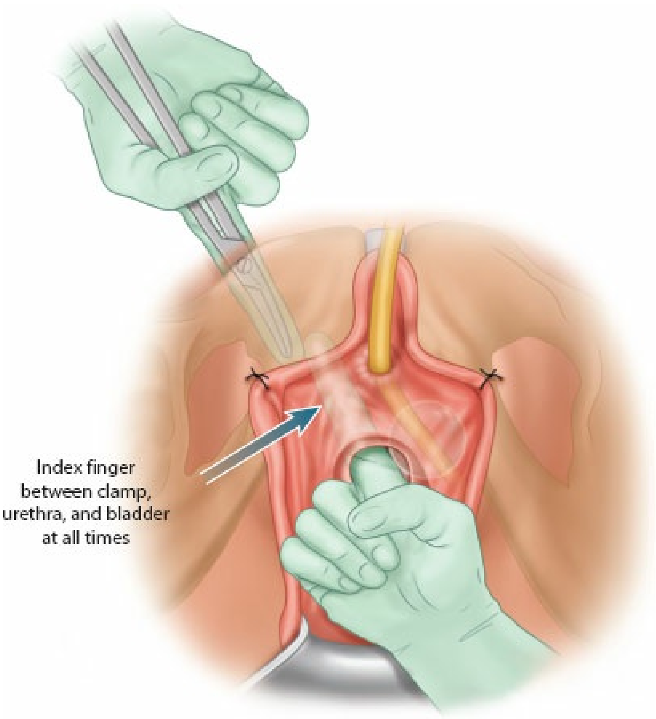

Figure 72.4 A tonsil-tip clamp or double-headed needle is passed from the abdominal incision, through the rectus fascia, and into the vaginal incision on either side of the urethra. Care is taken to stay just behind the posterior aspect of the pubic symphysis. The index finger of the nonpassing hand guides the clamp from below. (Reproduced from Blaivas JG and Chaikin D, Pubovaginal fascial sling for the treatment of all types of stress urinary incontinence: surgical treatment and long-term outcome, in Cardozo L and Staskin D, eds., *Textbook of Female Urology and Urogynecology*, Informa, London, U.K., 2006. With permission.)

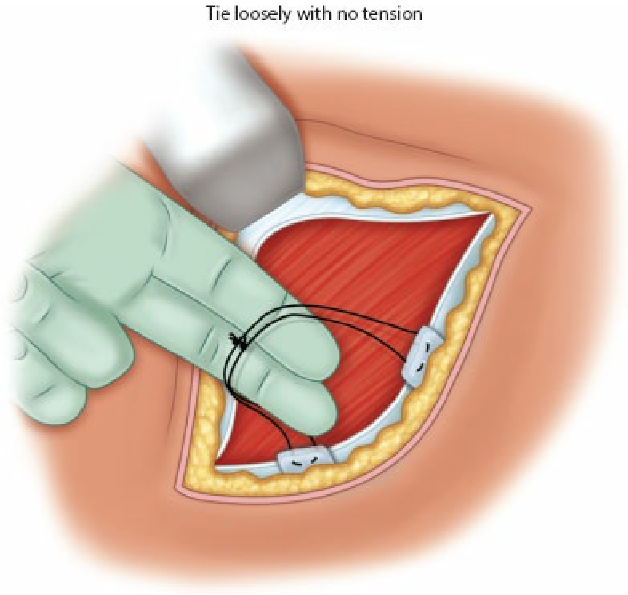

Figure 72.5 After the vaginal incision is closed, sling sutures are tied across the rectus fascia without tension. Typically, an assistant places two fingers between the suture knot and the rectus fascia to ensure tension-free placement. (Reproduced from Blaivas JG and Chaikin D, Pubovaginal fascial sling for the treatment of all types of stress urinary incontinence: surgical treatment and long-term outcome, in Cardozo L and Staskin D, eds., *Textbook of Female Urology and Urogynecology*, Informa, London, U.K., 2006. With permission.)

Postoperative Care

Patients are admitted for overnight observation. The vaginal packing is removed on postoperative day 1 (POD#1) and the urethral catheter is removed when the patient is out of bed and ambulating (usually POD#1). The patient is typically discharged home without a catheter unless she is unable to void or has elevated PVRs >150 mL. In this case, she will return to clinic in approximately 5 days for a repeat voiding trial. Alternatively, patients can perform CIC until voiding improves and PVRs are reduced. Some authors recommend leaving a catheter to drainage for at least 48 hours if the bladder was perforated during needle passage.

All patients are instructed not to lift objects heavier than 3 kg for 6 weeks. Vaginal intercourse is also avoided for at least 6 weeks and not resumed before follow-up physical examination by the surgeon. Frequent ambulation is encouraged, but again strenuous activity is to be avoided for 6 weeks. Follow-up visits are typically at 2 weeks, 6 weeks, 6 months, and annually thereafter.

OUTCOMES OF AUTOLOGOUS PVS SURGERY

Outcomes data for the use of autologous RF and FL as PVS slings are robust. In the earliest modern-day study from 1978, McGuire reported an overall success rate of 80% [9]. Since then, several retrospective studies with long-term follow-up (>48 months) have documented cure rates of 72.9%–94% [10–12]. In 1997, Cross et al. published a retrospective analysis of 150 patients who underwent PVS for urinary incontinence [13]. In their study, 98% of patients had predominantly SUI and 93% of all patients were cured of their incontinence based on the results of in-office questionnaires and telephone interviews. In one study with 7.1 years of mean follow-up of 153 patients, 71.7% were continent and only 3.3% required reoperation for SUI [14].

Studies comparing RF verses FL for use in PVSs have found comparable success rates between the two techniques. Beck et al. noted a 92.4% cure rate measured by absence of leakage on a postoperative cough test in 170 patients who underwent an FL PVS [15]. Similarly, Latini et al. reported that 83% of respondents who had undergone an FL PVS indicated that the procedure had a positive effect on their life, 82% would recommend the surgery to a friend, and 83% would undergo the procedure again [16]. They also noted that 20% of patients who had undergone an FL PVS reported localized numbness, 7% had pain, and 5% had tendonitis at the harvest site 1-week postoperatively.

While the results of these and numerous other studies that document the effectiveness of PVS surgery are encouraging, it is important to note that comparing *cure* rates between various studies is challenging due to variations in the definition of success, outcome criteria, length of follow-up, inclusion and exclusion criteria, incidence of concomitant surgery, and reporting of perioperative complications.

The PVS has also been shown to be an effective treatment for recurrent SUI after a failed corrective surgery. In a retrospective study from 2001, Richter et al. found that rates of postoperative voiding dysfunction were similar in patients getting their first anti-incontinence surgery and in patients who had undergone a previous retropubic suspension (46%) or needle suspension (24%) [17]. Interestingly, 88% of patients in that study felt that the sling improved their quality of life and 82% stated that they would undergo the surgery again; however, 11.8% of patients did require long-term CIC for persistent retention. In another study, Athanasopoulos et al. described outcomes in patients who had failed treatment with a midurethral sling. In this study, 29.9% of the 264 patients had a previously placed midurethral sling that was partially removed at the time of PVS surgery [18]. The overall success rate in terms of markedly improved or cured incontinence in the study was 84.7%. Lastly, in a more recent report by Lee et al., the authors found no difference in outcomes between 36 patients undergoing a primary PVS and 48 patients undergoing a secondary (history of previous major incontinence surgery) PVS procedure [19]. They reported a 76% success rate after a primary PVS procedure and a 69% success rate after a secondary PVS procedure. In summary, PVS surgery demonstrated high success rates in a variety of different types of patients.

Autologous pubovaginal slings also serve an important role during urethral reconstruction surgeries. In the authors' opinion, an autologous PVS provides excellent support to the urethra and decreases persistent or de novo SUI after urethral diverticulectomy surgery. This opinion is supported in the literature through multiple studies that have shown excellent results pertaining to continence and diverticula recurrence after concomitant autologous PVS and urethral diverticulectomy [20–22]. Other authors have published excellent results in terms of continence and spontaneous voiding after using an autologous PVS in conjunction with repair of even more complex urethral damage from etiologies such as protracted obstetrical deliveries, failed anti-incontinence surgeries, aggressive transurethral resections of the bladder neck, long-term indwelling urethral catheters, pelvic trauma, tumors, and radiation [23,24].

COMPLICATIONS OF AUTOLOGOUS PVS SURGERY

Typically, complications after PVS surgery may be effectively grouped by their temporal relationship to the procedure itself. Acute major global perioperative complications such as myocardial infarction, pulmonary embolism, deep vein thrombosis, and death are exceedingly rare [10,15,25–27]. Wound complications such as hematoma, seroma, and hernia formation have been observed in up to 15% of women undergoing an RF sling [28,29]. Thigh wound complications such as hematoma (14%), seroma (4%), and persistent leg pain (3%) have also been reported in patients after fascia lata harvest [15,28,30]. Incisional hernias occur at a rate of 0.8%–1% [10,31]. While several cases of urethral erosion have been reported after autologous PVS surgery, these are most likely a result of overly aggressive periurethral dissection or placement of the sling under excessive tension [32–36].

The most common nonurologic complications from PVS surgery are pulmonary, cardiovascular, neurologic, and gastrointestinal (bowel injury). In 2007, Anger et al. analyzed Medicare claims data for short-term complications after sling (all types) surgery among female beneficiaries aged 65 and older [37]. A total of 1365 sling procedures were included in the analysis. The authors found that 12.5% of women developed surgical or urologic complications in the 3 months after the procedure and 33.6% had a diagnosed UTI. Within the 1-year follow-up period, 6.6% of claims were for bowel injury or obstruction, 9.1% cardiac, 2.6% thromboembolic, 15.3% pulmonary, and 22.1% others. An overall death rate of approximately 3 per 10,000 procedures has been estimated for all SUI procedures (retropubic suspension, transvaginal suspensions, anterior repairs, and PVS) [5].

Voiding dysfunction secondary to bladder outlet obstruction after PVS surgery is often related to detrusor overactivity and impaired detrusor contractility. However, iatrogenic obstruction is also a common cause of postoperative voiding dysfunction and is usually the result of overtightening of the sling that results in hypersuspension of the urethrovesical angle. Transient urinary retention is common after PVS surgery and most patients return to spontaneous voiding with the first 10 days postoperatively [38,39]. The reported incidence of voiding dysfunction after PVS ranges from 2.5% to 35% [40–43]. Kochakarn and Leenanupunth noted that 39% of their patients performed CIC for a mean of 8.9 weeks [44], while Govier et al. noted that women in their study performed CIC for a mean of 3.3 weeks after PVS surgery [45]. In their study, Beck et al. observed postoperative voiding dysfunction for a mean of 2 months after surgery [15]. Additionally, Karram and Bhatia noted that the mean time to spontaneous voiding for women in their study was 20 days [46]. A meta-analysis by the American Urological Association Stress Urinary Incontinence Clinical Guidelines Panel in 1997 reported that the incidence of urinary retention more than 4 weeks after pubovaginal sling placement was 8% and the risk of permanent retention usually does not exceed 5% [2].

Preoperative voiding dysfunction has been shown to affect a patient’s ability to empty after anti-incontinence surgery, and therefore it is important to identify this problem during the initial history and physical examination. Preoperative urodynamic studies may be helpful in identifying patients who mount a low detrusor pressure and rely on valsalva for voiding. Such patients are not strictly excluded from having anti-incontinence surgery but should be counseled on the higher risk of postoperative obstruction and the possible need for long-term CIC. Mitsui et al. found that patients with a PVR greater than 100 mL ($p = 0.05$) or Q_{max} of less than or equal to 20 mL/s ($p = 0.09$) during preoperative urodynamics were more likely to require prolonged CIC (28% of patients required CIC for 4–40 months) [47].

Postoperatively, patients with voiding dysfunction can present with frank urinary retention, subtle irritative symptoms, or urgency incontinence. Recurrent UTIs may also be indicative of obstruction in the otherwise asymptomatic patients. Although no clear cutoff values for obstruction exist, the PVR volume is very important in the evaluation of voiding dysfunction and should be measured in spontaneously voiding patients prior to their discharge from the hospital [48].

Because postoperative obstruction following autologous PVS usually improves or resolves with time, it is appropriate and effective to initially treat persistent voiding dysfunction conservatively (CIC, indwelling catheter, timed voiding, double voiding, biofeedback, pelvic floor muscle training, and anticholinergic therapy). Most physicians advocate waiting 3 months prior to considering repeat surgical intervention for persistent obstructive symptoms.

SURGICAL MANAGEMENT OF VOIDING DYSFUNCTION AFTER PVS SURGERY

Surgical management of bladder outlet obstruction following a PVS traditionally involves a complete urethrolysis by a retropubic, transvaginal, or suprameatal approach. Early in the postoperative course, usually within 6 weeks of surgery, the authors of this chapter have had success with loosening of the sling via caudal pressure applied to the urethra with a cystoscope under anesthesia; however, worsening of the urethral rigidity secondary to periurethral fibrosis is a possible complication of this maneuver [15]. Other early interventions, such as transurethral resection or incision of the bladder neck, have been shown to be an ineffective means of managing postoperative obstruction [49].

Patients with persistent symptomatic obstruction after 6 weeks that requires intervention should undergo either an urethrolysis or a sling incision. Success rates for these procedures for all sling types (autologous, cadaveric, synthetic) range from 65% to 93% [39,40,43,50,51]. Specifically concerning urethrolysis, Foster and McGuire reported that transvaginal urethrolysis was successful in only 50% of PVS obstructions and thus concluded that transvaginal lateral dissection is insufficient in relieving the direct suburethral compressive force of the sling. To better approach the lateral wings of the sling, the authors recommended a suprameatal approach. Petrou et al. reported on a series of 12 patients who underwent such a procedure, 8 of whom had successful results [51]. Likewise, Carr and Webster noted a complete or significant resolution of symptoms in 86% of patients after retropubic urethrolysis [40]. Even in cases of failed urethrolysis, a repeat transvaginal, retropubic, or combined urethrolysis should be able to achieve excellent cure rates of up to 92% as long as the urethra is circumferentially mobilized away from the pubic bone [52].

On the other hand, there are some authors who report that single-sling incision has comparable success rates (84%–100%) and shorter operative time and less morbidity than a formal urethrolysis [53–55]. In 2005, Thiel et al. reported a 100% success rate in 11 women following lateral sling incision, with a 54% rate of recurrent stress incontinence [56]. Goldman also performed simple-sling incision in 14 women with iatrogenic urethral obstruction [57]. This included 3 patients with a midurethral polypropylene mesh sling. In this study, 13 of 14 (93%) patient had complete or significant improvement of voiding dysfunction and 1 (7%) required subsequent urethrolysis. Three patients (21%) developed recurrent SUI, one of which required treatment. In the authors' opinion, the most important factor to consider when deciding on sling incision or formal urethrolysis is the length of time from surgery. Within the first 3–6 months after surgery, a single-sling incision will likely be adequate.

CONCLUSIONS

The PVS surgery has evolved over the past 100 years. With the introduction of novel graft materials and less invasive methods of placement, women undergoing PVS surgery today may enjoy shorter convalescence periods than ever before. However, because synthetic, allograft, and xenograft materials have unpredictable biocompatibility profiles in vivo, these technological advancements bring unique risks. Autologous RF and FL slings induce minimal inflammatory response and are considered the "biocompatibility gold standard" against which all other sling materials are measured. Autologous PVS surgery affords patients cure rates up to 97%. Serious complications are rare and voiding dysfunction after surgery is often transient and can usually be managed conservatively. It is however important to avoid excessive sling tension during placement. As with all surgical procedures, a discussion of the specific risks, benefits, and alternatives to sling surgery is quintessential to obtaining informed consent preoperatively and to ensuring patient satisfaction postoperatively.

73 Tension-Free Vaginal Tape Procedure For Treatment of Female Urinary Stress Incontinence

Carl Gustaf Nilsson[*]

INTRODUCTION

The tension-free vaginal tape (TVT) procedure for the treatment of female urinary stress incontinence is a sling operation. For more than a century, sling operations have been developed and performed with satisfactory degree of success in terms of achieved dryness. The classical sling operations as described by Goebbel [1], Frangenheim [2], Stoeckel [3], and Aldridge [4] are all major invasive surgical procedures, with the inevitable risk of complications, postoperative morbidity, and voiding difficulties. Slings of many different materials—allografts, xenografts, and synthetics—have been used. Classical slings are placed at the bladder neck in order to correct hypermobility and to enhance pressure transmission of intra-abdominal pressure provoked by straining. This mechanism of action is in alignment with the most popular theories of the past century, describing the causes of urinary incontinence [5].

Growing awareness of the magnitude of the urinary incontinence problem in the aging population of the developed world has regenerated increasing interest in finding more effective, less invasive, and more affordable methods of curing incontinence. As hypermobility of the bladder neck correlates poorly with symptoms of incontinence and severity of leakage [6], a shift of interest from correcting anatomical changes to an attempt to restore function of the urethral closure mechanism has occurred. Many findings through the years have identified the midurethra as the focus of interest when dealing with female stress incontinence. Anatomical, physiological, and histological investigations indeed support the concept of the midurethra to be important in maintaining urinary continence in the female.

Pubourethral ligaments, inserting at the midurethra, has been identified by Zaccharin in the 1960s [7] and further nicely demonstrated by DeLancey in the 1990s [8]. Histological evaluation of the female urethra by Huisman revealed prominent vascularization specifically at the midurethra [9].

The early urodynamic investigations by Asmussen and Ulmsten further strengthen the impression of the more distal parts of the urethra playing a major role in the closure mechanism.

The maximal closure pressure is located at the midurethra, and in fertile women, pulsatility can be demonstrated at the same location, indicating strong vascular support [10]. Ingelman-Sundberg found that the ventral parts of the pubococcygeal muscles inserted into the anterior vaginal wall at the site of the midurethra and utilized this finding in his sling plasty [11]. Furthermore, Westby showed elegantly in radiographic experiments how, in continent women, the urethra closes at its middle section on holding urination and that the maximal closure pressure is situated at the same level of the urethra [12].

By combining these findings, a new theory for describing the causes of female urinary incontinence was presented by Petros and Ulmsten, the “midurethral theory” (in early literature, the integral theory) [13]. According to this theory, damage to the pubourethral ligaments supporting the urethra, impaired support of the anterior vaginal wall to the midurethra, and weakened function of the part of the pubococcygeal muscles, which inserts adjacent to the urethra, are responsible for causing stress urinary incontinence. Connective tissue is an important element of the involved structures. The quality of the connective tissue has an influence on continence [14].

DEVELOPMENT OF THE TVT PROCEDURE

The TVT procedure was developed on the basis of the elements of the midurethral theory. The goal was to create a minimally invasive operation, which would reinforce the pubourethral ligaments, strengthen the support of the urethra by the anterior vaginal wall, and achieve conditions that would favor ingrowth of fresh connective tissue into the region. The procedure was performed in local infiltration anesthesia from the very beginning in order to facilitate early same-day discharge of the patients from the hospital.

Several different sling materials were evaluated. The one finally chosen is a synthetic polypropylene monofilamentous mesh, with a pore size between 75 and 150 μm, which is optimal for ingrowth of fibrous tissue and allows leukocytes and macrophages to enter into the mesh, thus avoiding colonization of bacteria. The special weave of this type I mesh has been found to have favorable properties in terms of elasticity and strength [15].

An effort to standardize the operation was made in order to facilitate training of doctors to perform the procedure in a manor, which includes certain built in safety features and makes possible good clinical results. The use of local anesthesia—prilocaine (2.5 mg/mL) with adrenalin (2 μg/mL) diluted with saline to 0.25%—causes vasoconstriction in the operating region, which decreases the risk of intraoperative bleeding and hematoma formation. The volume of 75–100 mL of anesthetics recommended to be used results in hydrodissection of tissues at the operation site and facilitates passage of the specially designed instrument, with the attached polypropylene tape, through the right layers of tissue, thus avoiding complications as bladder injury.

If the local anesthesia is placed only in the region where the tape should be positioned, deviation by the instruments from this safe sector during performance of the operation causes the patient to react and, thereby, guides the surgeon to correct his or her performance. Local anesthesia interferes least with the function of the pelvic floor and allows intraoperative testing of optimal tension-free placement of the tape by a cough test in order to avoid postoperative voiding difficulties.

TVT OPERATION TECHNIQUE

The TVT device consists of an 11 mm wide and 40 cm long tape of polypropylene, which in both ends is attached to stainless steel, specially curved, 5 mm in diameter insertion trocars.

The tape is covered by plastic sheets to protect the tape from contamination and facilitate its passage through the tissues. A reusable handle fits to the trocars and is used to insert the trocars. A rigid catheter guide is placed into an 18 French Foley catheter and helps to deflect the bladder away from the path of the trocar insertion.

In 2010, a modernization of the original TVT device was launched. The TVT exact is used exactly by the technique described for the original TVT procedure. The differences between the two devices are the thickness of the trocar, the original having a diameter of 5 mm, and the TVT exact having a diameter of 3 mm. Both trocars have the same curvature and tip radius and the polypropylene tape has not changed. The narrower trocar reduces the penetration force needed. The TVT exact handle and trocar are combined in one piece, which is disposable.

The patient is placed in a lithotomy position avoiding more than a 70° flexion of the tights. After premedication with, for example, 0.5 mg midazolam, the local anesthetics are placed. The operation requires three small incisions: two 1 cm wide suprapubic skin incisions at the upper rim of the pubic bone, each 2–2.5 cm lateral to the midline, and a vaginal midline incision not more than 1.5 cm wide starting 0.5 cm from the external meatus of the urethra.

Five cc of anesthetics is placed under the skin at the site of the planned skin incisions. Another 20 cc is placed on each side retropubically following closely the posterior surface of the pubic bone down to the urogenital diaphragm. Vaginal infiltration of the anesthetics includes 10 cc on each side paraurethrally up to the urogenital diaphragm and another 5 cc under the vaginal mucosa at the site of the midurethra.

The skin incisions are made to facilitate passing of the trocars through the skin. After the vaginal incision is made, careful, minimal blunt dissection, using Metzenbaum scissors, should be undertaken paraurethrally between the vaginal mucosa and the pubocervical fascia not more than 2 cm deep. The TVT trocar is placed in its starting position within the dissected paraurethral tunnel, with the trocar tip between the index finger of the surgeon's hand in the vagina and the lower rim of the pubic ramus. With a slow controlled pressure, the trocar is brought through the urogenital diaphragm, the space of Retzius, and the rectus muscle fascia using the skin incision as an aim of direction. Attention must be paid to keep the trocar all the time in close contact with the dorsal surface of the pubic bone in order to avoid bladder perforation or entrance into the abdominal cavity. The same procedure is repeated on the other side. After passing each trocar to the extent that the trocar tip is visible at the skin incision, cystoscopy using a 70° optic is performed to assure bladder integrity. If bladder perforation is noted, the trocar is withdrawn and passed once more, paying more careful attention of staying close to the pubic bone and within the safe sector. Once bladder integrity is confirmed, each trocar is brought through and the final adjustment of the tape can take place. The recommendation is to fill the bladder with 300 cc of saline and perform a cough test. The patient is asked to cough vigorously while the tape is adjusted to a point when leakage is only a drop of saline at the urethral meatus. This procedure will assure tension-free placement of the tape and minimize risks of postoperative voiding problems. After the final adjustment of the tape has been made, the plastic sheets are taken off. At this point, it is important to control that no further tightening of the tape occurs by placing Metzenbaum scissors between the urethra and the tape when removing the plastic sheets. No fixation of the tape is performed.

CLINICAL PERFORMANCE OF THE TVT OPERATION

The results of the first clinical trial with the TVT operation were encouraging, showing an objective cure rate of 80% [16]. Thereafter, surgeons of six different centers were given personal hands-on training of the TVT technique, and a multicenter, two-country, prospective clinical trial was initiated. The aim of this study was to investigate the performance of the procedure in normal clinical settings outside the clinics of invention. One hundred and thirty-one carefully selected primary cases of genuine stress incontinence were enrolled. The 1-year follow-up results revealed an objective cure rate of 91% and another 7% to be significantly improved. Only 2% were regarded as failures. The complication rate was low, including one case of bladder injury and one wound infection. Three patients had short-term (≤3 days) voiding problems and only one patient experienced retention symptoms for 12 days [17]. These promising results prompted further studies in unselected groups of women with indications for surgical treatment of their urinary incontinence. In a prospective clinical trial of 161 consecutive TVT operations, which included 28% with prior failed incontinence surgery, 37% with mixed incontinence, and 11% with intrinsic sphincter deficiency, the overall objective cure rate at 16 months of follow-up was 87%, 7% were significantly improved and only 5% were classified as failures [18]. No serious complications occurred. The bladder perforation rate was 3.7% and 4.3% of the women experienced short-term voiding difficulties. De novo urge symptoms were noted in 3% of the women, while as many as 80% of those women who preoperatively complained of urge symptoms were relieved of these symptoms at their 16-month follow-up visit. Later, several reviews and meta-analyses have confirmed these favorable results [19–22].

LONG-TERM RESULTS

Table 73.1 shows the objective and/or subjective cure rates in follow-up trials of 10 or more years thus far published.

Some of the problems of evaluating long-term results of incontinence surgery are the growing number of patients lost to follow-up by time and the fact that in many of these often elderly patients' new illnesses appear that might affect bladder function and thus complicate estimation of long-term effectiveness and safety of an anti-incontinence surgical intervention.

The rate of lost to follow-up in the long-term reports, the results of which are presented in the table, ranges between 8% and 28%. This relatively low rate of lost to follow-up subjects 10 or more years after intervention allows one a reliable picture of the actual performance of the TVT operation over time.

The cure rates even 17 years after surgery are in the same order as those reported in the initial early trials, suggesting minimal decline in effectiveness over the years [29]. An attempt to predict the risk of failure or declining effectiveness of the TVT procedure has been done in many reports without being able to identify any single significant factor. A tendency of higher failure rates seems to be associated with high age at the time of operation and the presence of a low-pressure urethra.

An important finding of the long-term follow-up is the absence of signs of rejection or adverse tissue reaction of the polypropylene tape material. Neither was any erosion of the tape into the urethra or the bladder seen [29].

TVT AFTER FAILED INCONTINENCE SURGERY

The next step was to study the effectiveness of the TVT procedure in special groups of patients. Tables 73.2 and 73.3 show the objective and/or subjective cure rates found in patients with prior failed traditional incontinence surgery and prior failed midurethral sling (MUS) surgery, respectively. From the results, it can be concluded that the performance of the TVT procedure is as good as in primary cases when the primary operation had been a traditional method, mostly colposuspension or a pubovaginal sling [30–36]. When the primary failed operation had been an MUS procedure, the repeat MUS, in this context the TVT procedure, shows favorable cure rates, which though seem to be slightly lower than in primary cases and in which a tendency of decline in cure rate is seen after approximately 4 years [37–40]. The decline is partly explained by the fact that many women over time develop urgency symptoms not necessarily related to the surgery, but affecting their subjective perception of cure of urinary symptoms. A question is often raised: which approach for a repeat MUS preferred, the retropubic or the transobturator? There is no clear answer, but some studies indicate that a retropubic repeat procedure might perform better than a transobturator procedure [37,39,41]. Two meta-analyses arrive at different conclusions, one is that the retropubic approach is more effective than the transobturator one in correcting primary failed MUS surgery [42], and another finding is that there is no difference between the approaches [43].

TVT IN CASES OF INTRINSIC SPHINCTER DEFICIENCY

Intrinsic sphincter deficiency (ISD) can be defined in many ways, for example, as a low-pressure urethra (<20 cmH_2O) and/or a Valsalva leak point pressure less than 60 cmH_2O or stress urinary incontinence in the absence of urethral hypermobility. The majority of clinical reports dealing with ISD and TVT surgery define ISD as maximal urethral closure pressure (MUCP) less than 20 cmH_2O. Some add a low Valsalva leak point pressure to their definition, while the absence of urethral hypermobility seems to be a criterion not currently relevant. ISD has been regarded as a severe form of stress incontinence with poorer outcome after traditional incontinence surgery (as colposuspension) compared to cases with MUCP >20 cmH_2O. Clinical reports on cases of ISD treated by TVT surgery found cure rates close to 80%, rates that are close to the rates found in cases with higher values of MUCP [44–47]. Three comparative studies have compared TVT with a transobturator procedure in cases of ISD [47–50]. All three studies find a statistically significant poorer outcome with the transobturator procedure than with the TVT operation (Table 73.4).

TVT IN OBESE WOMEN

Obesity is a growing problem worldwide. It is a risk factor of developing urinary incontinence. One might, therefore, postulate that incontinence surgery results in poorer outcome in obese individuals than in normal-weight persons. As MUS surgery has become the gold standard of incontinence surgery and a vast majority of incontinence surgery performed worldwide is MUS surgery, it has become important to investigate the performance of MUS surgery in obese women with stress incontinence. Table 73.5 summarizes some of the few studies comparing obese women with normal-weight women treated with the TVT procedure because of stress incontinence. It can be seen that the cure rates in obese women are somewhat lower than in normal-weight women, with an average cure rate of slightly over 70%; the follow-up time period was mostly 2 years or less [51–54]. The report by Hellberg et al., with a follow-up of more than 5 years, reveals a statistically significant (p = 0.0005) 30% lower cure rate than in controls, a finding that might indicate that over time the obese women have a declining cure rate after TVT surgery [53].

TVT IN CASES OF MIXED INCONTINENCE

Mixed urinary incontinence is a condition when a patient suffers simultaneously of both stress and urgency incontinence. Mixed incontinence can be divided into cases with either predominant stress or predominant urgency incontinence assessed by subjective parameters or into urodynamically proven mixed incontinence with signs of leakage at stress and detrusor activity. Surgery for mixed incontinence is mostly recommended for cases with stress incontinence predominating mixed incontinence, with or without urodynamically proven detrusor overactivity. Study reports on the outcome of TVT surgery in cases of mixed incontinence are difficult to compare and interpret as the definition of mixed incontinence varies greatly and cure rates are expressed as overall cure, cure of the stress component, or cure of the urgency component. Table 73.6 gives the overall cure rates after TVT in subjects with mixed incontinence of the few reports from which these parameters could be extracted. A rather recent meta-analysis looking at the cure rate after MUS surgery indicates that there is a persistent and good cure of the stress component, while the cure of the urgency component is variable and less than the stress component between 30% and 85% at a follow-up of a few months up to 5 years [61]. From the studies with a longer follow-up, it seems as if cure rates decline with time [57,59]. This decline is not necessarily caused by the failure of the TVT procedure as the stress component does not show tendencies of recurrency. It is mostly the symptoms of urgency that increase, which in turn might be the consequence of concomitant illnesses evolving during follow-up.

COMPLICATIONS

Quality of life has become an important concept when discussing the outcome of incontinence surgery. The quality of life of the incontinent women is not solely reigned by the absence of urinary leakage, but as much by the absence of voiding difficulties, urinary tract infections (UTIs), and other adverse symptoms caused by complications associated with the surgical procedure. Minimal invasiveness and standardization of a surgical intervention is a means of bringing down the rate of complications. Systematic prospective registering of complications is the only possibility to get an accurate picture of the risk and the rate of specific complications.

Palva et al. [60]	89	36 months	72

Fortunately, a few such registers have been established and published [62–65]. The one from Finland is unique as it comprises every single TVT procedure performed in the country as it was introduced to the clinics within a systematic hands-on training program [62]. The Finnish material also includes the learning curve of all the surgeons involved. A French retrospective survey of complications associated with the TVT procedure was obtained by asking 92 urologists and gynecologists about the frequency of complications. All together, the survey included 12,280 TVT procedures [65] and is the most comprehensive survey of complications. The Norwegian register including 4281 TVT procedures is a prospective follow-up of complications associated with the TVT operation [64]. Another registry from Austria included 2795 cases, but does not involve all the clinics of the country [63]. A few other more comprehensive studies also focusing on the complication rates have been published [66–71]. The rate of the most common complications associated with incontinence surgery of these studies and the four registries are shown in Table 73.7. Interesting is to note that the rate of bladder injury is rather consistent in these reports, being on average 4.9%. The definition of voiding difficulties varies between the reports but mostly refers to the need for short-time intermittent catheterization within the first two postoperative days. The average rate of the reported postoperative voiding difficulties was 7.5%. In the report by Abouassaly et al., with the highest rate of voiding difficulties, only one patient needed an indwelling catheter for more than 48 hours [68]. The risk of postoperative UTI varies also somewhat, with the highest rate reported in the Austrian material. This might be caused by the fact that a policy of using an indwelling catheter postoperatively (63% of the cases) was adhered to. The average rate of UTI was 5.2%. The recommendation is to perform the TVT operation in local anesthesia, a condition that does not necessitate the use of a postoperative catheter in the bladder. In a report by Bodelsson et al., it was found that the risk of bladder perforation was three times higher if the TVT operation was performed in spinal anesthesia compared to local anesthesia [72].

The TVT operation has been found to be effective in the treatment of women with stress incontinence complicated by the simultaneous existence of urge symptoms or/and urge incontinence. In these cases of mixed incontinence, the cure rates reported are more than 80% [18,56,58]. Preexisting urge symptoms resolve in 50%–80% of the cases [18,61]. Occurrence of de novo urge symptoms varies between 0.2% and 15% (Table 73.7). Seventeen years of follow-up suggests that there is no risk of an increasing number of cases with de novo urge problems over time, the rate of these symptoms being 6% seven years postoperatively [29].

Although the TVT operation is partly a blind procedure, the risk of excessive (>200 mL) intraoperative bleeding and retropubic hematoma formation is rare. Excessive bleeding occurs on average in 2% of the cases (Table 73.7) and is mostly managed by manual compression and tamponade. In a systematic evaluation of the occurrence of postoperative retropubic hematoma formation, Flock et al. reported a rate of 4.1% among 249 consecutive cases, with only four cases exceeding 300 mL and requiring surgical intervention [73].

A potentiality of more serious vascular complications exists with a partly blind procedure. The incidence of such has been very low. The rate of serious vascular complications in the Finnish registry report was 0.07% and the Austrian registry reported a bowel perforation rate of 0.04%.

SUMMARY

Available data obtained from published clinical reports show that the TVT operation is effective in curing stress incontinence. In prospective trials where strict criteria for cure and significant improvement have been used, approximately 95% of women having a TVT operation are found to be cured or significantly improved of their stress incontinence. Furthermore, the TVT procedure seems to perform well in all categories of patients on whom incontinence surgery traditionally is recommended, that is, in primary cases of stress incontinence, in cases of prior failed incontinence surgery, and in cases with mixed incontinence, in those with intrinsic sphincter deficiency, and in overweight and obese women. The risk of intraoperative and short-term postoperative complications is low if proper training is provided and the operation is performed in its standardized way. No long-term adverse effects of the procedure have been reported.

In a cost-utility analysis by Manca et al., the TVT operation was found to be cost saving compared with open colposuspension [74].

74 Transobturator Tape for Surgical Treatment of Stress Urinary Incontinence: Outside-In Technique

Emmanuel Delorme and Jean-François Hermieu

INTRODUCTION AND HISTORY

In 1990, Mouchel [1] was the first to attempt to recreate the natural urethral supportive system with a mesh for the treatment of stress urinary incontinence (SUI). At about the same time, DeLancey [2,3] described the anatomy of the pelvic–pubic fascia and theory of the occlusion of the urethra on this retrourethral fascia by the pressure generated by exertion. More recently, Petros and Ulmsten [4,5] applied DeLancey's law clinically and introduced the notion of tension-free tape, describing the retropubic tape (RPT). The tape is held in place solely by friction with the tissues through which it passes.

The concept of the transobturator sling links the aforementioned concepts and clinical experience: it reproduces, in location and orientation, the effect of the suburethral fascia covering the urogenital gutter, behind the urethra, from one puborectalis muscle to the other one.

The transobturator tape (TOT) sling is held in place by friction between the tape and the musculoaponeurotic structures of the obturator foramen. It is a perineal procedure. The procedure is performed in the space between the aponeurosis of the levator ani muscle above, the perineal membrane below, the obturator foramen laterally, and the urethra and paraurethral space medially (Figure 74.1). This perineal space does not contain any vascular, nervous, or visceral structures. The transobturator urethral suspension pathway is flatter than for retropubic suspension.

Compared to RPT, the first aim of transobturator route was to decrease the risk of visceral (bladder, digestive structures), vascular (Santorini's plexus, iliofemoral vessels), and neurological (obturator and pudendal nerves) problem. The second aim was to reduce voiding dysfunction because a horizontal urethral suspension is theoretically less likely to cause dysuria than a retropubic suspension.

The first TOT was implanted in 1999 and the first retrospective series was published in 2001 [6].

ANATOMY

The first anatomical studies published or communicated on TOT were based on the work of Delmas [7]. The obturator foramen is constituted by, from outside in, the middle adductor muscle, the external obturator muscle, the obturator membrane, and the internal obturator muscle. On its medial aspect, the obturator foramen is divided into two parts by the parietal insertion of the levator ani muscle. The upper part, above the levator, is the pelvic area. It contains, at the level of its superolateral angle, the obturator canal that is crossed by the obturator pedicle. At this level, the obturator foramen is very close to the bladder that rests on the levator ani muscle. The lower part of the obturator foramen is under the obturator insertion of the levator ani muscle (Figure 74.2). The perineal space is located under the superior aponeurosis of the levator ani muscle, above the perineal membrane, and from bottom to top is laterally bound by the ischiopubic ramus and the internal obturator muscle; its medial limit consists of the paraurethral space and urethra. This perineal space does not contain any vascular, nervous, or visceral structures. The tape should be located within this perineal space (Figures 74.1 and 74.2). In this perineal part of the obturator foramen, only two anatomical structures could cause some risks during placement of the tape:

The urethra, which must be identified and protected by the finger when passing the tunneling device.

The pudendal pedicle and more specifically its terminal branch, the dorsal nerve of the clitoris. This nerve follows the medial side of the ischiopubic ramus from back to front.

When introducing a surgical instrument into the obturator foramen from outside in, the bony ramus protects the pudendal nerve.

Outside the obturator fossa, in the groin, the two terminal branches of the obturator nerve are located. The anterior branch is away from the area where the TOT is done, but the posterior branch is internal and close to the groin passage of the TOT. This is the reason why the groin route of the TOT must be very close the ischiopubic bone [8].

SURGICAL TECHNIQUE (TUNNELING DEVICE FROM OUTSIDE TO INSIDE)

Prosthesis and Surgical Instruments

The tunneling device is a needle with the functional part shaped into a suitable curve, fitted with a fastening system enabling traction of the tape through the obturator foramen. There are various types of tunneling devices with different systems for securing the tape to their tip. The tape is usually made of knitted monofilament polypropylene. The tapes are either highly elastic, requiring a plastic sheath for placement, or low-elasticity tapes that do not require a plastic sheath.

Anesthesia

Any type of anesthesia is acceptable, as the adjustment of the position of the tape does not necessarily require patient participation. The anesthesia can be general, regional (spinal), or local.

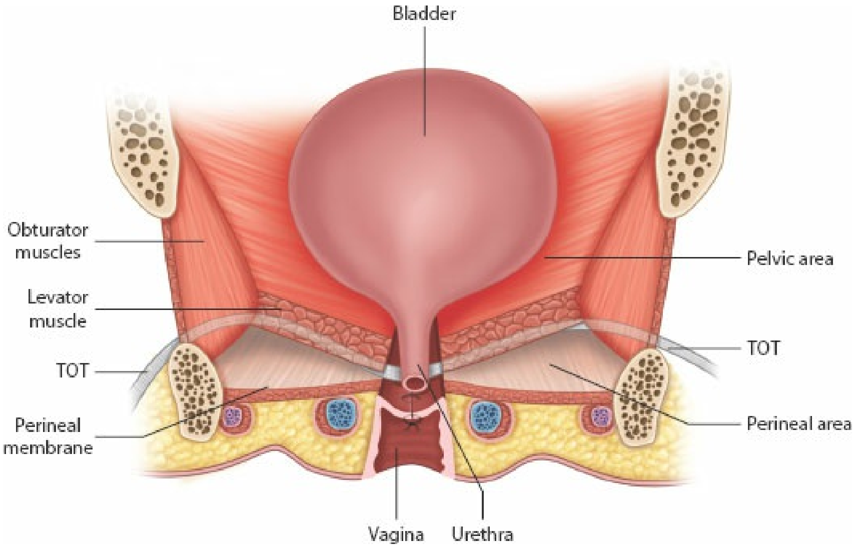

Figure 74.1 Transobturator tape is a perineal tape (with permission from Abiss).

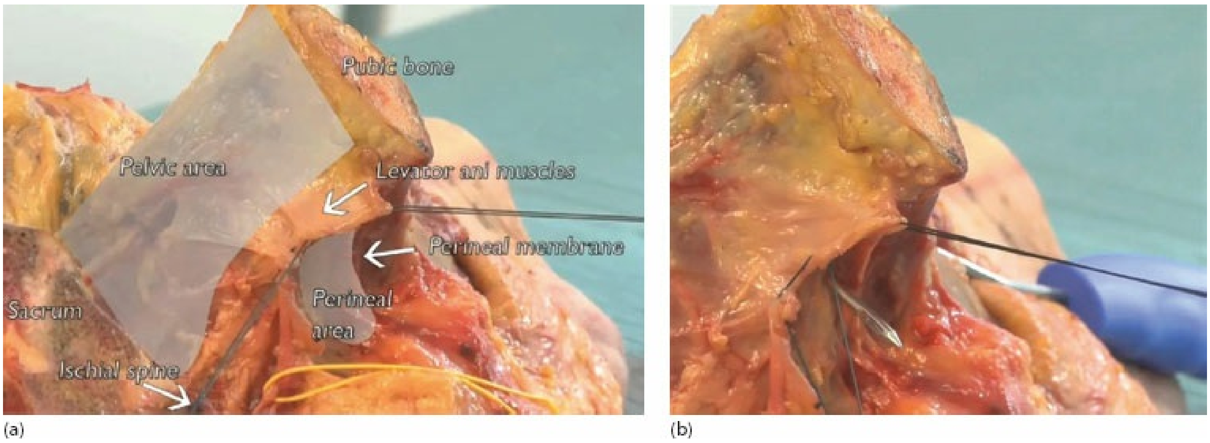

Figure 74.2 (a) Anatomy; (b) the needle is in the perineal area under the levator muscle.

Patient Position

The patient is placed in the dorsal lithotomy position. In this position, the hips are slightly less flexed avoiding risk of neural injury.

Surgical Technique

For operative guidance, a urethral catheter may help to manually locate the urethra more easily.

The sagittal retrourethral incision, which crosses the full thickness of the vaginal wall, must be wide enough to insert a finger (Figure 74.3). From this incision, dissect the vagina laterally on either side of the urethra. The dissection continues up to the ischiopubic ramus. The dissection is made in the deep anatomical plane, between the suburethral fascia and the urethra and not in the superficial surgical plane between the suburethral fascia and the vaginal skin. The lateral dissection should not disrupt the perineal membrane.

A puncture skin incision is made 15 mm laterally to each ischiopubic ramus at the horizontal level of the clitoris (Figure 74.4).

The tip of the tunneling device should emerge lateral to the middle third of the urethra. This course is controlled by aiming for the urethral meatus with the tunneling device (Figure 74.5). A finger is inserted as a guide inside the incision, laterally to the urethra, but above and behind the pubic bone. In conclusion, it is the arrival point of the tip of the tunneling device on either side of the urethra that determines at which level the tape will be positioned (Figure 74.5).

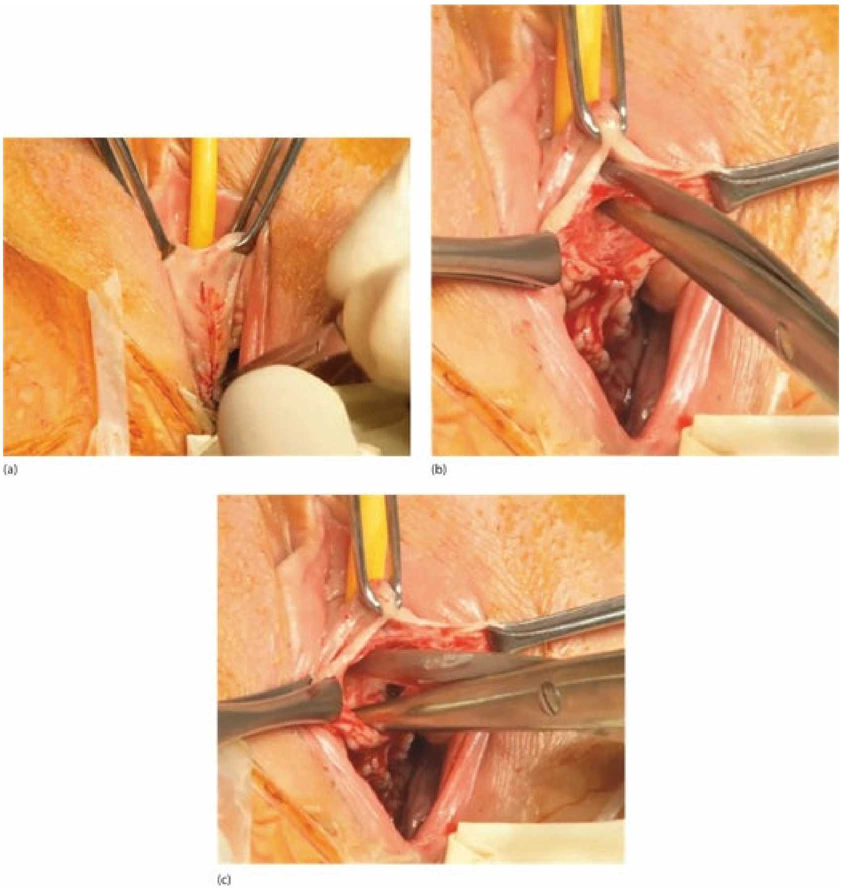

Figure 74.3 Vaginal incision and dissection: (a) mucosal incision; (b) suburethral fascial incision; (c) dissection between urethra and fascia, respecting the perineal membrane.

The tip of the tunneling device is guided inward, toward the urethra, aiming for the urethral meatus beneath the ischiopubic bone. The safest method is to guide the tunneling device around the ischiopubic ramus keeping it in close contact with the bone. When the tip of the tunneling device leaves contact with the bone, the needle crosses the obturator muscles, and immediately it can be felt by the operative finger behind the pubic bone (there remains only the perineal membrane for the needle to cross to be in close contact with the finger). The "blind" path of the needle is very short when using this method. The course of the tunneling device is a horizontal route and the needle comes out laterally to the urethra (in an acute angle between the ischiopubic bone and the urethra [Figure 74.6]). By applying this technique, the tape will be behind the middle third of the urethra, away from the bladder neck. The aim of this movement is to trace a perineal trajectory with the surgical instrument while staying underneath the superior fascia of the levator ani muscle. An index finger in the incision is used to ensure that the tunneling device does not come through the vagina and does indeed pass above the lateral fold at a distance from it. The tip of the index finger in the vaginal incision is used to push the urethra back upward and inward, protecting it from the needle. The finger will thus come into contact with the tip of the tunneling device laterally under the pubic overhang. The latter is then guided by the finger into the vaginal incision. The "blind" path when the tunneling device leaves the bone and comes into contact with the finger is very short (less than 15 mm). If it seems longer, then it is advisable to withdraw the tunneling device and start again. Once complete, it is advisable to look and check that the vagina has not been pierced by the tunneling device.

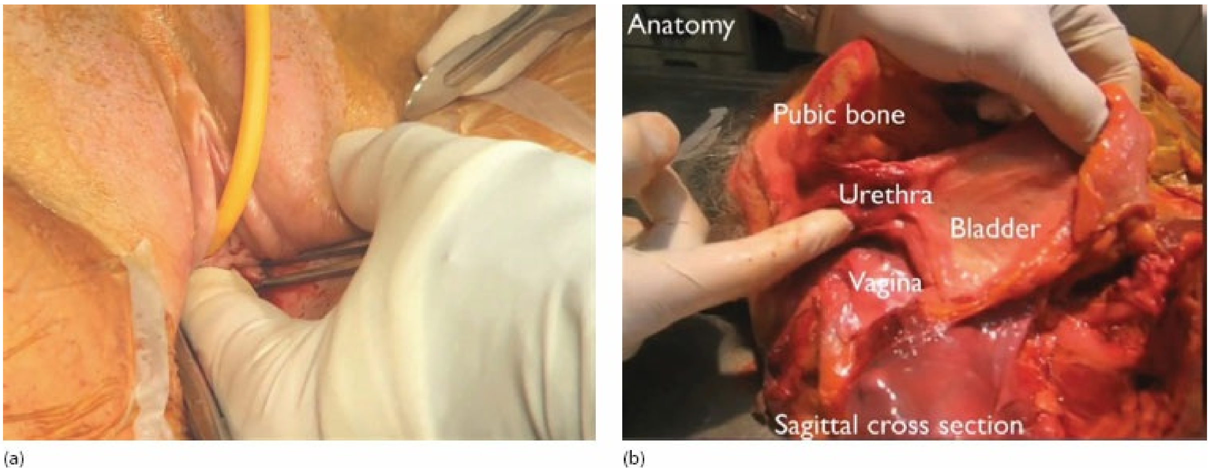

Figure 74.4 (a) Finger lateral to the urethra pushes the perineal membrane behind the pubic bone. (b) The obturator incision is at the horizontal level of the clitoris, close to and outside the ischiopubic bone.

(b)

Figure 74.5 (a and b) Tunneler horizontally targeting the urethral meatus.

The tip of the tape is secured onto the tip of the needle/trochar and then drawn into place.

Adjustment of the tape behind the urethra can also be achieved using anatomical parameters. Two points are important when adjusting the position of the tape, to reduce the risk of urethral compression that can induce dysuria:

1. With a low-elasticity tape, a visible space must be left between the tape and urethra (around 5 mm) (Figure 74.7).
2. With a high-elasticity tape, the tape must be resting against the urethra without pressing on it.

The surplus tape outside the skin is cut off. The vaginal incision is closed with a few simple resorbable sutures. The obturator incisions do not need to be sutured—take care to separate the skin from the tape. If they are point-like and vertical, they will tend to close up naturally when the lower limbs are brought into the horizontal position at the end of the procedure. Suture material at this level can cause discomfort. It is not necessary to insert a vaginal mesh.

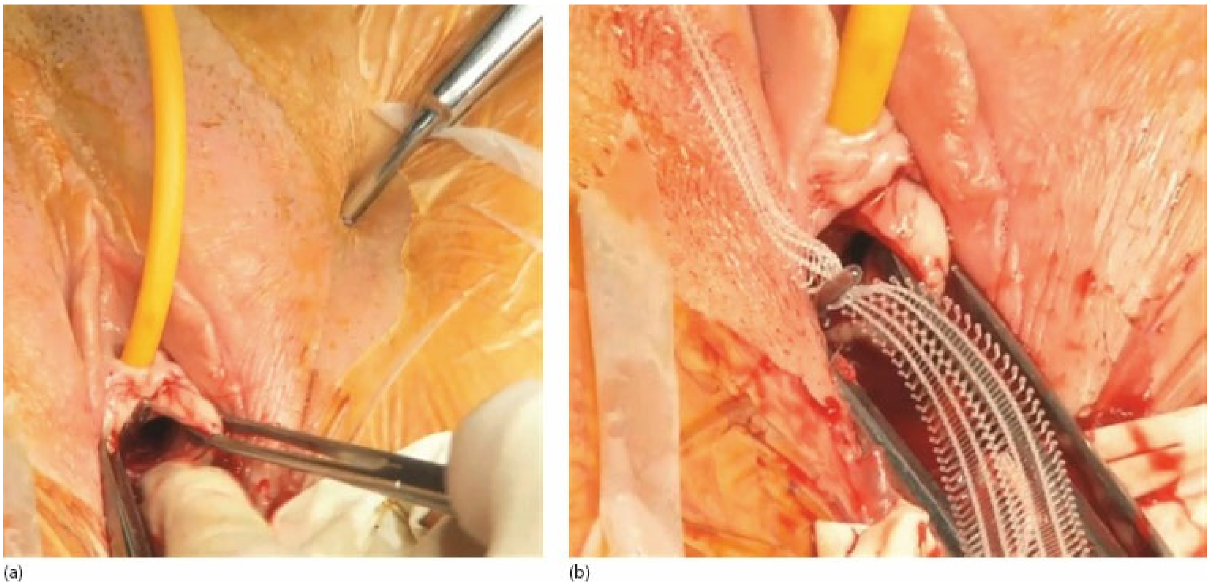

Figure 74.6 (a) The tunneller crosses the obturator fossa and (b) is outside the incision.

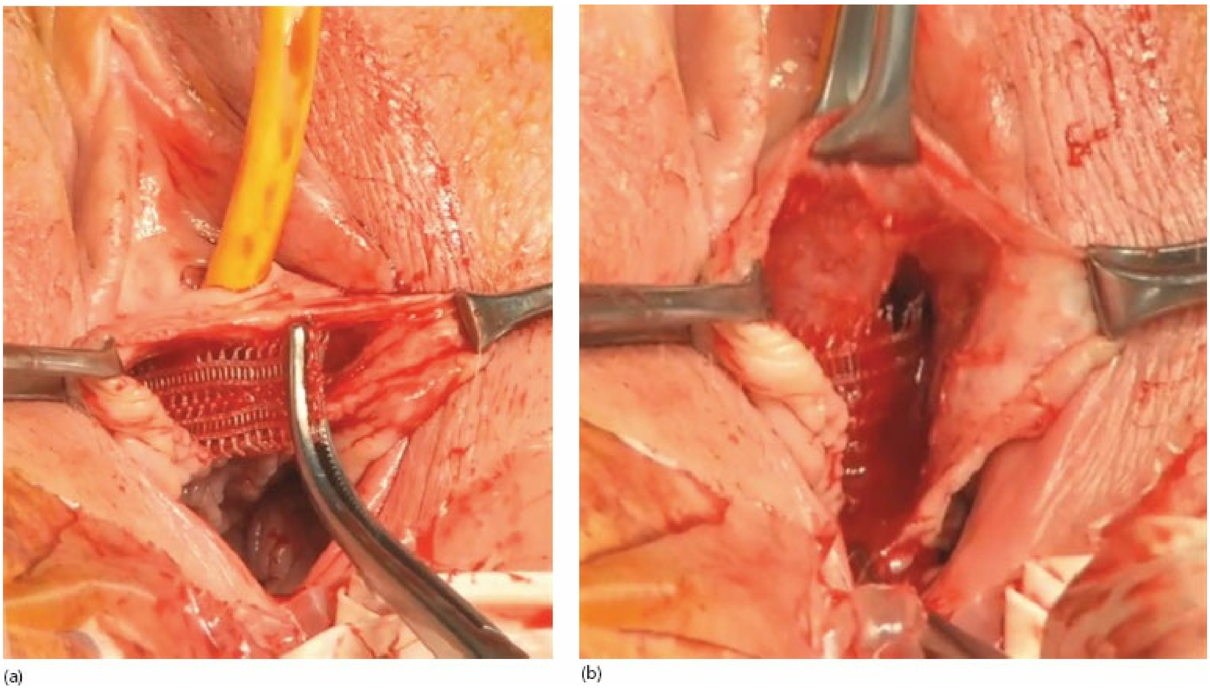

Figure 74.7 (a) Adjustment of the tape behind the urethra; the technique depends on the elasticity of the tape (a low-elasticity tape should be adjusted 5 mm away from the urethra). (b) Tape in place.

Postoperative Care

The catheter is usually removed at the end of surgery or the day after the procedure. Postmictional residue is measured with ultrasound or catheterization. If there is no significant postmictional residue, which is usual, the patient can be discharged.

CLINICAL PERFORMANCE OF TOT

This study is based to a large extent on the French recommendations on treatments for urinary incontinence using suburethral tapes published in 2010 by J.F. Hermieu [9–12].

Outside-In TOT, History, Results, and Compilations

Our preliminary series of patients who have undergone surgery for SUI with TOT® was only a retrospective feasibility study with follow-up generally of less than 1 year [6,13]. This study proved the feasibility of the intervention.

The synthetic material used (nonwoven polypropylene with silicone) later proved to cause vaginal erosion and sometimes severe infections.

The outcomes with the series of tapes placed by the transobturator route were spoiled by a higher number of cases of vaginal erosion and infections than the retropubic sling. This was essentially secondary to the use of materials unsuited to the vaginal route—multifilament polypropylene or heat-welded sprayed polypropylene. Meschia [14] reports in a comparative study on tension-free vaginal tape (TVT)/IVS erosion rates of 0% and 9%, respectively. Other publications report infectious complications with this type of material [15,16].

The consensus is currently to use for TOT® polypropylene monofilament knitted mesh [17] as defined by Ulstem for the retropubic route.

The rate of vaginal erosion with polypropylene monofilament knitted mesh tapes is 0.1%–2.4% [18,19] with a slight advantage for the retropubic route.

The TOT® route has been specified, thanks to anatomical studies [7]. Concerns about perioperative lesions to the obturator pedicle have been lifted by dissection work that has showed that the tunneler, then the tape, passed through the lower part of the obturator foramen, that is to say 2.2–2.5 cm from the pedicle with an average of 2.6 cm [20]. The TOT® is in the perineal space between the perineal membrane and the levator ani muscles.

The series published on the outside-in transobturator route confirm the anatomical data. The risk of perioperative complications is low, bladder wounds exceptional (0%–0.8%), and urethral wounds rare (0%–2.5%) [21,22].

In our prospective study [23] on 185 patients, there were no perioperative complications and no immediate revision surgery was performed. There were 23 immediate postoperative complications. Intermittent catheterization involved a total of 16 patients. For 14 of them, catheterization was necessary for less than 10 days. Two patients suffered from EVA > 3 postoperative pain. The same two patients continue to suffer from chronic pelvic pain with, respectively, 12 and 18 months follow-up. Four patients suffered from urinary tract infections and one patient suffered from pyelonephritis. There were no cases of late-onset serious complications (urethral or vaginal erosion), visceral injuries, or bleeding.

The average median follow-up was 23 months. For 68 patients follow-up has been demonstrated for more than 36 months. SUI was cured in 85.3% of cases and improved in 91.2% of cases. Among the urinary urgency patients in the preoperative phase, with urge urinary incontinence or without leakage, urinary urgency was cured in 51.4% of cases, improved in 22.9%, and unchanged in 25.7% of cases.

The de novo dysuria rate amounted to 3.3% at 3 months and 4.4% at over 36 months.

The efficacy of TOT® for treating SUI and its low morbidity have been reported in numerous publications (see Table 74.1) and confirmed by the most recent work [24–26].

Comparison of Outside-In TOT® with Other Types of Suburethral Tapes

Inside-Out TOT®

In 2003, de Leval [31] proposed an inside-out transobturator route with the following objectives: to retain the advantages of the transobturator route and to avoid the supposed disadvantages of the outside-in transobturator route (exceptional risk of bladder wounds, risk of urethra wounds caused by the introducer device passed from the outside in, to avoid an incision and excessive dissection of the vagina in order to insert a finger as far as the bone guiding the needle as it emerges in order to avoid any bladder/urethra injury).

Anatomical studies have shown that the pathway of the tape was closer to the pudendal pedicle and the posterior terminal branch of the obturator nerve than in the *outside-in* route [8,32]. The clinical studies have shown that this route is safe when technically it is implemented in line with the initial description. The rate of perioperative complications was identical to that of the *outside-in* route [33].

The Debodinance study [34] is a nonrandomized prospective study of a series of 100 women. At 1-year follow-up, he does not report any significant difference in terms of perioperative or late-onset complications, postoperative dysuria, or de novo urge incontinence. The 1-year cure rate is 94% in the inside-out group and 90% in the outside-in group (NS). These data are confirmed not only by Liapis [35], Lee [36], and Vervest's series [37] but also by Chae (series of 640 patients with 1-year follow-up) [38] and Cheung's [39] series with 5-year follow-up. For the majority of authors, the comparative study of the complications for the *inside-out* and *outside-in* routes does not show any significant difference between the two [40] (cf. Table 74.2).

Table 74.1 Outcomes for Outside-In TOT®

	No. of patients	Technique	Follow-up (months)	Cure rate (%)	Improvement rate (%)	Subjective cure rate (%)
Delorme (2003) [27]	32	Outside-in heat-welded PP	17 (13–29)	90.6	9.4	
Costa (2004) [28]	183	Outside-in heat-welded PP	7 (1–21)	80.5	7.5	
Krauth (2004) [17]	140	Outside-in knitted PP	12			85.5
Spinosa (2005) [22]	117	Outside-in heat-welded PP	16.3 (7–22)	92.3	4.22	
Roumeguere (2005) [29]	120	Outside-in heat-welded PP	12 (12–30)	80	12	
Deval (2006) [30]	129	Outside-in heat-welded PP	17.2 (4–28)	89.9		77.5
Castaings (2013) [23]	185	Knitted PP	23 (3–40)	85.3	5.9

Transobturator Tape or Retropubic Tape

In Sung's meta-analysis [43], over 303 references were identified. Unfortunately, 285 of them were not comparative studies, did not have a control group, or were not explicit enough to be used. The meta-analysis was only able to use 18 articles, 6 randomized studies (representing 492 women), and 12 cohort studies (representing 2009 women).

It was not possible to clearly evaluate the objective cure rate due to evaluation criteria that were unclear and varied from one study to the other. The relative risk of subjective curing of SUI by the transobturator route compared to the retropubic route is 0.82 (CI 95%, 0.19–0.83). The relative risk of perioperative complications with the transobturator route compared to the retropubic route is 0.40 (CI 95%, 0.19–0.83) when it is based on randomized studies and 0.21 (CI 95%, 0.10–0.44) when it is based on cohort studies. The most common complication is bladder perforation (3.5% with the retropubic route, 0.2% with the transobturator route), followed by hematoma (1.6% vs. 0.08%), and then infection (less than 1% in both groups).

The relative risk of de novo urge incontinence at 1-year follow-up with the transobturator route compared to the retropubic route is 0.63 (CI 95%, 0.12–3.33) when it is based on randomized studies and 0.48 (CI 95%, 0.23–1) when it is based on cohort studies.

This meta-analysis, however, is open to criticism. Its results are based on studies that include some that are indisputably biased. The results are determined based on several variables (route first of all, but also type of tape). The lengths of the follow-up are not homogeneous.

Latthe’s meta-analysis [44] uses five randomized trials comparing TVT-O and TVT and six trials comparing TOT® and TVT. These studies are not all included in Sung’s meta-analysis. The subjective cure rate for the transobturator route, whether outside-in or inside-out, at 2- and 12-month follow-up, was no better than for the retropubic route (OR 0.85; 95% CI 0.60–1.21). Complications such as bladder injury (OR 0.12; 95% CI 0.05–0.33) and voiding dysfunction (OR 0.55; 95% CI 0.31–0.98) are less frequent than for the retropubic route. On the other hand, pain in the root of the thigh (OR 8.28; 95% CI 2.7–25.4) and vaginal wounds as well as exposure of the mesh (OR 1.96; 95% CI 0.87–4.39) are more common after placing the sling by the transobturator route.

A certain number of recent studies have confirmed the comparable efficacy and low morbidity of the RPT and the TOT® after a short follow-up period (3 months) [45]. Over a longer follow-up period, the outcomes remain comparable and stable: 2 years [46], 5 years for Angioli [47] with 71% of patients cured of SUI, but only 60% of patients satisfied in each group, but this is a small series (72 patients). The risk of de novo urgency would appear to be significantly lower after placing a TOT® than a RPT even with a long follow-up period for some [48], but this is not found in all the series of patients [49] (Table 74.3).

Table 74.3 Comparison TOT®/RPT

[a] Less than 1 week after surgery.

[b] More than 1 week after surgery.

In conclusion, overall TOT® and RPT have similar outcomes in the treatment of SUI. The use of RPT is accompanied by a risk of bladder injury that does not exist with TOT®. The TOT® has an increased risk of inguinal pain compared to RPT—the majority of publications reporting inguinal pain concern inside-out TOT® series [60,61].

TOT® and Pain

The transobturator route and more particularly the inside-out route may be implicated in the etiology and pathogenesis of postoperative pain [62–64] and traumatic neuropathy [62]. The risk of nerve injuries to the pudendal nerve and the posterior terminal branch of the obturator nerve is controversial from the anatomical point of view for the inside-out transobturator approach [7,65]. Pudendal nerve damage has been proven in some studies on the *inside-out* approach [66]; however, the rarity of this complication does not lead to a conclusion that there is a greater neurological risk with *inside-out* than with *outside-in* approach. The risk of injury to the posterior terminal branch of the obturator nerve has been demonstrated anatomically [32]. When using the inside-out technique, passing as close as possible to the external side of the ischiopubic ramus limits the risk of injury to the posterior terminal branch of the obturator nerve.

Poorly discriminated pain in the groin and root of the thigh region, usually transient, is more common in inside-out procedures [44]. Passing through the pelvic insertion of the adductor longus muscle may be responsible for postoperative pain [32].

Inguinal pain is found in most of the *inside-out* TOT® series, but is found or described less often in *outside-in* series [61,67]. In our first series [6], no patients had inguinal pain; in our second series published [23] at 3-year follow-up, only two patients had pain worse than 3 on a scale of 0–10.

Cases of dyspareunia have been described after a TOT® procedure, although studies on sexuality before and after a TOT® procedure objectively show an overall improvement in the quality of patients' sex lives after a TOT® as SUI interferes with their sex lives [68].

Pain can have several other etiologies: infection of the implant requiring its removal and also idiopathic retraction of the implant. Chronic inflammatory reactions have also been described and perhaps painful scar neuromas during prosthetic ingrowth [69]. Treatment of such pain requires the removal of the sling straps [70,71].

SPHINCTER DEFICIENCY

The urodynamic definition of sphincter deficiency varies from one study to another. It is difficult to compare the different series of patients.

For some, tapes give less good results in treating sphincter deficiency than SUI [57]. The TOT® is less effective than RPT in cases of sphincter deficiency [23,26,72].

Although tapes have lower efficacy on sphincter deficiency than on SUI, they still have their uses in the treatment of sphincter deficiency; for Goktolga, 57.4% of patients are satisfied after 5 years [73].

Some studies show that placing a tape by the retropubic route is more effective in the short and medium term than the transobturator route, when there is sphincter deficiency (86.94% compared to 34.89%) [74–76].

The RPT has been proposed to treat TOT® failure, with 75% long-term success [77]. This is confirmed by Schierlitz's [78] prospective comparative study, which proves the greater efficacy of RPT compared to TOT® in treating sphincter deficiency at 3-year follow-up. The median time to repeat surgery for TOT® was 15.6 months compared with 43.7 months for RPT ($p < 0.001$).

Urethral hypermobility seems to be a criterion, much more decisive than sphincter deficiency, in the efficacy of tape and particularly of TOT®. Fixity of the urethra is a factor of failure of TOT® [79,80].

CONCLUSION

Surgical Technique

The surgical technique for the implantation of a TOT (*outside-in* procedure), although simple, should be very strict. The following technical points must be respected to ensure the safety of the procedure:

- The vaginal incision must be deep to ensure that the dissection is performed in the anatomical plane between the urethra and retrourethral fascia.
- The trajectory of the tunneling device should be oriented toward the middle third of the urethra; this is achieved by aiming for the urethral meatus until it can be felt with the finger at the top inside the vaginal incision, behind the pubic bone; the needle's path is horizontal.
- The tunneling device should remain in close contact with the bony ischiopubic ramus throughout its trajectory.
- The tip of the finger must be inserted into the incision, to protect the urethra and then to accompany the tip of the tunneling device into the vaginal incision.

Clinical Conclusions

The most significant advantage of the TOT procedure compared to RPT is the lower risk of visceral complications and hemorrhaging. There is tendency for less dysuria and urgency after placing a TOT than with an RPT.

The TOT seems to have three weaknesses compared to the RPT:

1. There is a greater risk of vaginal erosion, in particular laterally, but this is due to poor insertion technique.
2. The TOT seems to be less effective than the RPT in treating sphincter deficiency.
3. The risk of postoperative pain appears to be greater after placing a TOT. More postoperative pain is reported in publications for tapes placed by the *inside-out* route than after the *outside-in* TOT approach.

75 Single-Incision Minislings

Mickey Karram and Radhika Sharma

INTRODUCTION

In 2006, the single-incision synthetic midurethral sling (MUS) was introduced as a modification to traditional retropubic and transobturator MUSs. These slings were designed to require less dissection in the midurethral area without the need to make additional incisions suprapubically or in the groin. They are placed entirely through an incision in the vagina having no exit point. They were designed to minimize the risk of bladder perforation associated with traditional retropubic MUS and the risk of groin discomfort or other issues related to the inner thigh associated with passage of transobturator slings through the obturator membrane and adductor compartment. Single-incision minislings are anchored into the obturator internus muscles or connective tissues of the endopelvic fascia of the retropubic space behind the pubic bone, and more recently, some are anchored directly into the obturator membrane.

Early SIMS had decreased efficacy compared to standard MUS and long-term data were lacking. However, recently, long-term outcome data have become available regarding the effectiveness of SIMS as compared to their standard MUS counterparts.

A survey of urologists in the United States suggests that 10% of practicing urologists have already adopted this technology for regular use in patients with primary stress urinary incontinence (SUI). However, the U.S. Food and Drug Administration (FDA) has recently required the manufacturers of SIMS pursue additional studies to further document long-term efficacy and safety. This mandate leads to the voluntary withdrawal from the market of at least two commercially available SIMS. These studies, which will be ongoing over the next 2 years, will determine the future of these devices.

INDICATIONS AND PATIENT SELECTION

Indications for SIMS are similar to the indications for the more traditional MUS in that they can be offered as an initial, definitive treatment of SUI. Because the minisling is less invasive than a retropubic or transobturator MUS, it may be desirous for some special patient populations. Because it avoids the retropubic space, the minisling may be considered specifically in patients who have undergone previous retropubic and abdominal procedures and may be at higher risk for significant pelvic adhesions. Because it does not entail complete passage of trocars to the skin level, it may be considered in patients with significant soft-tissue mass or obesity in the areas of traditional MUS trocar site exit (i.e., truncal or intertrigonal obesity) that may surpass the length of the trocar. Because single-incision minisling procedures can be done under local anesthesia, they can also be considered in patients with significant comorbidities in whom general anesthesia is contraindicated.

DESCRIPTION OF VARIOUS TYPES OF SINGLE-INCISION SLINGS

Five SIMS are commercially available at the present time in the United States: MiniArc single-incision sling (SIS) system, MiniArc Precise SIS system, MiniArc Pro SIS system (American Medical Systems, Minnetonka, MN), Solyx SIS system (Boston Scientific Corp., Natick, MA), and Altis SIS (Coloplast, Minneapolis, MN).

The MiniArc SIS (Figure 75.1) is a polypropylene mesh (8.5 cm × 1.1 cm) with permanent self-fixating tips that is deployed with a supplied metal 2.3 mm needle/trocar. The mesh is connected to the tip of the needle before insertion; the mesh and needle are inserted; and the needle is removed, leaving the mesh behind. Self-fixating tips are constructed of polypropylene and have two anchoring barbs that help resists up to 5.5 lb of pullout force to remove the mesh. A redocking maneuver can be set up before insertion to allow retrieval and reinsertion of the mesh if necessary.

The MiniArc Precise has a similar setup and procedure to the MiniArc SIS. The advantage of the

Precise sling is preventing mesh rotation and disengagement. This mesh is also geared at improving the control of sling tension that had been lacking in previous models of the single-incision synthetic slings.

The MiniArc Pro system varies with its earlier two counterparts by incorporating a visual feedback system allowing repeatable, standardized control. A feedback system has been employed that utilizes a stationary scale and an indicator that moves relative to the scale if the mesh is elongated or tensioned. This marking system allows for the placement of the sling under the portion of the urethra being supported in a consistent manner.

The Solyx SIS system (Figure 75.2) includes a polypropylene mesh tape (9 cm in length) with permanent barbed self-fixating tips and a metal and plastic delivery device or trocar. This system is designed similarly to the MiniArc SIS system, in that each tip of the sling is sequentially attached to the end of the delivery device for mesh placement, which is removed after insertion. The edges of the center 4 cm of the mesh (advertised as the suburethral portion) are bonded together to potentially reduce irritation and the possibility of mesh erosion or extrusion.

The Altis SIS system (Figure 75.3) is a macroporous, knitted, monofilament polypropylene sling (7.75 cm) spanning between the obturator membrane complexes. The sling has a low elasticity at 7.5% similar to collagen fibers; it also has a radiopaque coating for imaging. Affixed to each side of the sling is a monofilament suture. The anchors on the sling are designed to secure maximum pullout force while allowing a flexible secure placement. The tensioning sutures on either end of the mesh allow for a movable anchor with two-way adjustability. This theoretically is meant to prevent sling movement during the healing period.

SURGICAL TECHNIQUE

1. *Preoperative considerations*: Insertion of a minisling may be performed under many different types of anesthesia, including general, spinal or epidural, regional, and local. Perioperative antibiotics (e.g., fluoroquinolone or first-generation cephalosporin) are generally administered before the incision.
2. *Patient positioning*: The patient is positioned in the dorsal lithotomy position with legs in stirrups. The perineum and vagina are sterilely prepared and draped so as to exclude the anus. Lateral labia majora retraction stitches may be placed or a self-retaining retractor may be used to improve vaginal exposure. A weighted vaginal speculum is placed, and bladder drainage is accomplished with a Foley catheter.
3. *Vaginal incision*: A 1–1.5 cm midline incision is marked starting 1 cm below the urethral meatus, and the area is infiltrated with injectable grade saline or 1% lidocaine with epinephrine for hydrodissection of the periurethral tissues. An Allis clamp may be placed distal to the incision, with care taken not to traumatize the urethral meatus, to facilitate visualization. An incision is made sharply with a scalpel.
4. *Vaginal flap dissection*: Dissection of lateral vaginal flaps proceeds in a standard fashion with attention to developing an appropriately robust and well-vascularized vaginal flap, while not jeopardizing the thickness of the periurethral tissue. This flap is carried laterally and anteriorly until the endopelvic fascia is encountered, but the retropubic space is not entered (Figure 75.4a and b).
5. *Preparation of the Sling*: The sling is prepared by inserting the tip of the delivery device or needle into the self-affixing end of the mesh apparatus, ensuring that the mesh is oriented on the outside of the delivery needle.
6. *Insertion of sling*: To place the MiniArc SIS or Solyx SIS, the tip of the delivery needle with mesh assembly attached is inserted into the previously dissected vaginal space and aimed along a path 45° from the midline (Figure 75.5). The placement should be immediately posterior to the

ischiopubic ramus; the needle can be “walked off” the posterior aspect of the bone, maintaining a close proximity to the posterior surface of the bone. The tip should be advanced until the midline marking on the mesh is situated under the middle of the urethra. The needle is removed from the mesh, attached to the other end of the mesh device, and inserted on the contralateral side in a similar manner, ensuring the mesh lies flat under the urethra, until the proper degree of desired tension is achieved. The delivery device is disengaged and removed. The MiniArc SIS can be arranged with a delivery/inserter needle to facilitate reconnecting the needle tip into the self-affixing tip of the mesh device. This arrangement allows for the mesh to be inserted further, if more tension is desired. The redocking procedure entails threading a 2–0 polypropylene suture through the tip of the mesh assembly and then through the tip of the delivery device, knotting one end. This end of the mesh is placed first, in the usual fashion, and then the delivery needle is removed, leaving the suture in place. The opposite side is also placed in the usual fashion. If further tensioning is warranted, the free end of the suture is reinserted into the end of the delivery needle, and the needle is advanced along the suture, sliding into the tip of the mesh device. Once docked, the entire mesh device can be advanced further into the patient.

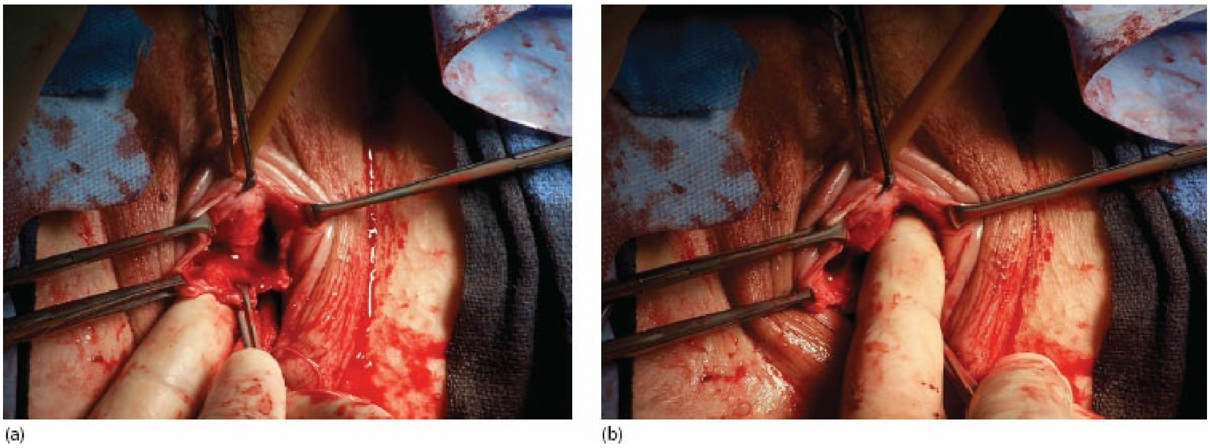

Figure 75.4 (a) Distal anterior vaginal wall incision made prior to passage of a single-incision sling. (b) Note the index finger of the surgeon is used to palpate the lower edge of the inferior pubic ramus.

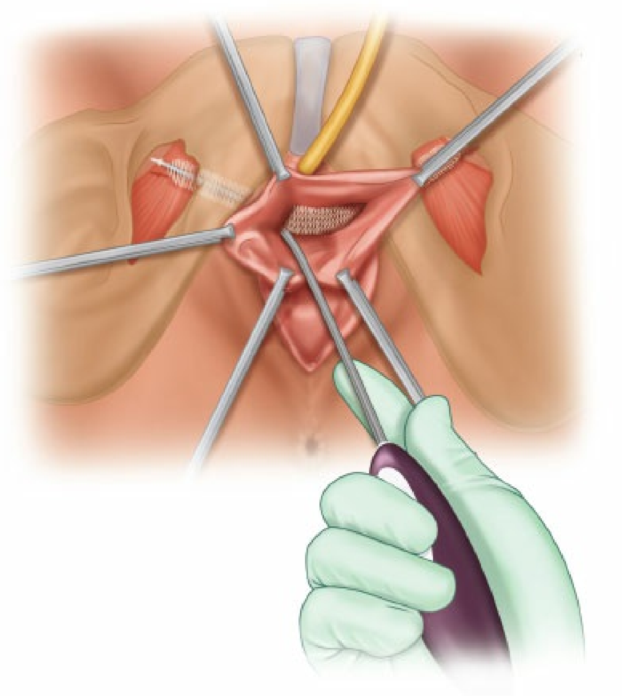

Figure 75.5 Technique for placement of the MiniArc single-incision sling. The sling is placed directly into the obturator internus muscle. (Reproduced from Baggish MS and Karram MM, *Atlas of Pelvic Anatomy and Gynecologic Surgery*, 3rd ed., Elsevier, St. Louis, MO, 2011. With permission.)

The placement of the Altis adjustable SIS proceeds by the same initial steps (steps 1–4) as previously outlined. After appropriate dissection is completed, the fixed anchor is pushed into the tissue until it is slightly beyond the ischiopubic ramus. The handle is pivoted toward the obturator internus muscle and membrane. A metal tip of the trocar extends past the anchor allowing for an easier placement of the anchor into the obturator membrane. The fixed anchor is pushed through the obturator internus muscle and membrane. Gentle traction is applied to the suburethral sling to confirm proper fixation. The adjustability of the sling is independent of its insertion and does not lock, which allows the loosening of the sling should it be found to have been set too tightly.

7. *Cystoscopy*: Cystoscopy should be performed to evaluate for bladder injury.
8. *Vaginal closure*: The vaginal incision is closed in the same way as described previously in which the anterior sulcus is trimmed, and the vaginal incision is closed.

Outcomes

Up until recently, very little data existed on the outcomes of SISs especially when compared to more traditional transobturator and retropubic MUS. Table 75.1 reviews outcome data on single-incision MUSs. All studies were compared to either retropubic or transobturator MUS. Outcomes of the studies were objective and subjective and assessed at 12 and 24 months postoperatively. Objective outcomes encompassed negative cough stress test (CST) and the 1 hour pad test. Subjective cure rates included the reported episodes of leaking following the procedure, subjective reports of SUI, self-assessment of cure, overall satisfaction with results, and resolution of symptoms. Randomized control trials included the use of MiniArc, Ajust, Ophira, and Solyx slings. Studies on tension-free tape (TVT)-Secur were excluded from Table 75.1.

Abdel-Fattah's recent meta-analysis of randomized controlled trials comparing SISs (after excluding TVT-Secur) to transobturator and retropubic MUS showed no difference in patient-reported outcomes and objective cure rates. The analysis also revealed lower postoperative pain scores and earlier return to normal activity in the SIS groups.

Table 75.1 Outcome Data on Single Incision Mus

Study, dates	Design	Enrolled	Inclusion criteria	Intervention	Outcome and follow-up
Enzensberger et al., 2010	RCT Austria	95	+CST, subjective SUI	MiniArc vs. TOT	MiniSling noninferior to TVT-O in objective cure rate. Postoperative pain at 48 hours, length of operation shorter for minisling.
Oliveira et al., 2008	RCT Portugal	60	Clinical and urodynamic SUI	MiniArc vs. TVT-O	Objective and subjective cure rates equivalent.
Merali et al., 2012	RCT Canada	37	All participants SUI	MiniArc vs. TOT	Objective cure rates at 12 months postoperatively were equivalent.
Schellart et al., 2009–2011	RCT Multicentered Netherlands	193	Urodynamic SUI	MiniArc vs. TOT	1 year follow-up MiniArc noninferior to Monarc subjective and objective cure rate, less postoperative pain with MiniArc.
Basu et al., 2009–2012	RCT United Kingdom	71	SUI symptoms and objective evidence of SUI, or failed conservative treatment	MiniArc vs. TVT	3-year failure rate significantly higher for single-incision sling vs. retropubic sling; both procedures had reduced efficacy over time.
Mostafa et al., 2009–2010	RCT Multicenter United Kingdom	137	SUI, failed or declined pelvic floor physical therapy, or primary continence procedure	Ajust vs. TOT	Lower postoperative pain profile in Ajust group, subject, and objective cure rates did not differ between Ajust and TVT-O slings.
Djehdian et al., 2008–2011	RCT Brazil	130	SUI, no prolapse > Stage I	Ophira vs. TOT	Minisling was inferior to TOT, minisling shorter operative time, and less postoperative thigh pain.
Piccione et al., 2008–2010	Prospective multicenter	95	Clinically symptomatic and urodynamic SUI	Ajust	Objective and subjective cure rates improved in patients treated with Ajust sling.

COMPLICATIONS AND SURGICAL TIPS

Complications that can occur are similar to the complications that can occur with retropubic and transobturator MUS. These include bladder injury or perforation, bleeding, vaginal mesh extrusion, urinary tract mesh erosion, voiding dysfunction, and urinary retention. Viscous organ damage and major vascular injury still may occur but in theory should be much less common because the needle/trocar trajectory through the retropubic or obturator space is significantly more truncated by design of the minisling.

Bladder perforation may occur at the time of sling insertion; the self-affixing points of the MiniArc SIS and Solyx SIS may make removal and reinsertion of the device difficult because these slings are not designed to be removed. Removal of the MiniArc SIS may be facilitated by setting up the redocking procedure with a suture. If bladder perforation occurs and is discovered on cystoscopy, the sling should be immediately removed. A secondary insertion should not be attempted at that operative time. In the authors' opinion, cystoscopy should be routinely performed at the time of placement of a SIS.

Because of the shorter length of inserted mesh, more tension is placed on the minisling at the time of insertion than is placed on other types of MUS. The implanted sling should be in close apposition to the urethra with no laxity in the material. The surgeon should use a clamp or right angle to determine that there is no redundancy in the sling material.

CONCLUSION

SISs were reported to have higher failure rates with increased rates of mesh erosion; however, several recent trials have demonstrated the efficacy of SISs to be comparable to more traditional transobturator and retropubic MUS. Specifically, the MiniArc when compared to standard MUS demonstrated similar efficacy. This could be secondary to improved design with alteration of the trajectory as well as improved surgeons' understanding of the minisling procedure. The compilation of recent outcome data demonstrates that there may be a role for SISs given their lower postoperative pain score, more favorable recovery time and earlier return to normal activities. However, further long-term outcome and safety data as mandated by the FDA will most likely ultimately determine the fate of these procedures.

76 Readjustable Slings: Safyre and Remeex

Paulo C.R. Palma and Cassio Riccetto

INTRODUCTION

Slings have been the chosen option for most of the patients complaining stress urinary incontinence (SUI) for a long time. Synthetic slings have turned major surgeries into minimally invasive procedures and also reduce operative time and hospital stay as well as postoperative discomfort and the recovery period. Complex patients include those with multiple recurrences after the previous treatment attempts, specially using mesh, with dysfunctional voiding due to fixed urethra, and with previous urethral reconstructive surgery. Until recently, autologous material was mostly used for this subset based on two major concerns: risk of prosthetic implant infection and urethral erosion leading to pain and urethral fistulas [1]. Readjustable slings were proposed to allow for a safe and effective management of complex incontinence. In this chapter, we will focus on two most popular commercially available adjustable slings: Safyre and Remeex.

SAFYRE

The readjustable and self-anchoring Safyre sling (Promedon, Argentina) is a tension-free, synthetic sling, placed at the midurethra that makes urethral erosion unlikely. It was developed in the 1990s according to the integral continence theory [2]. This device allows for tension readjustment if postoperative persistent urinary leakage or retention occurs [3,4].

Features

From a conceptual standpoint, Safyre corresponds to a sling. So, the creation of a suburethral support zone increases urethral resistance and diminishes the rotational as well as the descending movement of the urethra when abdominal pressure increases. Additionally, it improves the coaptation of the urethral lumen at rest and under stress. However, contrary to the classical pubovaginal slings, the Safyre is applied in the middle third of the urethra, where the pubourethral ligaments, responsible for natural stability of the urethra, are inserted [2].

Safyre consists of a polypropylene monofilament mesh that acts as a urethral support, held between two self-anchoring tails made of polydimethylsiloxane polymer (silicon) (Figure 76.1). The Safyre self-anchoring system is created by a sequence of 4 mm cones displayed in a palm tree trunk conformation, creating a hooklike effect and attaching to the surrounding structures as the pelvic fascias and the abdominal rectus muscle as well. These tails are the key for the readjustable self-anchoring system. In order to minimize the surgical damage to pelvic floor natural support structures, a special 3.5 mm in diameter needle allows for retropubic placement, through both suprapubic and transvaginal approaches, according to the surgeon's best skills. The versatile needle is assembled for transvaginal approach when the hooked extremity is introduced inside the needle holder, and for suprapubic approach when assembled the other way (Figure 76.2). A special curved needle with a hooklike extremity is used for the transobturator approach (Figure 76.3). For this unique feature, i.e., universal approach, Safyre is the only sling so far that allows for comparing retropubic and transobturator procedures using the same device, in regarding to efficacy, safety, and complications.

In a comparative study, Safyre VS and Safyre T were analyzed. After a mean follow-up period of 18 months (ranged from 12 to 36 months), according to Blaivas and Jacobs criteria, 116/126 patients (92.1%) who underwent Safyre VS procedure and 94/100 (94%) who underwent Safyre T were found continent, and 3/126 (2.4%) and 2/100 (2%), respectively, reported significant improvement. In the same study, the impact on quality of life was assessed using the International Consensus of Incontinence Questionnaire Short Form (ICIQ-UI-SF), which showed significant improvement in all questions compared with preoperative assessment (90% of patients reported that they had less urinary symptoms after surgery, in both groups). At the end of follow-up period, the stress test was negative in all the continent and incontinent patients, and the incontinent group was using one pad per day at the most [5].

Retropubic Placement through Transvaginal or Suprapubic Approach (Safyre VS)

Two 0.5 cm transverse incisions are made close to the superior aspect of the pubic bone 5 cm apart from each other. A longitudinal vaginal incision 1.5 cm in length is made, starting 1 cm from the urethral meatus. Notice that this incision is not allowed encroaching on the bladder neck. Dissection is done to create a 1 cm tunnel lateral to the urethra for the introduction of the needle. First, the needle is advanced through the vaginal tunnel until the perforation of pelvic floor at the level of the midurethra. Then, it is redirected against the back of the pubic bone and advanced continuously to the previously made landmarks in the suprapubic area. Cystoscopy is performed to rule out bladder perforation. After the removal of the holder, Safyre VS is attached to the needle and pulled out to the suprapubic area. The same maneuvers are repeated on the other side. The proper tension of the sling is adjusted maintaining a Metzenbaum scissors between the urethra and the sling, to prevent undue tension. The extremities of the sling are cut and the Metzenbaum scissors removed. No further fixation is needed and the incisions are closed in the usual manner (Figure 76.4). An indwelling catheter is left in place overnight.

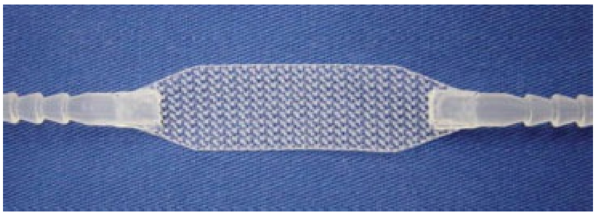

Figure 76.1 Safyre consists of a polypropylene mesh that acts as a urethral support, held between two self-anchoring tails made of polydimethylsiloxane polymer.

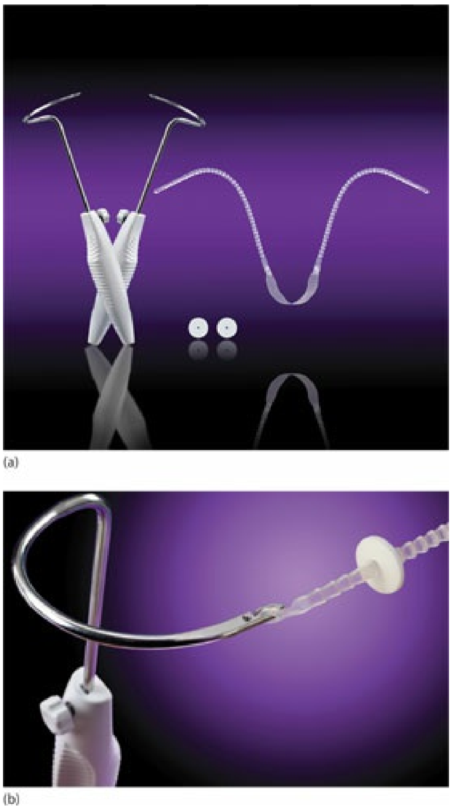

Figure 76.3 (a) Safyre T Plus set. (b) Detail of the helical needle, with a hooklike extremity is used for the transobturator approach.

Transobturator Approach (Safyre T)

Safyre T is a monofilament polypropylene mesh, which is held between two self-anchoring silicone columns that associate the universal approach with readjustability [6]. A 2 cm long vertical vaginal incision is performed at 0.5 cm from the urethral meatus. Minimal vaginal dissection is performed laterally toward the inferior ramus of the pubic bone; this minimal dissection avoids damage to the urethral innervations and allows for the passage of the needle and the anchoring columns. Skin punctures are made bilaterally in the genitofemoral folds at the level of the clitoris. The needle is passed around and under the ischiopubic ramus through the skin, obturator membrane, and muscles and finally out through the vaginal incision. This is accomplished by introducing the needle vertically in the previously made skin incision until the obturator membrane and muscle are perforated. Next, the needle is brought to a horizontal position with the tip heading to the surgeons index finger in the vaginal incision. This maneuver allows the surgeon to bring the needle safely to the vaginal incision. Safyre T sling is then hooked by the tip of the needle and brought to the previously made incision. The same maneuvers are repeated on the other side. A forceps or scissors is placed between the tape and the urethra during intraoperative adjustment, avoiding any tension of the tape. The exceeding silicon columns are cut leaving five cones over the skin. This extra length is introduced in the subcutaneous tissue, toward the labia majora for safety and to facilitate the anchoring tails postoperative identification should it be necessary. The skin and vaginal incisions are closed in the usual manner (Figure 76.5). Cystoscopy should be performed if there is any concern about bladder injury [5,6]. Foley catheter was left in place overnight.

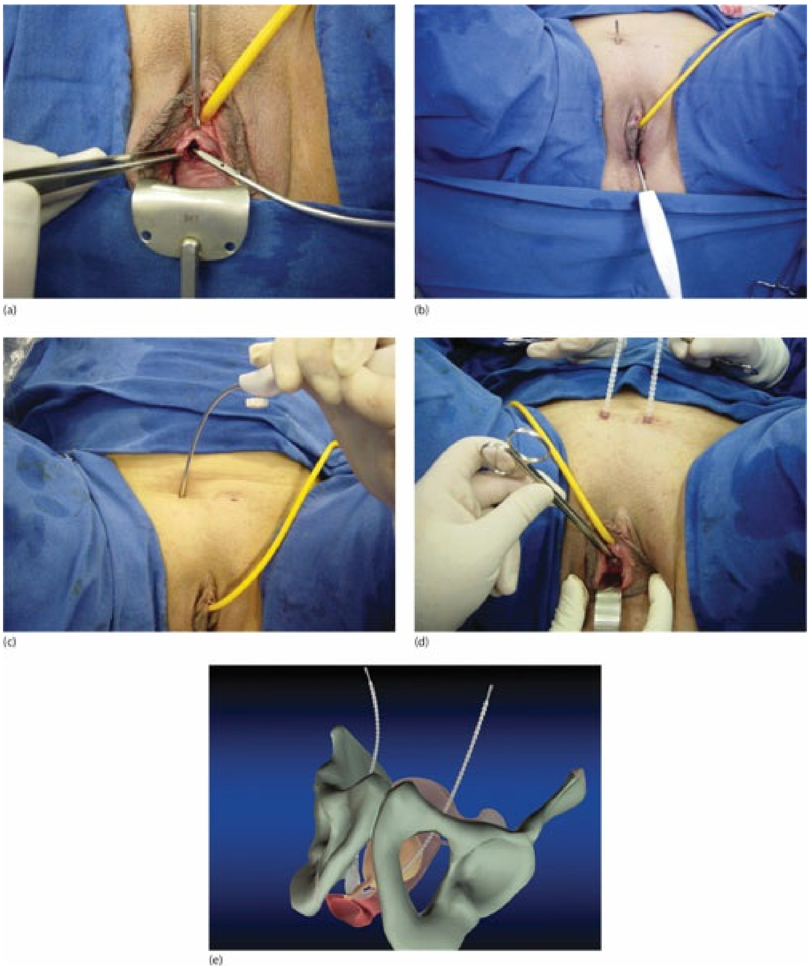

Figure 76.4 Safyre VS technique. (a) Vaginal incision. (b) In the transvaginal, the needle is inserted through the vaginal incision, laterally to the urethral approach. (c) Otherwise, in the suprapubic technique, the needle is inserted through the suprapubic punction and guided by the surgeon's finger until the vaginal incision. (d) The proper tension of the sling is adjusted maintaining a Metzenbaum scissors between the urethra and the sling to prevent undue tension. (e) Scheme of the standard technique.

Safyre T and Urethral Reconstruction

Exceptionally, we advised the placement of Safyre T at the same moment of urethral reconstruction in selected patients as shown in Figure 76.6 based on the need to provide suburethral support for the neourethra. For this, a Martius flap is gentile interposed between the neourethra and Safyre T, which was left loosened. In this situation, we used to keep patients with a thin Foley catheter (12 or 14 French) for 21–28 days and then take it out and start adjustments if necessary.

Readjustment Technique

Tightening

The procedure to tighten Safyre can be performed under local or spinal anesthesia. As the extremities of the polydimethylsiloxane tails can be easily palpable in the subcutaneous tissue, local anesthesia with lidocaine 1% solution seems to be the method of choice. Usually, the readjustment of only one tail is enough, avoiding the risk of significant deviation of the urethral axis.

A small incision is made over the palpable tail extremity (close to the superior aspect of the pubic bone or genitofemoral folds), and it is gently dissected out and pulled carefully, until proper tension is achieved (Figure 76.7). The bladder is filled with 300 mL saline solution before the procedure, so the patient can be asked to cough and do repeated Valsalva maneuvers to check if leakage occurs. Generally, the readjustment is ideally made within 30 days from the surgery, but, theoretically, it can be done at any time after the procedure, because of the formation of a fibroblastic pseudocapsule surrounding the polydimethylsiloxane tail of the Safyre that permits easy dissection and mobilization of the tails inside this pseudocapsule, whenever it is necessary.

Loosening

The procedure to loosen the Safyre should be done in the first month to avoid fibrosis and can be performed under spinal, intravenous, or local anesthesia. A longitudinal vaginal incision 1.5 cm in length is made, starting 1 cm below the urethral meatus, and the polypropylene mesh is dissected out from the urethropelvic fascia. The tails are dissected bilaterally, grasped with hemostatic clamps and pulled back, until a Metzenbaum scissors or a right-angle clamp can be comfortably interposed between the mesh and the urethra. A Foley catheter is left in place overnight.

Comments

The retropubic approach has becoming the most popular approach for Safyre implant due to its preferable use in complex and recurrent patients, but as the transobturator approach avoids the scarred retropubic space in patients with previous failed procedures, it should be considered when retropubic area is considered inaccessible. The transmuscular insertion of transobturator Safyre, through the obturator and puborectalis muscles, along with the subcutaneous tunnel, provides good fixation and anatomical reinforcement of the urethropelvic ligaments, reproducing the natural suspension fascia of the urethra. Among the advantages of this technique, safety, short-operative time, and short hospital stay should be highlighted [7].

Safyre is a hybrid sling for readjustability that is based on the pseudocapsule induced by the silicone columns that allows for moving the anchoring tails upward or downward as needed. As opposed to TVT or other polypropylene minimally invasive slings, the smooth surface of Safyre mesh allows for easy primary adjustment during the implant and even during eventual readjustment, besides keeping its resistance and shape due to its low deformity rate. Moreover, the elasticity of polymetylsyloxane tails can provide fine movements according to the changes of patient’s abdominal pressure, acting as a dynamic support. We have previously reported the good results using either the retropubic [4] or transobturator approach. In our series, readjustments were performed under local anesthesia with almost 60% of cure or improvement of residual incontinence.

Other study compared the efficacy and safety of synthetic transobturator and aponeurotic retropubic slings for the treatment of SUI in women. Forty patients were randomized for Safyre T transobturator sling or aponeurotic retropubic sling. Healing rate was 90.5% (19/21) and 95% (19/20), respectively, after 12 months. The transobturator group presented lesser complications rate than the retropubic group. Authors concluded that the transobturator and the aponeurotic slings techniques were equally effective, but the transobturator sling has shown fewer complications and lesser surgical time than the aponeurotic sling [8].

The diagnosis of obstruction is frequently underestimated and most of patients who do not develop complete urinary retention tend to be diagnosed in the late postoperative period, usually after they had presented with urinary tract infection. Although retention can subside after 4 weeks postoperatively, we advise the loosening procedure within this period in order to avoid fibrotic reaction around the sling and to allow for the patients to resume them as soon as possible. Safyre self-anchoring system is unique as far as postoperative readjustability is concerned. The procedure is minimally invasive and no large abdominal incision is required for harvesting fascia. Sling fixation to the aponeurosis of the abdominal rectus muscle as in classical slings is also unnecessary. Its late adjustments of sling tension are possible in patients presenting persistent incontinence or urinary retention, avoiding major surgeries such as urethrolysis or the need for another sling insertion. The readjustment rate in our series was 10% leading to a success of 40% of the cases and improvement in 20% of this subset of patients [5]. It is our understanding that sling tightening in incontinent patients may be done at any time; on the other hand, loosening the sling must be done between 4 and 6 weeks at the latest to avoid bladder outlet obstruction caused by fibrosis.

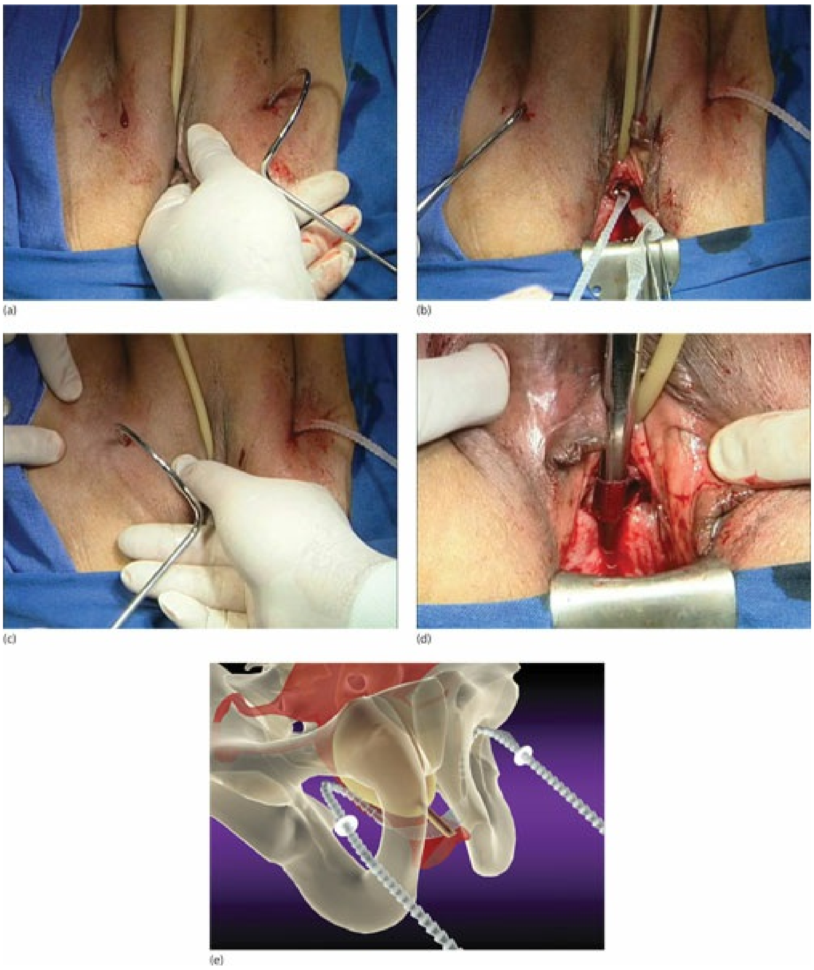

Figure 76.5 Safyre T technique. (a) The needle is passed around and under the ischiopubic ramus through the skin, obturator membrane, and muscles and finally out through the vaginal incision. (b) The same maneuvers are repeated in the other side. (c) Safyre T sling is then hooked by the tip of the needle and brought to the previously made incision. (d) A forceps or scissors is placed between the tape and the urethra during intraoperative adjustment, avoiding any tension of the tape. (e) In selected cases, a special silicon washer can be used to keep the proper sling adjustment in the postoperative period.

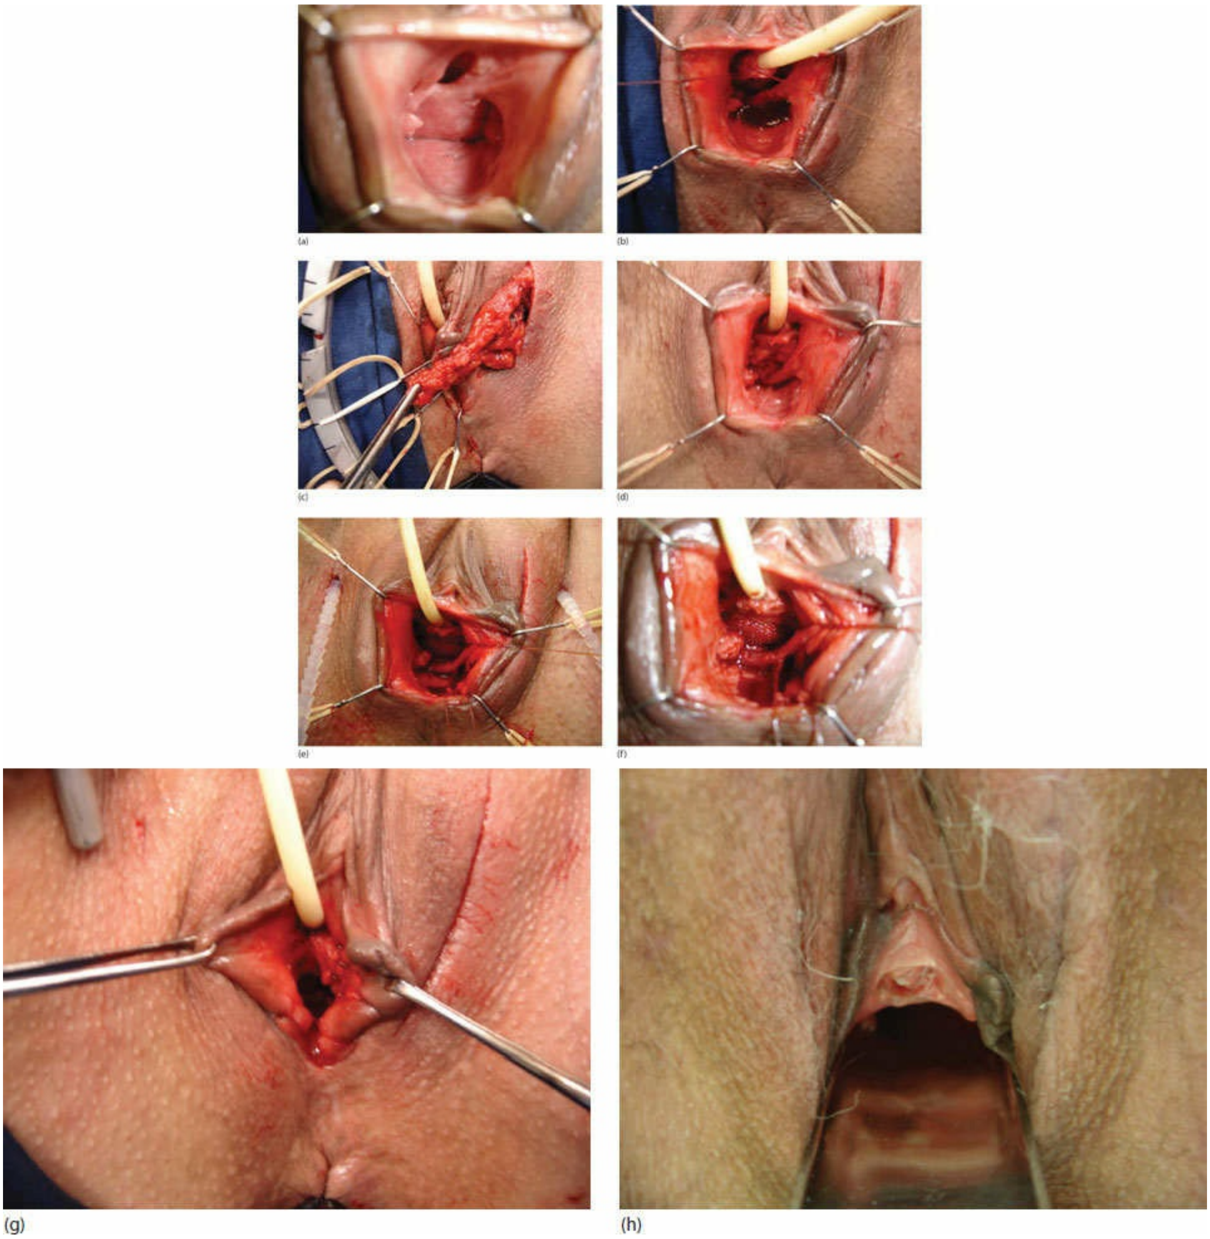

Figure 76.6 Single-procedure urethroplasty plus Safyre T implant. A Martius flap is interposed between the neourethra and Safyre to prevent neourethral erosion. Safyre was left loosened and adjustment can be performed after 30–40 days postoperative, if necessary. (a) Preoperative. (b) Urethroplasty with vaginal wall (double layer). (c) Harvesting of Martius flap. (d) Placement of Martius flap. (e and f) Safyre implant.

Regarding complications, there were no vascular, bowel, or obturator plexus injuries. No patients reported voiding symptoms after 4 weeks of the procedure, confirming the low “de novo” detrusor overactivity rate.

In conclusion, results showed that transobturator approach is as effective as the retropubic procedure in the management of female SUI providing high cure rate along with a significant improvement in the quality of life. Safyre combines the advantages of the transobturator approach with readjustability and may be an attractive surgical alternative.

SAFYRE T CROSSOVER

In spite of improvement in techniques and devices, there is a subset of patients who fail to respond to corrective standard anti-incontinence procedures. These patients have lost completely the urethral sphincteric function and the urethra acts solely as a conduct. The subset of patients may benefit from undergoing a more obstructive sling that may be fixed with more tension than usually required or ideally by using a standard sling [5]. In this scenario, patients must be informed about the possible need for postoperative intermittent self-catheterization and urinary symptoms that may occur subsequently. We first described transobturator crossover readjustable sling for treating these complex cases [9].

Technique

The procedure is performed using the Safyre T Plus. This hybrid sling consists of a monofilament polypropylene mesh that acts as a urethral support held between two self-anchoring columns that are made of an implant grade polydimethylsiloxane polymer. These columns are the basis of the readjustable self-fixing system. The kit has also two soft and radiopaque silicone washers that not only improve fixation when tension is necessary but also allow for easy identification should readjustment become necessary.

The procedure is performed with the patient in lithotomy position. An 18F Foley catheter is placed to empty the bladder. A 2 cm vaginal incision is made, 1 cm below the urethral meatus. The vaginal wall is dissected from the underlying periurethral fascia, bilaterally to the inferior ramus of the pubic bone. The urethra is identified and a right angle clamp is passed between the pubic bone and the urethra, exiting on the other side. One of the extremities of the sling is grasped and brought about behind the urethra to the contralateral side. The same maneuvers are repeated on the other side. Next, bilateral skin punctures are made in the genitofemoral fold at the level of the clitoris, and curved needles are introduced through the obturator foramen. The path is made through the skin, obturator membrane and muscles, around the ischiopubic ramus, and finally out through the vaginal incision. The sling is hooked by the tip of the needle and brought out through the previously made incision. These steps are made on the opposite side to create a spiral sling for better coaptation of the urethra. Silicone washers are used to facilitate latter adjustments should it become necessary. The incisions are closed in the usual manner, and a Foley catheter is left in place overnight (Figure 76.8). In Figure 76.9 is demonstrated the final position of the crossover sling using tridimensional helical computer tomography.

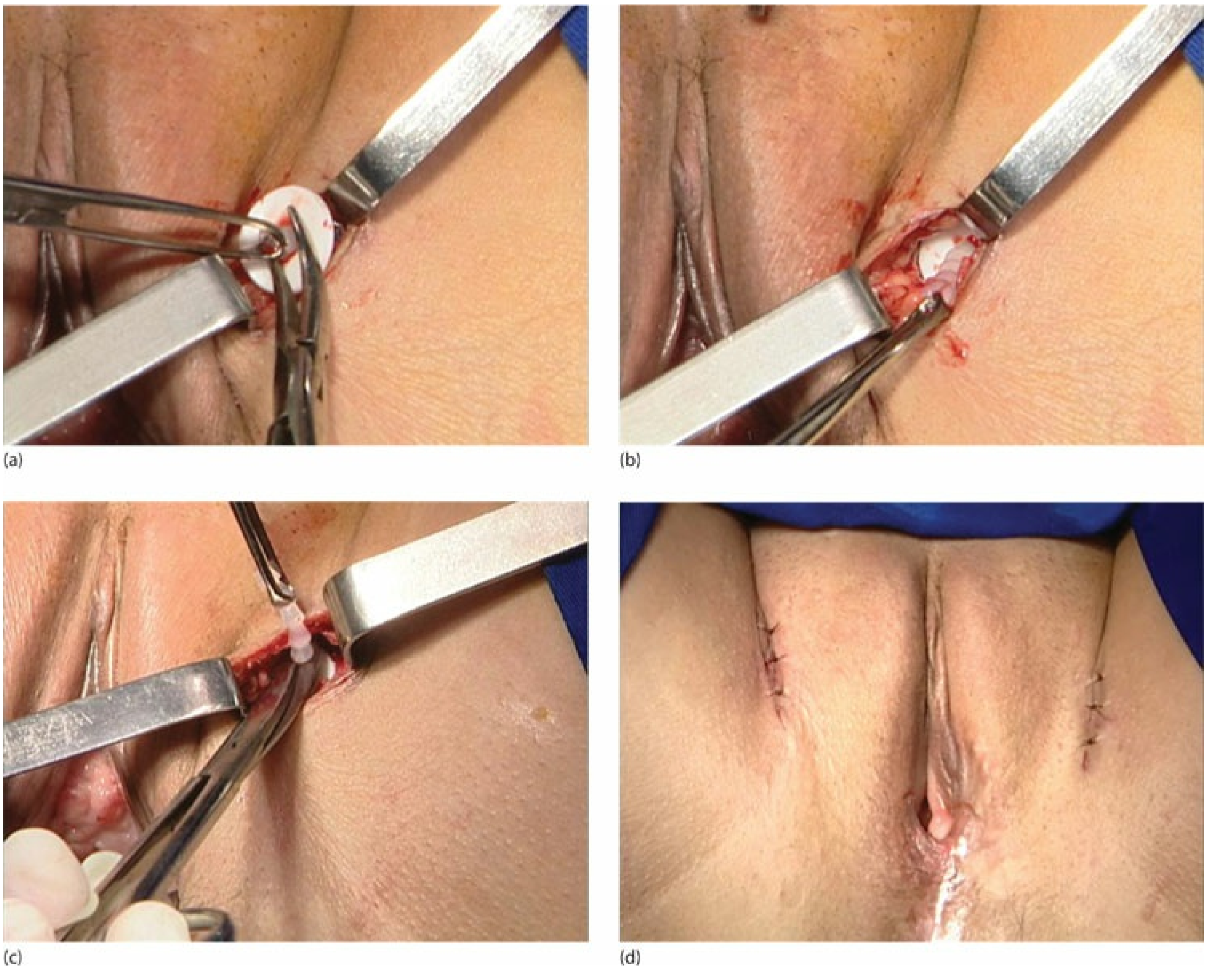

Figure 76.7 The procedure for tightening Safyre is similar, even when retropubic or transobturator approach was used. A small incision is made over the palpable tail extremity (close to the superior aspect of the pubic bone or genitofemoral folds), and it is gently dissected out and pulled carefully, until proper tension is achieved. (a) Dissection of the tail extremity and insertion of silicon washer. (b) Adjustment of the sling tension. During this procedure, the patient can be asked to cough or perform a Valsalva maneuver. (c) The extremity of silicon tail is then cut. (d) The procedure can be performed at one side or bilaterally, taking care to avoid deviation of the urethral axis.

For readjustment, local anesthesia is applied in the region (2% lidocaine with epinephrine). A longitudinal incision is made of 2.5–3 cm in the previous surgical scar. Fat tissue is bluntly dissected and an attempt is made to reach out the silicon cones. These cones are often easily found but in some cases; they may be found underneath the aponeurosis of adductor longus muscle, making an incision necessary. After identifying the silicon column, its extremity is grasped with an Allis clamp, pulled out, and the washer is moved downward increasing coaptation until no urine leakage is seen during Valsalva maneuver. After continence is achieved, the exceeding cones are trimmed off.

Our first published series that included 16 patients after 12-month follow-up, 15 women were continent by subjective and objective assessments, and only 1 remained incontinent. This patient denied any further treatment. If we defined failure as a patient report of less than 50% improvement, with subsequent need for further surgery, the failure rate would be 1 out of 16. The cure rate was 93.7%. Complications included one urethral perforation that was solved by primary closure of the urethral wall; “de novo” urge incontinence developed in 2/16 patients. One patient became incontinent 1 month after the procedure and underwent a successful sling readjustment. The readjustment was performed under local anesthesia. In the same series, there were two patients had undergone a neourethral reconstruction associated to a Martius flap procedure to avoid vaginal erosion with good clinical outcome. These two patients experienced urinary retention after receiving the crossover sling and were put on clean intermittent self-catheterization for 2 weeks. There was no urethral or vaginal erosion during the follow-up [9].

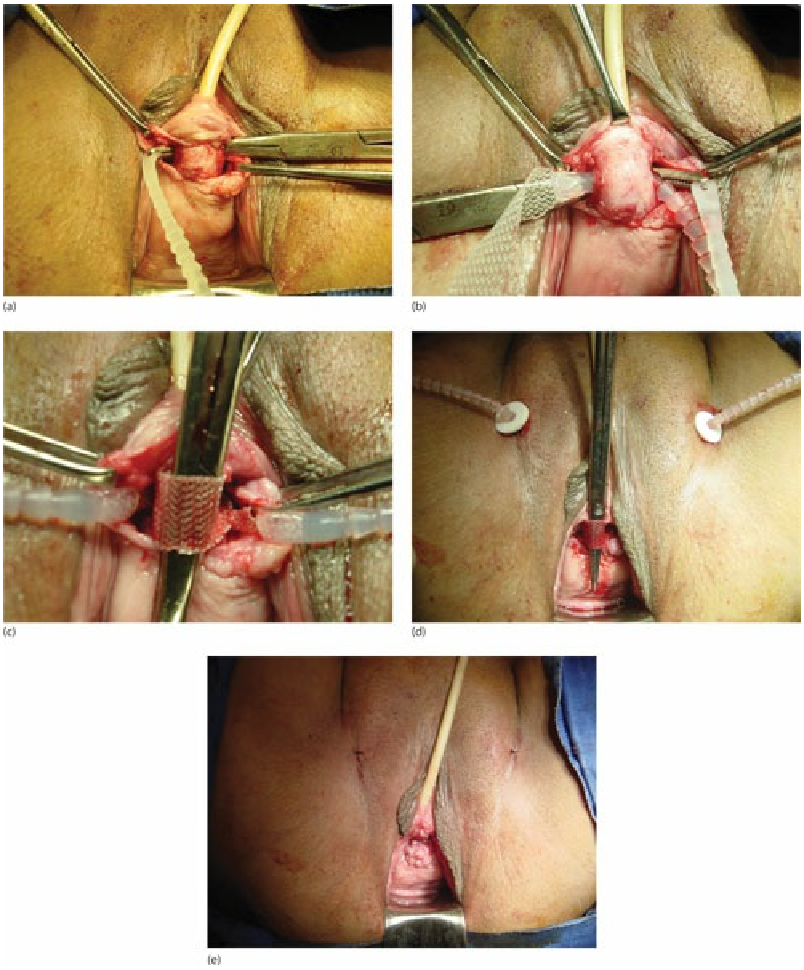

Figure 76.8 Safyre T crossover technique. (a) The urethra is identified and a right-angle clamp is passed between the pubic bone and the urethra, exiting on the other side. (b) One of the extremities of the sling is grasped and brought about behind the urethra to the contralateral side. The same maneuvers are repeated on the other side. (c) Bilateral skin punctures are made in the genitofemoral fold at the level of the clitoris; the silicon tails are pushed in the same manner of in a transobturator sling, creating a spiral sling for coaptation of the urethra. (d) Silicone washers are used to facilitate latter adjustments should it become necessary. (e) The incisions are closed in the usual manner.

Comments

Patients with multiple prior anti-incontinence procedures represent a difficult population to treat. They often have an incompetent, difficult to compress urethra, likely because of a combination of urethral denervation and violation of the periurethral fascia as well as their underlying risk factors for SUI [10]. They typically had an “open” urethra with low VLPP.

The transobturator crossover sling is a relatively simple alternative to major operative procedures in women requiring salvage anti-incontinence surgery. The transobturator approach allows for the anatomical reconstruction of the natural support of the urethra and at the same time, avoids the scared retropubic space in patients with previous failed procedures. The insertion, through the obturator muscle and membrane and the adductor longus muscle aponeurosis, along with the washers, provides good fixation and anatomical reinforcement of the urethropelvic ligaments, reproducing the natural suspension fascia of the urethra. Readjustment can be easily performed under local anesthesia, and only one patient required readjustment in our first published series. Among the advantages of this technique, we can mention that it avoids retropubic dissection, can be performed in a short operative time with short hospital stay. We also treated two patients with neourethral reconstruction because of the urethrovaginal fistula resulting from a complicated labor. These patients had no previous anti-incontinence procedure but did have a nonfunctional neourethra after urethral reconstruction. In selected patients with severe SUI and failed multiple prior surgeries, we have performed transobturator crossover sling surgery as a salvage procedure. In our first published data, this technique has proved to be easy to perform and effective and had minimal complications, which led us to conclude that it was a significantly less-morbid alternative to bladder neck closure and continent diversion. Also, we describe a new transobturator procedure that provides circumferential coaptation of the urethra for SUI treatment in this difficult patient population. Rutman et al. [11] described a circumferential retropubic sling procedure using a 1 cm × 15 cm piece of soft polypropylene mesh prepared with a zero polyglactin suture applied at each end mostly for neurogenic patients. A clamp was used to pass the mesh between the urethra and pubis. There was a mean 87% overall improvement in symptoms. Of the 37 patients described, 92% remained dry between catheterizations.

As the management of failed slings may be a difficult situation, spiral sling may be an attractive procedure, especially in patients with normal detrusor function. We believe that crossover sling supports the midurethra, preventing urethral hypermobility and improving coaptation.

REMEEX

TRT Remeex System (Neomedic International) was first described by Iglesias et al. and claimed to allow for postoperative adjustments that could be made hours, months, or even years after surgery [12,13], which means that the surgeon could provide a long-term continence and avoid reoperating again a patient with a sling failure. The TRT Remeex System provides the surgeon with the experience of adjusting the sling urethral support with the patient in standing up position and doing the efforts that drives her to incontinence. This unique property provides the surgeon the ability to adjust the sling to the desired urethral support level, thus avoiding urine leakage or retention. Also, it is supposed to have a dynamic pressure transmission system. According to this concept, when coughing, the patient advances the rectus muscle, advancing the varitensor, and increasing the sling urethral support while it’s needed. This reconstructs the intra-abdominal pressure transmission system of normal continent patients. The readjustment is made while the patient is standing up and doing the efforts that drives her to incontinence.

The system is composed basically of five components (Figure 76.10):

- Monofilament polypropylene mesh 1.25 cm × 2.5 cm attached to a polypropylene 1.0 filament (traction thread).
- Varitensor is the regulator mechanism. It is made of Chirulen (ultrahigh-molecular-weight polypropylene) and titanium.
- Manipulator must be attached to the varitensor to manipulate the regulation mechanism. Rotation either clockwise or counterclockwise elevates or lowers the level of the sling.
- Disconnector allows for connection/disconnection of the manipulator to the varitensor.
- Trocar (traction thread passer).

Technique

Patient positioning and preparation are the same as described previously for the Safyre VS. Surgical technique can present minimal variations according to surgeon preference, but can be standardized as follows. A suprapubic transversal incision of about 3–4 cm in the lower abdomen is made until exposure of the rectus muscle aponeurosis is accomplished.

The anterior vaginal wall is incised for 3–4 cm longitudinally at the level of the urethrovesical junction and dissected out laterally. The needles are then driven at each side of the urethra up toward the abdominal wall, tangent to the posterior aspect of the pubic bone, after puncturing through the endopelvic fascia. At this point, cystoscopy is performed and the needles are repositioned in case of bladder perforation. Polypropylene sutures are then connected to the needles and pulled up until they appear in the abdominal incision. With the varitensor positioned at 10 cm above the level of the abdominal aponeurosis, the sutures are inserted into the varitensor and their ends are knotted to each other. While maintaining the varitensor in the horizontal position, the manipulator is rotated clockwise until the varitensor is positioned 3 cm above the aponeurosis. Both abdominal and vaginal incisions are closed in the usual manner. Urethral catheter is left in place (Figure 76.11).

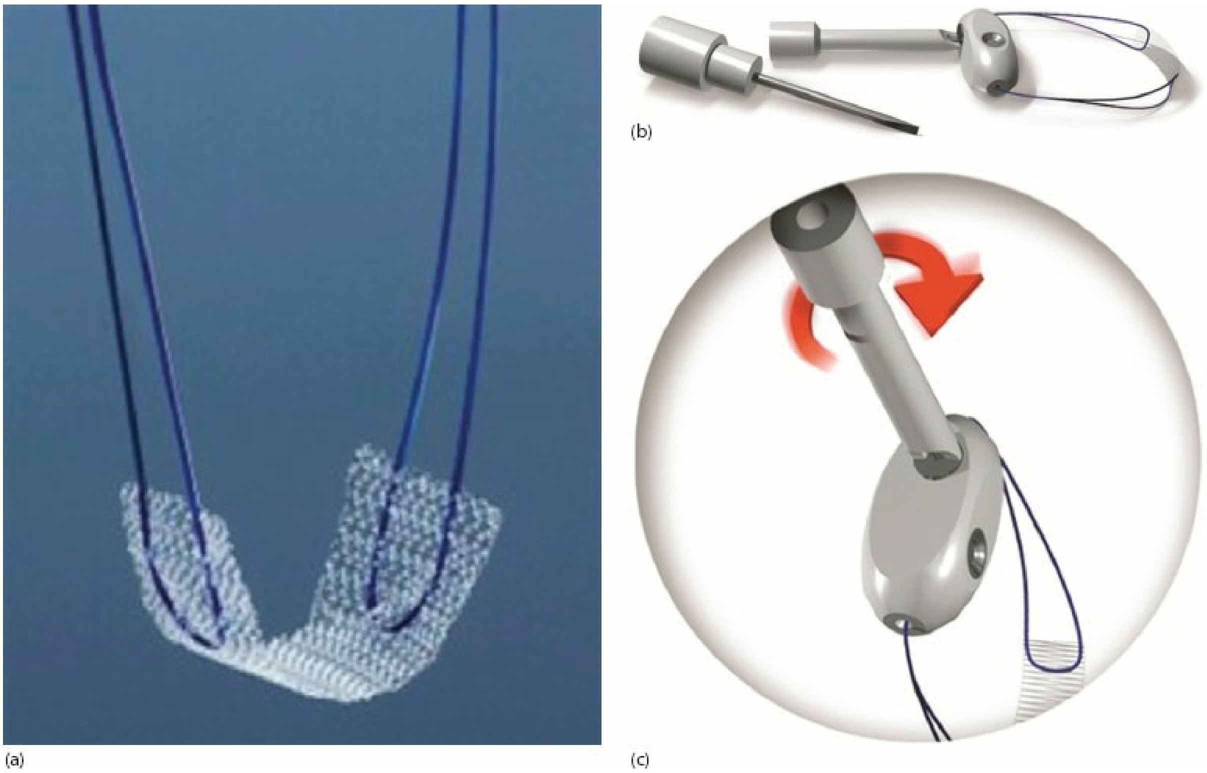

Figure 76.10 TRT Remeex System. (a) 1.25 cm × 2.5 cm monofilament polypropylene mesh attached to a polypropylene 1.0 traction thread. (b) Manipulator and varitensor attached to the sling and disconnector. (c) Manipulator in place showing a clockwise rotation for adjustment.

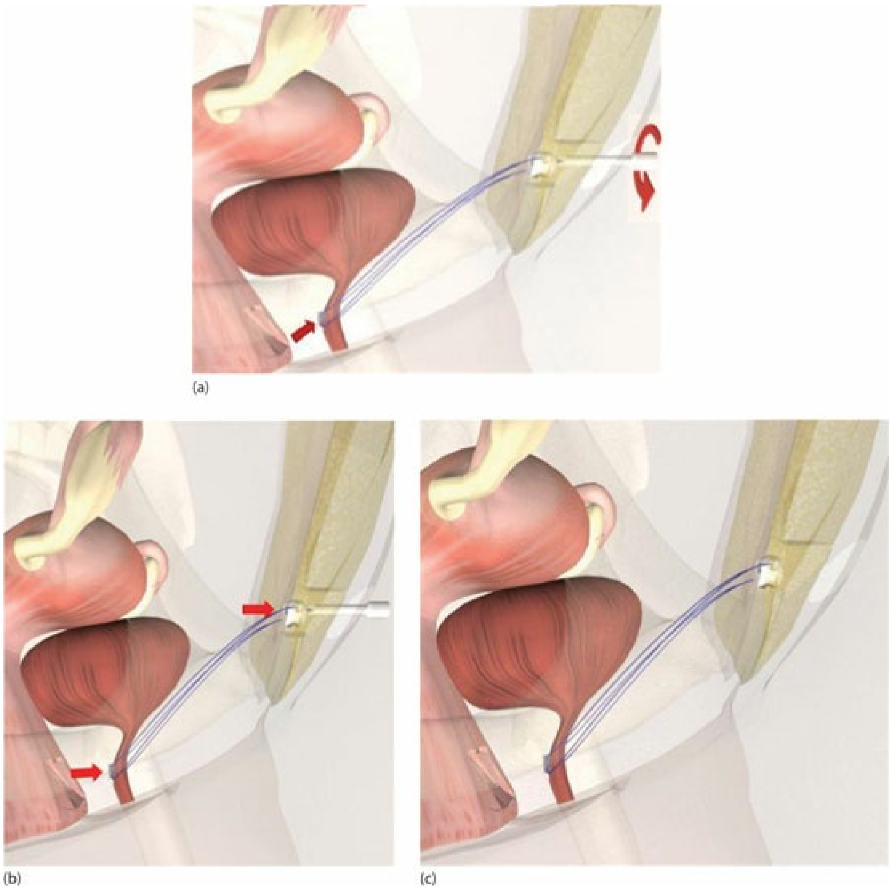

Figure 76.11 TRT Remeex System technique. (a) Remeex prosthesis in place. (b) With a quarter of a turn, the manipulator and the disconnector are withdrawn. (c) The varitensor remains in place. The sling support level can be modified if needed by replacing the manipulator and the disconnector under local anesthesia. (Reproduced by permission of Dr. Antoni Castello.)

For adjustment, the bladder is filled with 300 mL in the next day following surgery and Foley catheter is removed. The patient is oriented to perform Valsalva maneuver and straining. If urine loss is documented, making four complete turns on the manipulator and repeating the provocative maneuvers make adjustment of the sling support. Additional adjustment is carried out in the same manner if needed. After urine loss is resolved, the patient is tested for spontaneous void and postvoid residual. If more than 100 mL is left as residual urine, the sling is loosened. If not, the manipulator is turned 90° in any direction, and the disconnector manipulator is easily removed from the varitensor, which stays buried in the fat above the aponeurosis of the rectus muscle as a permanent regulation mechanism, which can be used at anytime as needed [14]. The sling adjustment is made step-by-step (checking continence every four turns of the manipulator). When the patient is continent, we know that four turns before she was incontinent. This allows the surgeon to provide the minimum necessary urethral support for that particular patient under stress and no more.

Comments

The TRT Remeex System implantation technique has been associated to advantages such as ease to apply, lack of the morbidity presented by the abdominal techniques, allowance of late-term readjustments under local anesthesia if needed, and satisfying results at short- and midterm follow-up [14].

Iglesias et al. observed a subjective satisfaction rate of 90.5% using the TRT Remeex System for treating female SUI. However, the studied population was small, follow-up time was considerably short (mean 12 months) and 62% of patients had a previous unsuccessful anti-incontinence procedure, but were analyzed altogether along with the rest of the cohort who had no previous surgery. Also, objective assessment of incontinence improvement was not performed, but only by subjective self-reported patient impression [12]. Authors emphasize the technique should be recommended for patients with intrinsic sphincteric deficiency or previous surgical failure.

Martinez et al. reported on a success rate of 93% after using the TRT Remeex System in women with a diagnosis of SUI associated to pelvic organ prolapse. However, short follow-up time (average 8 months), a small cohort (29 patients), and the lack of an objective assessment to define success (self-reported improvement) allow for no definitive conclusion whatsoever [15].

More consistent results were shown for the use of the TRT Remeex System in the treatment of male urinary incontinence. Sousa-Escandon et al. reported on a prospective, multicenter study involving 51 patients with urinary incontinence mainly due to radical prostatectomy. There were 65% of patients considered cured (use of no pads, small pads, or security napkins) and 20% significantly improved at a mean follow-up of 32 months. No major intraoperative complications occurred and postoperative pain was minimal and successfully controlled by oral analgesics [16].

According to the Spanish TRT Remeex System Registry XII–2004, 92% of patients were continent under stress and 7% improved after undergoing TRT Remeex System implant [13].

A prospective evaluation reported by the Fundacio Puigvert involving 125 patients and a mean follow-up of 38 months reported a cure rate of 87% based on pad test, clinical, and urodynamic criteria. Twenty-one patients benefited from readjustment of the sling during the follow-up. The tension was increased in 17 cases (continent at discharge) due to recurrence of stress incontinence, and reduced in 4 due to obstruction. The varitensor was removed in one case due to infection [17].

More recently, long-term results after 5 years were presented in a cohort of 30 patients, most of them with severe intrinsic sphincter deficiency and fixed urethra. In this series, according to objective evaluation (pad text and cough stress test), 93% were considered cured/improved. Only two patients (7%) underwent readjustments during the follow-up [18].

CONCLUSION

Adjustable slings have shown to provide satisfying success rates, to be associated to minimal intraoperative complications and to be a safe procedure. Readjustments can be done under local anesthesia at immediate or delayed follow-up as needed. However, the evolution of transobturator prosthesis and the emerge of minislings have moved adjustable slings for restrict subset of patients.

As the devices presented are used in specific situations nowadays, the reports are rarely published. So, more studies are needed for both techniques to corroborate the existing data in a sense to provide longer follow-up and more precise success criteria assessments.

Nonsurgical Transurethral Radio Frequency Collagen Denaturation of the Bladder Neck and Proximal Urethra for the Treatment of Stress Urinary Incontinence

Saad Juma, Elizabeth Timbrook Brown, and Roger R. Dmochowski

INTRODUCTION

Stress urinary incontinence (SUI) is characterized by involuntary urine loss during physical activity such as coughing, sneezing, laughing, exercise, or lifting [1,2]. A common cause of SUI in women is the rotational descent of the bladder neck and proximal urethra (bladder neck hypermobility) resulting in the inappropriate opening of the proximal urethral lumen during periods of increased intra-abdominal pressure [1,2].

Although SUI is not a life-threatening disorder, it can greatly affect a patient’s quality of life (QoL). Thus, patient input in the selection of treatment is paramount. There is no existing pharmacotherapy approved by the U.S. FDA for the treatment of SUI. Available treatment options for women with SUI include Kegel exercises, behavioral modification, biofeedback, transurethral injection of bulking agents, and various forms of midurethral slings and retropubic suspensions. Currently, there is a clinical trial assessing the safety and efficacy of suburethral injection of autolougous muscle-derived cells for SUI [3]. Nevertheless, midurethral sling procedures are currently considered the standard of care in treating women with SUI. To add to the armamentarium of less invasive treatment options for SUI, the use of radio frequency energy has been explored.

HISTORY OF RADIO FREQUENCY THERAPY

Electromagnetic energy, when transmitted to biologic tissue, can cause heating of the target. The degree of heating and the physical effects vary according to the frequency and wavelength of the electromagnetic energy as well as the duration of exposure. High-frequency electromagnetic energy (radio frequency) is the basis for radio transmissions, while very high (microwave) levels are used in radar or, more familiarly, in microwave ovens. Light at high frequencies and wavelengths, as produced by lasers, can also have a rapid heating effect of its target.

Application of radio frequency, microwave, or laser energy results in excitation of water molecules and rapid heating of biologic fluids and tissue, with subsequent tissue remodeling or destruction. The controlled application of electromagnetic energy at radio frequency and microwave frequency levels has been widely used to treat a spectrum of medical conditions. High levels of radio frequency, as in electrocautery, are commonly used for hemostasis [4]. Application of high-energy radio frequency is also widely used for the thermal destruction (ablation) of arrhythmic cardiac tissue [5], shrinkage of excessive soft palate tissue [6], shortening of injured spine and joint ligaments [7,8], shrinkage of joint cartilage [9], reduction of liver tumors [10], and reduction of benign hyperplastic prostatic tissue [11,12]. Such procedures utilize relatively high levels of radio frequency energy to heat body tissues to the point of necrosis, which results in gross tissue shrinkage.

In contrast, the application of lower levels of radio frequency energy generates lower tissue temperatures (65°C–75°C). As a result, tissue necrosis and gross shrinkage do not occur. Instead, application of controlled, low-level radio frequency energy results in acute, focal collagen denaturation (Figure 77.1), with subsequent microremodeling of the affected collagen upon cooling and healing (Figure 77.2) and without associated gross tissue necrosis or neurovascular injury. After healing, the denatured collagen results in reduced dynamic compliance of the surrounding untreated tissue without stricture formation. Lower levels of radio frequency energy have successfully been used to treat conditions such as fecal incontinence (e.g., the Secca procedure) [13], gastroesophageal reflux disease (e.g., the Stretta procedure) [14], and arthritis [15].

RADIO FREQUENCY TREATMENT FOR SUI

Radio frequency therapy may be used to treat women with SUI, offering them a minimally invasive treatment option. Two forms of radio frequency technology have been used for the treatment of SUI in female patients: high-energy transvaginal and low-energy transurethral radio frequency treatment.

Transvaginal Radio frequency Therapy

Transvaginal radio frequency bladder neck suspension (SURx; Cooper Surgical, Trumbull, CT), originally performed laparoscopically, is a surgical procedure wherein two parallel vaginal incisions are created lateral to the urethra at the level of the proximal urethra. The vaginal mucosa is dissected off the underlying endopelvic fascia to expose the surface area for treatment. Subsequently, a transvaginal probe is used to apply high-energy radio frequency to heat and shrink the underlying tissues [16,17]. Radio frequency energy is delivered until blanching or charring of the tissues is noted. Similar energy is applied on both sides of the proximal urethra, always maintaining position 1 cm lateral to the urethra. The goal of this procedure is to shrink the endopelvic fascia, thereby increasing support for the bladder neck [16].

In an early study of the procedure performed laparoscopically in 94 women (mean age, 48.7 years) with proximal urethral and bladder neck hypermobility, 81.2% of 85 patients at 1 year reported improved or complete continence. Urodynamic evaluation showed no leakage during the Valsalva maneuver in 78% of patients. A 12-month, multicenter, single-arm trial of transvaginal high-energy radio frequency therapy using general anesthesia was conducted in 120 women with SUI who were treated as outpatients [17]. Among 86 patients who underwent urodynamic testing at baseline, 76% demonstrated improvement in the Valsalva leak point pressure (LPP) at 12 months. Additionally, 64% of patients reported improved continence or no change in continence status, while 19% experienced increased frequency of SUI episodes. Further studies were unable to reproduce earlier successful results and high rates of additional treatments were required [18–20]. It was determined that transvaginal radio frequency ablation is too dependent on precise technique, and it is no longer marketed [21].

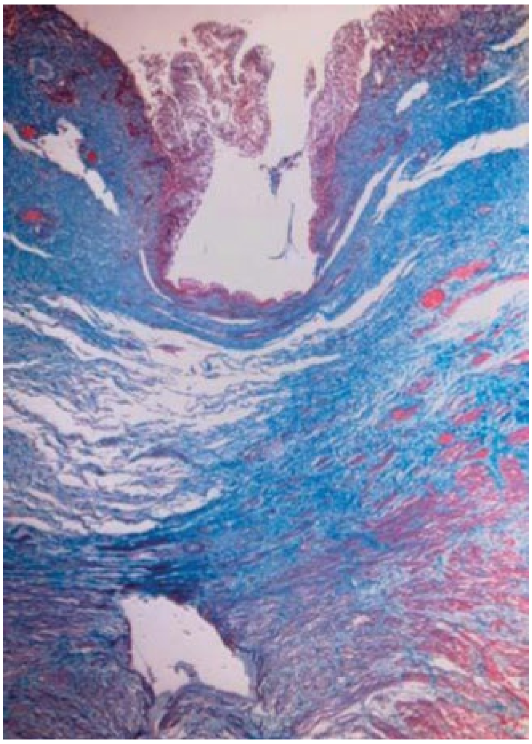

Figure 77.1 Acute histology (trichrome stain) through needle electrode path in porcine urethra immediately following radio frequency energy treatment. Viable, denatured submucosal collagen stains bright blue and small vessels are undamaged. (Courtesy of Novasys Medical, Inc., Newark, CA.)

Transurethral Radio frequency Collagen Denaturation

Transurethral radio frequency collagen denaturation (Renessa; Novasys Medical, Inc., Newark, CA) is approved by the FDA for treating women with SUI due to bladder neck hypermobility. This procedure differs in several ways from transvaginal radio frequency bladder neck suspension. Unlike the high-energy transvaginal radio frequency procedure, transurethral radio frequency collagen denaturation is applied through four small needle electrodes and does not require surgical incisions. Additionally, in high-energy radio frequency ablation, target tissue is heated to produce tissue necrosis followed by gross shrinkage of the endopelvic fascia [16,17,22]. In contrast, transurethral radio frequency causes collagen denaturation and does not produce tissue necrosis, resulting in a functional (reduction in tissue compliance) rather than an anatomic change. Initial animal studies of transurethral collagen denaturation of the bladder neck and proximal urethra evaluated its gross and histologic impact, and physiologic effect demonstrated its feasibility and safety, suggesting a beneficial effect [23].

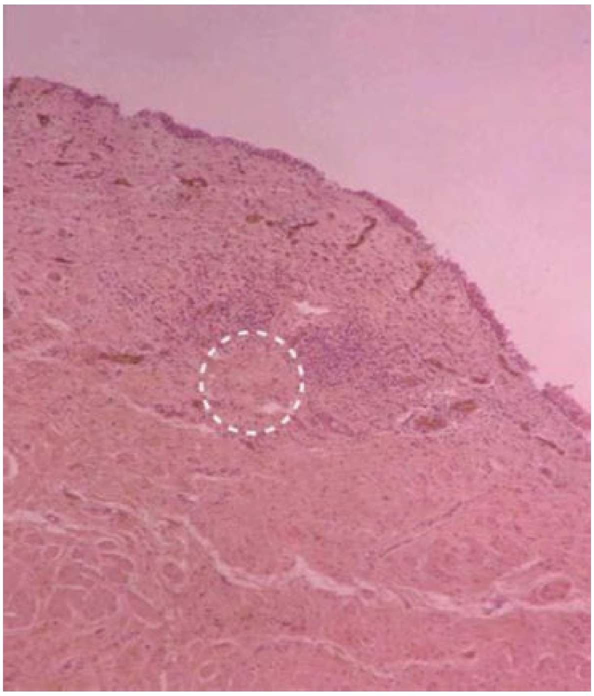

Figure 77.2 Porcine bladder neck histology (H&E stain) at 2 months following radio frequency collagen denaturation. The tiny submucosal sphere of denatured collagen (*circle*) deep in the unaffected mucosa is only identified by chronic inflammatory cells clustered on its superior border. (Courtesy of Novasys Medical, Inc., Newark, CA.)

Indications and Contraindications

Transurethral radio frequency collagen denaturation offers women with SUI due to hypermobility an office-based, minimally invasive treatment option. It is not meant to replace existing treatment options, but to complement the spectrum of available treatments. Radio frequency collagen denaturation is indicated for the treatment of anatomic SUI (bladder neck hypermobility). Patients with SUI, secondary to intrinsic sphincter deficiency, are not good candidates for this treatment. Women with anatomic SUI who have failed Kegel exercises, who are not good surgical candidates, or who wish to avoid or postpone surgery are ideal candidates for radio frequency collagen denaturation of the bladder neck and proximal urethra. Additionally, patients who experience suboptimal primary surgical results may benefit from transurethral radio frequency collagen denaturation.

Women who have undergone a surgical procedure and experience residual or recurrent incontinence must be carefully evaluated before considering further treatment options. Although radio frequency collagen denaturation is sometimes considered following suboptimal surgical results, this technique is not specifically approved by the FDA for use in this setting.

Anesthesia

Transurethral radio frequency collagen denaturation can be performed in the office setting using local anesthesia, with the option to administer pretreatment oral sedation. The feasibility, safety, and comfort of using oral instead of intravenous sedation were demonstrated in two prospective trials [24,25]. In a study by Lenihan and colleagues, the first six patients received an oral sedative plus an oral analgesic, as well as a local periurethral anesthetic block using 2% lidocaine. The remaining 10 patients (63%) received only an oral sedative or analgesic. Postoperatively, patients classified their pain on a visual analog scale from 0 ("no pain") to 10 ("terrible pain") [24]. The mean score was 1.8, with 38% of patients selecting zero. Subsequently, Wells et al. performed a multicenter, single-arm study in 33 women who received only a mild oral sedative (diazepam 10 mg) administered 60 to 90 minutes prior to treatment, along with a bilateral periurethral block using 10 cc total of 2% lidocaine [25]. This in-office anesthetic regimen using oral sedation allowed for treatment completion in all patients without the need to convert to intravenous sedation (100% feasibility). Postoperatively, the patient-rated mean pain score was 1.4 (±1.8), including 42% of patients who rated their pain as zero.

Technique

A prophylactic oral antibiotic is administered, and the patient may opt to receive an oral sedative. Once the patient is placed in the low lithotomy position, she is given a periurethral lidocaine block (Figure 77.3). The bladder is drained with a urinary catheter, after which 30 cc of sterile, room-temperature water is instilled into the bladder and the catheter is removed. The transurethral radio frequency probe (Figure 77.4) is inserted until the probe tip is within the bladder lumen. The balloon at the probe tip is then insufflated and the device gently withdrawn until the balloon is anchored palpably within the bladder neck, at which time the length of the urethra is measured. During treatment, four 23-gauge nickel titanium needle electrodes are then deployed from the probe shaft immediately distal to the balloon, traversing the mucosa and positioning the tips within the submucosa of the bladder neck and proximal 1 cm of the urethra (Figure 77.5). The probe, connected to a radio frequency generator (Figure 77.6), delivers radio frequency energy for a 60-second cycle while sterile, room-temperature water simultaneously irrigates the mucosa to prevent thermal injury. The submucosa immediately surrounding the four needle tips is heated and maintained at 65°C for a minimum of 30 seconds, resulting in microscopic, focal collagen denaturation without substantial tissue necrosis. The probe is repositioned after each treatment cycle, and the cycle is performed nine times, using simple deployment and rotational maneuvers, resulting in collagen denaturation of 36 circumferential, microscopic focal sites within the bladder neck and proximal urethral submucosa. Once the final cycle is completed, the needles are retracted, the balloon is deflated, and the radio frequency probe is removed. The patient is asked to void immediately after treatment.

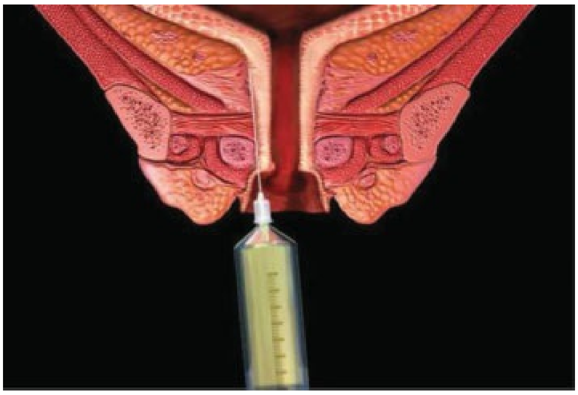

Figure 77.3 A sterile 25-gauge 1.25 in. needle is fully inserted parallel to the urethral wall. After injection of 2–3 cc of 2% lidocaine into the tissue adjacent to the bladder neck, an additional 2 cc was injected during the first 1 cm of needle withdrawal, anesthetizing the proximal urethral tissues. Similar bilateral injections were administered. (Courtesy of Novasys Medical, Inc., Newark, CA.)

Postprocedure Care and Recovery

Since no incisions are required for radio frequency collagen denaturation and general anesthesia is not used, posttreatment recovery is typically rapid and uncomplicated. Most patients complete the procedure under local anesthesia and leave the physician's office within 1 hour. In an ongoing 36-month trial, approximately one-third of patients resumed normal daily activities within hours to 1 day following the procedure, while 91.9% of patients returned to normal activities within 2 days [26]. Indwelling or intermittent catheterization was not required by any patient at discharge.

Efficacy

The pilot trial of transurethral radio frequency collagen denaturation evaluated safety and the effect of this procedure on incontinence episode frequency and patient QoL [27,28]. In addition, this trial analyzed the outcomes of four treatment regimens that differed in total number and anatomic locations of radio frequency applications within the lower urinary tract. In a study of 41 women (mean age, 48.8 years) with SUI and evidence of bladder neck hypermobility [27], patients were randomized to receive one of four radio frequency regimens: (1) group 1 (n = 10), radio frequency energy was administered at 24 sites in the proximal urethra, with a total radio frequency duration of 7.5 minutes; (2) group 2 (n = 10), 36 sites including 12 in the vesicourethral junction and 24 in the proximal urethra, with a total duration of 10.5 minutes; (3) group 3 (n = 11), 48 sites including 24 in the distal bladder neck and 24 in the proximal urethra, with total duration of 12.0 minutes; and (4) group 4 (n = 10), 60 sites including 24 in the distal bladder neck, 12 in the vesicourethral junction, and 24 in the proximal urethra, with a total duration of 15.0 minutes. Following the procedure, preexisting urinary tract infections were identified from screening urine cultures in three women, and one patient at baseline had active urge symptoms and was using anticholinergic medication. Consequently, these four patients were excluded from the efficacy analysis, but included in the safety assessment. Patients were evaluated at 2 weeks, 2–3 months, and 6 months posttreatment. Change from baseline in the incontinence quality of life (I-QoL) score was the primary efficacy variable. The I-QoL instrument, a disorder-specific, validated questionnaire [29,30], generates an overall score from 0 to 100 (0 indicates worst possible I-QoL), as well as three subscale scores.

Six months after the procedure, there were increases in mean overall I-QoL scores in all four treatment groups, with significant improvements in groups 2 ($p = 0.004$) and 4 ($p = 0.02$) (Table 77.1) [27]. The majority of patients in all groups experienced at least a 10-point increase in overall I-QoL scores. With the exception of group 1 (who received the fewest number of radio frequency applications, all isolated to the proximal urethra), patients reported varying reductions in daily incontinence episodes, with significant decreases noted in groups 2 ($p = 0.04$) and 4 ($p = 0.004$). In addition, daily pad use with moderate to severe baseline SUI experienced at least a 10-point improvement in I-QoL scores compared with similar patients in the sham group (50%; $p = 0.03$) [31].

Table 77.1 Changes from Baseline to 6 Months Posttreatment in the Pilot Study of Transurethral Radio frequency Collagen Denaturation in Women with Stress Urinary Incontinence

	Group 1 ($n = 8$)	Group 2 ($n = 9$)	Group 3 ($n = 11$)	Group 4 ($n = 9$)
Mean I-QoL scores				
Baseline	44.1	53.9	54.9	53.6
6 Months	54.3	76.6	66.4	80.6
Increase ≥10 points, %	63	78	70	67

Abbreviation:I-QoL, incontinence quality of life questionnaire.

[a] Negative numbers indicate decrease in incontinence episodes.

[b] Negative numbers indicate decrease in pad usage.

At 12 months, 87 (79.1%) patients in the radio frequency-treated group and 49 (77.8%) patients in the sham group underwent LPP testing [31]. There were no significant differences regarding demographic or other baseline characteristics between these two evaluable populations. Women in the radio frequency-treated group experienced a 13.2 cm H_2O increase in LPP at 12 months compared with a 2.0 cm H_2O decrease in those in the sham group ($p = 0.02$) (Table 77.2).

A retrospective analysis of the results of this controlled trial sought to determine whether menopausal status and/or use of hormone replacement therapy (HRT) had any effect on the outcome as measured by the percent of patients that at least decreased in all groups, with improvement reaching statistical significance in group 4 ($p = 0.03$).

In a subsequent retrospective analysis [28], the incidence of I-QoL overall score improvement of at least 10 points ranged from 44% to 70% among all groups. The percentage of patients who experienced at least a 50% reduction in daily incontinence episode frequency ranged from 63% to 89%, and the “cure” rate (defined as “no incontinence” episodes or pad use between 6 and 12 months) ranged from 22% to 67%.

A 12-month, randomized, controlled trial compared the transurethral radio frequency collagen denaturation with a sham procedure [31]. In total, 173 women with SUI due to hypermobility (mean age, 50 years) were randomized to receive active radio frequency treatment ($n = 110$) or sham procedures ($n = 63$). The sham procedure differed from active treatment in that the probes lacked needle electrodes and the generator, while appearing and sounding similar, did not actually deliver radio frequency energy. All procedures were performed in an outpatient setting under conscious sedation.

Impact on patient QoL was based on the incidence of a 10-point or greater improvement in I-QoL scores at 6 and 12 months. Objective treatment efficacy was evaluated through Valsalva LPP testing at 6 and 12 months. At 12 months, 89 (80.1%) patients in the radio frequency-treated group and 53

(84.1%) patients in the sham group underwent QoL assessments. The 12-month analysis excluded 21 women lost to follow-up; 8 women with I-QoL changes that could not clearly be attributed to the study procedure, owing to a change in medical history (e.g., hysterectomy during the trial period, urinary tract infection at 12 months); and 2 women with baseline I-QoL scores of at least 90 points who could not numerically achieve a 10-point or greater score improvement. The percentage of patients with at least a 10-point improvement from baseline in overall I-QoL scores is shown in Table 77.2. When all patients were included regardless of baseline severity of SUI, there was no significant between-group difference at 12 months. In contrast, significantly more radio frequency-treated patients (74%) had a 10-point improvement over baseline in I-QoL scores [32]. In the radio frequency-treated group, 43 women had moderate to severe SUI including 13 (30%) premenopausal women, 23 (53%) postmenopausal women using HRT, and 7 (16%) postmenopausal women not using HRT. There was no significant difference in the 12-month incidence of a 10-point or greater I-QoL score improvement between postmenopausal women using HRT (70%) and those not using HRT (71%). Likewise, no significant differences in a 10-point or greater score improvement occurred between premenopausal women and either postmenopausal women using or not using HRT.

Table 77.2 Percent of Patients with At Least a 10-Point Improvement from Baseline in Incontinence Quality of Life Scores and Change from Baseline in Valsalva Leak Point Pressure in a 12-Month Controlled, Randomized, Sham Procedure–Controlled Trial

	Radio frequency collagen denaturation	**Sham procedure**
≥10-point improvement in I-QoL scores		
All patients (n = 142)	48%	44%
Mild SUI[a] (n = 69)	22%	35%
Moderate to severe SUI[a] (n = 73)	74%	50%
Change in Valsalva^{LPP} (*cm* H_2O)	+13.2 ± 39.2	−2.0 ± 33.8

[a] Severity at baseline based on I-QoL score: 0–60 points, moderate to severe SUI; 61–90, mild SUI.

A separate retrospective analysis to determine long-term efficacy was conducted in 21 women in the radio frequency group who had not undergone additional SUI treatment in the interim and were available for follow-up at least 3 years posttreatment [33]. Patients completed the 3-day diaries and the I-QoL questionnaire. Diary analysis revealed that 56% of patients had at least a 50% reduction in SUI episodes at follow-up. Evaluation of I-QoL scores showed a significant improvement versus baseline, with a mean score improvement of 12.7 points (p = 0.04). Results demonstrated that the effectiveness of this procedure at 1 year was maintained for at least 3 years in more than half of patients.

The long-term efficacy of nonsurgical transurethral radio frequency collagen denaturation was assessed in a multicenter, prospective, open-label, single-arm trial in 136 women with SUI secondary to bladder neck hypermobility. Patients had failed earlier conservative treatment and had not received surgical or bulking agent therapy. Interim results after 12 months were initially reported [26].

Intent-to-treat analysis revealed significant reductions compared with baseline in the number of daily and weekly leakage episodes due to activity ($p < 0.0026$ for both), with 50% of patients reporting at least a 50% reduction in activity-related leaks (Table 77.3). As measured by stress pad weight tests, 69% of women exhibited at least a 50% reduction in leaked urine volume (median reduction, 15.2 g; $p < 0.0001$). Furthermore, 45% of women were dry (29% no SUI; 16% <1 g leakage). There were also significant improvements in the median scores on the I-QoL questionnaire ($p < 0.0001$) and in the mean scores on the urinary distress inventory (UDI-6; $p < 0.0001$) (Table 77.4). In total, 71.2% of women exhibited I-QoL improvement including 50.3% with at least a 10-point improvement, and 61.8% of patients reported improvement on the UDI-6 (Table 77.4). A subsequent study provided a 36-month follow-up for these patients showing a mean I-QoL score improvement of 17 points from baseline (p = 0.0004), suggesting a durable QoL improvement up to 3 years [34] (Table 77.5).

In a recent study, a Markov model was used to compare the cost effectiveness of transurethral radio frequency collagen denaturation with sling or Burch procedures for treating SUI in patients who had previously failed conservative therapy. There was a 17%–30% lower mean cost for radio frequency relative to comparative sling or Burch procedures [35]. In this analysis, radio frequency appears to have a lower cost with fewer adverse events (AEs) compared with surgical treatments, though this study did not include long-term follow-up or cost of treatment for recurrent SUI.

Thus, preliminary trials suggest a treatment advantage for transurethral radio frequency collagen denaturation compared to sham procedures in the treatment of SUI [36]. However, there have not been randomized trials comparing this approach to other alternative treatments to date.

Safety

In the pilot study, no serious adverse events (SAEs) were associated with the procedure or identified up to 6 months afterward [27]. The most common AEs recorded during the procedure, recovery, and 30-day posttreatment period are listed in Table 77.6. One case of urinary retention presented 24 hours following discharge and required an indwelling catheter for 48 hours, with no further retention episodes. No other AE required therapeutic intervention, and no patient found her symptoms distressing enough to request an unscheduled physician visit. Over 12 months posttreatment for each of the radio frequency regimens in this study, no SAEs were reported [28]. Between 6 and 12 months, 8% of patients reported at least one episode of dysuria and 22% noted at least one episode of urgency, although none of these AEs affected patient QoL.

Table 77.3 Changes from Baseline in Median Number of Leaks Caused by Activity in 12 Months from a 36-Month Trial (Intent-to-Treat Population, *n* = 136)

	Baseline	**12 months**	**Change**
Leaks/day, *n* (range)	2.1 (0.1–35.0)	1.1 (0.0–20.0)	−0.6 (−34.3 to 18.9)

Table 77.5 Incontinence Quality of Life Questionnaire ≥ 10-Point Improvement, Imputed Results by Severity at Baseline throughout a 36-Month Study Period

Visit	Mild ($n = 50$)	Moderate ($n = 65$)	Severe ($n = 24$)
3 months	42% (21)	60% (39)	79% (19)
6 months	36% (18)	62% (40)	83% (20)
12 months	34% (17)	63% (41)	83% (20)
18 months	32% (16)	78% (51)	79% (19)
24 months	38% (19)	66% (43)	79% (19)
36 months	36% (18)	69% (45)	88% (21)

The randomized, sham procedure–controlled trial supported the safety of this procedure [31]. No SAEs were reported. Except for dysuria, wherein the incidence was numerically but not significantly greater among women in the radio frequency-treated group, there were no significant between-group differences in the incidence of all other AEs (Table 77.7). All cases of dysuria, hematuria, and hesitancy were transient and mild to moderate, and all urinary tract infections were simple and resolved with antibiotic therapy. In general, the safety profile for transurethral radio frequency collagen denaturation was comparable to that of the sham procedure.

In the 36-month study, transurethral radio frequency collagen denaturation was safe and well tolerated [26,34]. At 3 days posttreatment, the most common AEs were dysuria ($n = 7$; 5.2%), urinary retention ($n = 6$; 4.4%), pain ($n = 4$; 2.9%), and urinary tract infection ($n = 4$; 2.9%). Average pain score reported on a 10-point visual analog scale was 1.6. At 1-year posttreatment, one patient experienced increased leakage, judged by the investigator to be probably related to treatment. Symptoms of urgency or urge incontinence were reported by eight patients; in six, these symptoms resolved by 12 months and one patient reported these symptoms for 25 months. One patient still reported urge and urge incontinence symptoms at 36 months. At 18 months, one patient experienced a myocardial infarction deemed by the investigator to not be related to the procedure [34].

SUMMARY

There are a variety of treatment options for SUI. Initially, conservative measures such as Kegel exercises and behavioral modification can be helpful, but for severe SUI more invasive treatment options are often necessary. Traditional Burch procedures are an option but currently the midurethral sling is considered the standard of care. If a patient does not desire a surgical procedure or is not a good surgical candidate, minimally invasive injection therapy is an option. Urethral bulking agents are currently available and autologous muscle–derived cell injection therapy is in clinical trials.

Nevertheless, clinical evidence indicates that nonsurgical, transurethral radio frequency collagen denaturation is an effective, safe, and cost-effective therapy in the spectrum of treatment options for women with SUI due to bladder neck hypermobility. Since the procedure does not result in gross anatomic changes, it likely would not preclude subsequent surgical procedures if needed, though at 3-year follow-up the efficacy appears durable. Thus, in the properly selected patient, radio frequency collagen denaturation offers SUI patients with an office-based, minimally invasive treatment option, with a nominal disruption of their usual daily activities.

78 Artificial Urinary Sphincter for Treatment of Stress Urinary Incontinence in Women

David Castro-Diaz, David Staskin, and Roger R. Dmochowski

INTRODUCTION

The artificial urinary sphincter (AUS) remains an alternative to slings or periurethral injection therapy in the management of urinary incontinence, especially when the aforementioned interventions have failed. The AUS has been most often used for treatment of incontinence due to primary urethral sphincter deficiency (type III stress urinary incontinence [SUI], or intrinsic sphincter deficiency [ISD] [1–3]). ISD may be the result of periurethral fibrosis from prior anti-incontinence procedures, neurological disorders (spinal cord injury, peripheral neuropathy), radical pelvic operations, pelvic radiation therapy, or the effects of aging and estrogen deficiency on the urethra and anterior vaginal wall. These conditions affect the ability of the urethra wall elements to coapt, thereby producing a poorly functional sphincteric mechanism. The pubovaginal sling is considered the gold standard for the treatment of ISD, yet some patients will have less than adequate results despite several attempts [4]. The AUS enhances higher intraurethral pressures by increasing pressure circumferentially around the urethra, lessening the transmission of intra-abdominal pressures. Therefore, in some cases, the AUS may benefit women with urethral weakness and good anterior vaginal wall who have sphincteric dysfunction.

The AUS may be inserted either by a transabdominal or a transvaginal approach. The device is composed of three parts: the inflatable cuff, the pressure-regulating balloon, and the pump. The cuff is placed circumferentially around the bladder neck, the pressure-regulating balloon is positioned in the prevesical, and the pump is placed in the labia majora. When the pump is compressed, fluid within the system is transferred from the cuff into the regulating balloon. This decompression opens the bladder neck allowing the patient to void. After a period of time (usually between 1 and 2 minutes), the pressure-regulating balloon initiates cuff refilling by transfer of fluid through a resistor in the pump, re-establishing urethral compression, coaptation, and continence. The American Medical System-800 is the AUS currently available for implantation (Figure 78.1).

PREINSERTION ASSESSMENT

Women with SUI who may be considered candidates for implantation of an AUS should undergo detailed evaluation including a focused urological history and physical examination. Women with SUI from primary urethral sphincter deficiency will experience significant volumetric loss of urine with abdominal straining or other physical exertions. Delineation and characterization of incontinence type as stress, spontaneous, or mixed (associated with some degree of urinary urgency) is important so as to correctly identify those women who may have contributory detrusor overactivity. Bother and amount of urinary loss should be quantified (most commonly with a urinary diary or pad test) to accurately counsel the patient about options. Prior anti-incontinence interventions may have induced bladder neck and periurethral fibrosis and decreased urethral vascularity and integrity of the periurethral tissue and anterior wall of the vagina. Therefore, any history of surgical intervention should be assessed. The history should also assess the patient for any neurological or orthopedic disorders that may affect the patient's manual dexterity and therefore affect her ability to activate the labial pump mechanism.

Physical examination should be performed, directed to the vagina and lower abdomen. Examination may reveal previous surgical procedures by virtue of surgical scarring or other fibrotic changes. Important examination findings include: weakened pelvic floor, associated prolapse defects, or atrophic vaginitis. Urethral hypermobility should be measured by direct examination or the Q-tip test. The lack of hypermobility of the bladder neck or urethra may suggest a better candidate for the AUS. Vaginal vault capacity and ancillary vaginal findings should be noted. Objective demonstration of SUI in the supine or upright position is critical as a correlate to subjective assessment.

Laboratory assessment includes obtaining urine sample for analysis and culture. Urodynamic study (UDS) is critical to assess bladder function and determine bladder storage capabilities. Urine storage at low intravesical pressures is critical for placement of the AUS, given the compressive effect of the device. UDS evaluates bladder filling pressures and bladder capacity. High-pressure urinary storage is a contraindication to AUS placement and critical to determine so as to optimize therapy. UDS also may detect detrusor overactivity, which may require additional medical therapy for optimization of care. Abdominal leak point pressure assists in the assessment of sphincteric function and assists in the delineation of ISD. Urethral pressure profilometry confirming low urethral closure pressures (<25 cm H_2O) has been suggested by some experts [5]. Additional testing modalities may include uroflowmetry and measurement of postvoid residual urine. Intermittent catheterization postoperatively may be a component of therapeutic strategy for some women with poor bladder contractility.

Radiographic evaluations may include a voiding cystourethrogram (VCUG) with resting and straining views and can be combined with UDS. A well-supported urethra with an open bladder neck at rest is consistent with ISD. The VCUG will also confirm any coexistent urinary tract fistula or vesicoureteral reflux.

IDEAL CANDIDATES

The AUS is indicated for women who suffer from ISD who demonstrate low-pressure urinary storage. Conservative measures (such as medication therapy, behavioral management, and topical vaginal hormones) should be considered and exhausted prior to operative intervention.

Women who are found to have elevated intravesical storage pressures are at risk for upper tract deterioration with the AUS (hydronephrosis and renal functional impairment). These women should demonstrate a response to antimuscarinic or to alternative therapies on UDS evaluation prior to AUS implantation. Augmentation cystoplasty may be considered in those women who demonstrate persistently high pressures despite maximal medical therapy. Augmentation may be performed either concomitant with or in a staged manner after the AUS implantation.

Women with incomplete emptying and high preoperative postvoid residuals may be considered for AUS implantation; however, intermittent self-catheterization should be considered following the procedure and should be taught preoperatively. If unwilling or unable to perform intermittent catheterization, the woman may still be a candidate but should be aware that elevated residual urine volumes may be problematic in the postoperative period. Manual dexterity should be determined so as to operate the labial pump after AUS implantation. As compared to the pubovaginal sling, the AUS appears less likely to cause permanent urinary retention. The Crede maneuvers may assist voiding for some women after cuff deactivation. However, these women should be meticulously selected, with preoperative demonstration of effective bladder evacuation by the Valsalva effort.

Child-bearing potential is not an exclusion for sphincter implantation. Some authors suggest that when pregnancy occurs, the device should be deactivated in the third trimester to diminish pressure on the cuff and bladder neck. Deactivation during labor and delivery to promote bladder emptying is considered recommended practice. Cesarean section is not contraindicated as AUS components are within the retropubic space [6].

TRANSVAGINAL IMPLANTATION

The transvaginal approach for AUS cuff placement provides the singular advantage of improved urethrovaginal dissection given the immediate access to the periurethral space. Multiple anti-incontinence procedures may make dissection extremely difficult, and direct visualization is promoted by this approach. Inadvertent and unrecognized injury to the vaginal wall and urethra are decreased by the transvaginal approach [7,8].

After admission to the surgical care area, preoperative broad-spectrum antibiotics are administered parenterally at least 1 hour prior to surgery. After the administration of regional or general anesthesia, the patient is placed in the dorsal lithotomy position. The lower abdomen and vagina are clipped and prepared with a 10-minute scrub with a povidone-iodine or Hibiclens solution. A posterior-weighted vaginal retractor is placed for exposure of the anterior vaginal wall. Lateral labial retraction sutures or a self-retaining retraction system may be utilized for retraction of the labia. A 14 F Foley catheter is inserted in sterile fashion for bladder drainage.

A midline incision is made in the anterior vaginal wall. The incision should extend from a point midurethra to the proximal bladder neck (Figure 78.2). With sharp dissection, the vaginal wall is dissected from the underlying urethra on either side. The vaginal flaps should be dissected so as to create thick flaps for purposes of closure of the vagina wall over the AUS cuff. Blunt finger dissection may be used to separate the endopelvic fascia from its lateral attachments to the pubic rim in a woman who has not had prior surgery. The fascia should be swept from lateral to medial, so as to gain access into the retropubic space (Figure 78.3). The retropubic space should be entered sharply in women who have had previous surgery using dissecting scissors positioned against the pubic symphysis angled toward the ipsilateral shoulder. When the retropubic space is dissected bilaterally, final mobilization of the bladder neck and urethra is completed.

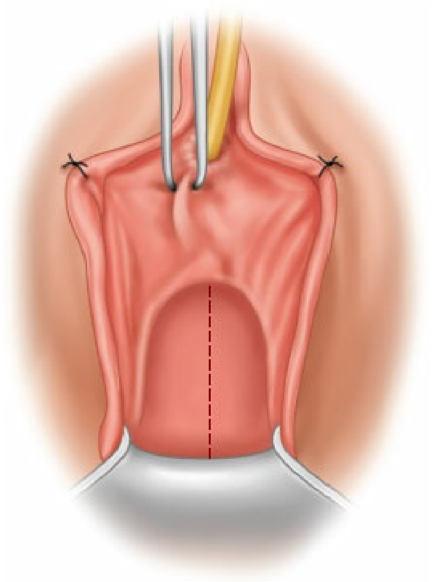

Figure 78.2 With the patient in dorsal lithotomy position, a midline vaginal incision is performed.

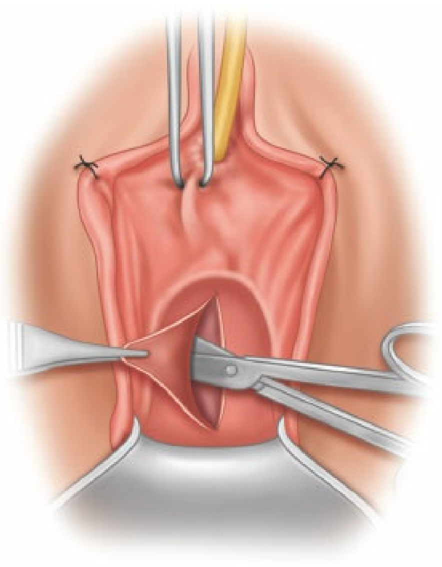

Figure 78.3 Using a combination of sharp and blunt dissection, the vaginal mucosa is dissected off of the underlying tissues and the retropubic space is entered bilaterally.

Next, the anterior aspect of the proximal urethra and bladder neck is separated from the fascial attachments to the pubic symphysis. Blunt finger dissection or sharp dissection may accomplish this component of the procedure. Suprameatal incision (1–2 cm) and dissection may be used (Figure 78.4a) in some women to assist in delineation of the dorsal urethra [9]. The sharp dissection should be performed in the midline immediately inferior to the pubic symphysis (Figure 78.4b). At this stage of the procedure, aggressive dissection may lead to unintentional bladder or urethral tear. Urinary tract injury has conventionally led to abandonment of the procedure. Some authors, however, including Salisz and Diokno have reported successful repair of this type of injury with subsequent successful implantation of the device [10].

After circumferential dissection of the proximal urethra and bladder neck, a right-angle clamp is passed around the urethra from left to right. The cuff measuring tape is passed around the bladder neck and the circumferential dimension of the bladder neck is assessed. Using a larger cuff size is preferred if there is a concern about exact dimension exists. Using a right-angle clamp, the appropriate-sized cuff is placed around the bladder neck (Figure 78.5). If the AUS pump is to be placed into the right labia majora, the cuff should be drawn from right to left. If the pump is to be placed in the left labia, the cuff is placed from left to right. The cuff is then locked in place and rotated 180° so that the locking button of the cuff lies anteriorly, opposite to the anterior vaginal wall (Figure 78.6).

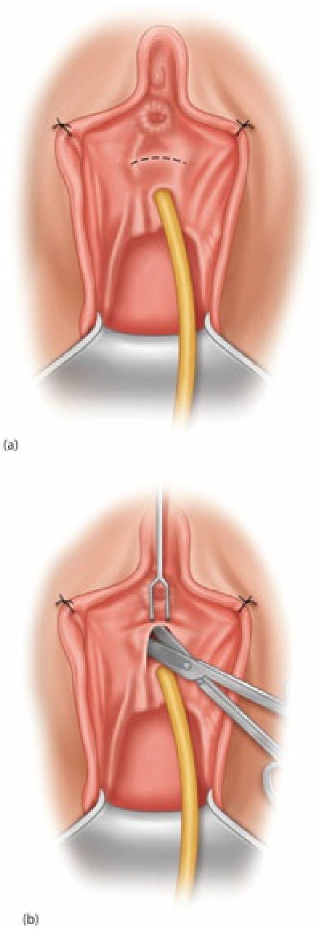

Figure 78.4 (a) If dense scarring is encountered anterior to the urethra, a separate incision can be made above the urethral meatus. (b) The suprameatal dissection is performed in the midline, just below the pubic symphysis.

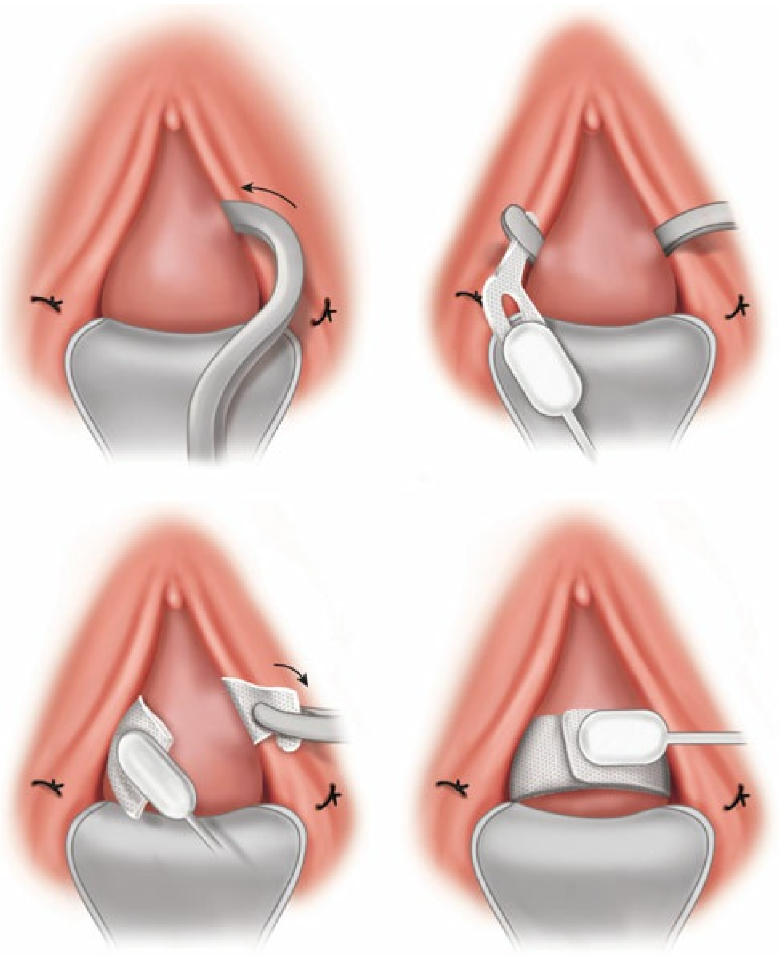

Figure 78.5 The cuff of the artificial urinary sphincter is passed around the bladder neck and locked into place.

On the ipsilateral side to which the pressure-regulating balloon and pump mechanism will be implanted, a transverse suprapubic incision (approx 4 cm) is created. A straight clamp is passed using digital guidance from the suprapubic incision lateral to midline down to the ipsilateral side of the vaginal incision. The cuff tubing is grasped, and the clamp is withdrawn, pulling the tubing up into the suprapubic incision. Rubber-shod clamps should be utilized during this phase of the procedure to ensure that the end of the tubing is not open to the field. The anterior rectus sheath is then incised vertically and the retropubic space is developed adjacent to the bladder. The pressure-regulating reservoir is then inserted into this space. The reservoir is then filled with sterile saline to a volume compatible with reservoir size and requirements for the unique individual (usually 22 mL).

From the suprapubic incision, a subcutaneous tunnel is formed into the labia majora with a combination of blunt and sharp dissection. The pump is passed into the labia majora to reside at the level of the urethral meatus with the deactivation button facing anteriorly (outwardly). During implantation, a Babcock clamp is used to secure the pump in this position. The tubing is trimmed to the appropriate lengths and the ends are irrigated to remove air or debris. The preparation of the cuff and the reservoir is performed according to the instructions specified by the manufacturer. A straight connector is then placed between the pump and the balloon reservoir. A right-angle connector attaches the pump to the cuff. Quick connectors provided in the implantation kits are used to secure these attachments.

The suprapubic and vaginal incisions are irrigated copiously with an antibiotic solution. The wounds are then closed in several layers with absorbable sutures to ensure complete of all implanted materials with host tissue. If the anterior vaginal wall is of suspect quality, interposition of a vascularized flap (e.g., Martius flap) should be considered. Following closure, a vaginal packing is placed. Prior to awakening the patient, the AUS cuff is deactivated.

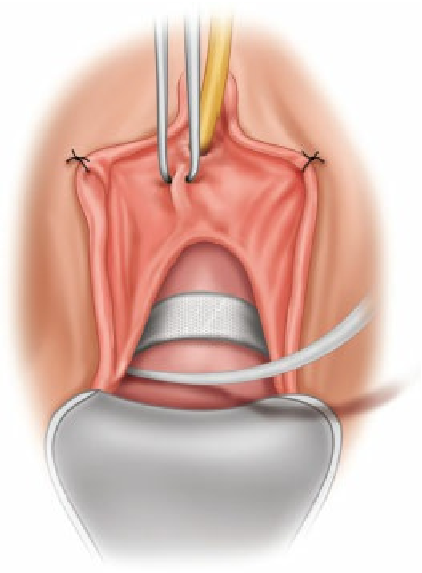

Figure 78.6 The cuff is rotated 180° clockwise so that the locking button lies anterior to the urethra, away from the anterior vaginal wall.

The vaginal packing and Foley catheter can be removed on the first postoperative day. The cuff should be in a deactivated position for a period of 6 weeks.

TRANSABDOMINAL IMPLANTATION

The transabdominal approach allows easy access to the retropubic space and removes the need for of an anterior vaginal wall incision [11]. Similar to the transvaginal approach, after admission to the surgical unit, the woman should receive parenteral broad-spectrum antibiotics 1 hour prior to the start of the operation. After induction of anesthesia, the patient should be placed in the dorsal lithotomy position allowing access to both the abdomen and vagina. The abdominal wall and vagina should be shaved and a 10-minute skin preparatory scrub should be performed. A 14 F Foley catheter is placed and the bladder drained.

A lower midline or Pfannenstiel incision should be made to allow appropriate access to the retropubic space. The retropubic space is developed using a combination of sharp and blunt dissection. If the space does not develop easily, the dissection should follow the posterior aspect of the pubic bone and the periosteum, trying not to injure the anterior bladder wall. This may be assisted by the use of electrocautery. If a cystotomy occurs, this should be performed with absorbable sutures.

At the bladder neck, dissection should proceed laterally and may be facilitated by vagina manipulation with sponge stick or manual assistance (Figure 78.7). The bladder neck is located by palpation of the Foley catheter balloon and the endopelvic fascia is entered approximately 2 cm on either side of the bladder neck. The dissection of the vesicovaginal plane is continued through the endopelvic fascia until the internal aspects of the vaginal fornices are visible. The bladder neck is then dissected from the vagina, taking great care to avoid perforation of the vaginal wall. Intentional anterior cystotomy may be used to assist in mobilization of the bladder neck and facilitate separation of the vesicovaginal plane. Any cystotomy is repaired in multiple layers with absorbable sutures. Any accidental perforations of the vaginal wall are also repaired at this phase of the implantation. If significant injury of the vaginal wall eventuates, the option of a pubovaginal sling should be considered. If an AUS is implanted in this situation, the interposition of a Martius flap is preferred for coverage purposes.

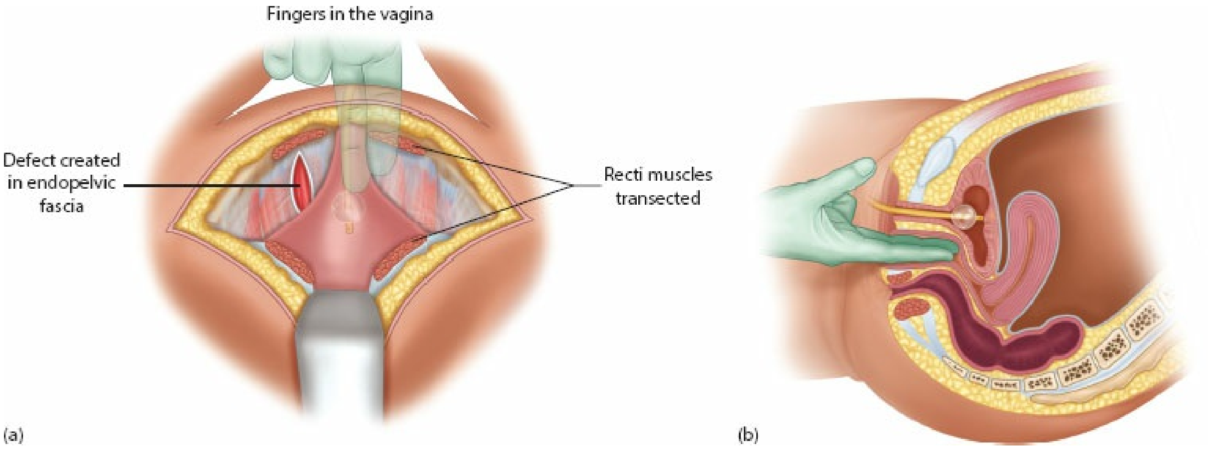

Figure 78.7 Aiding the dissection with an intravaginal finger: (a) frontal view and (b) lateral view.

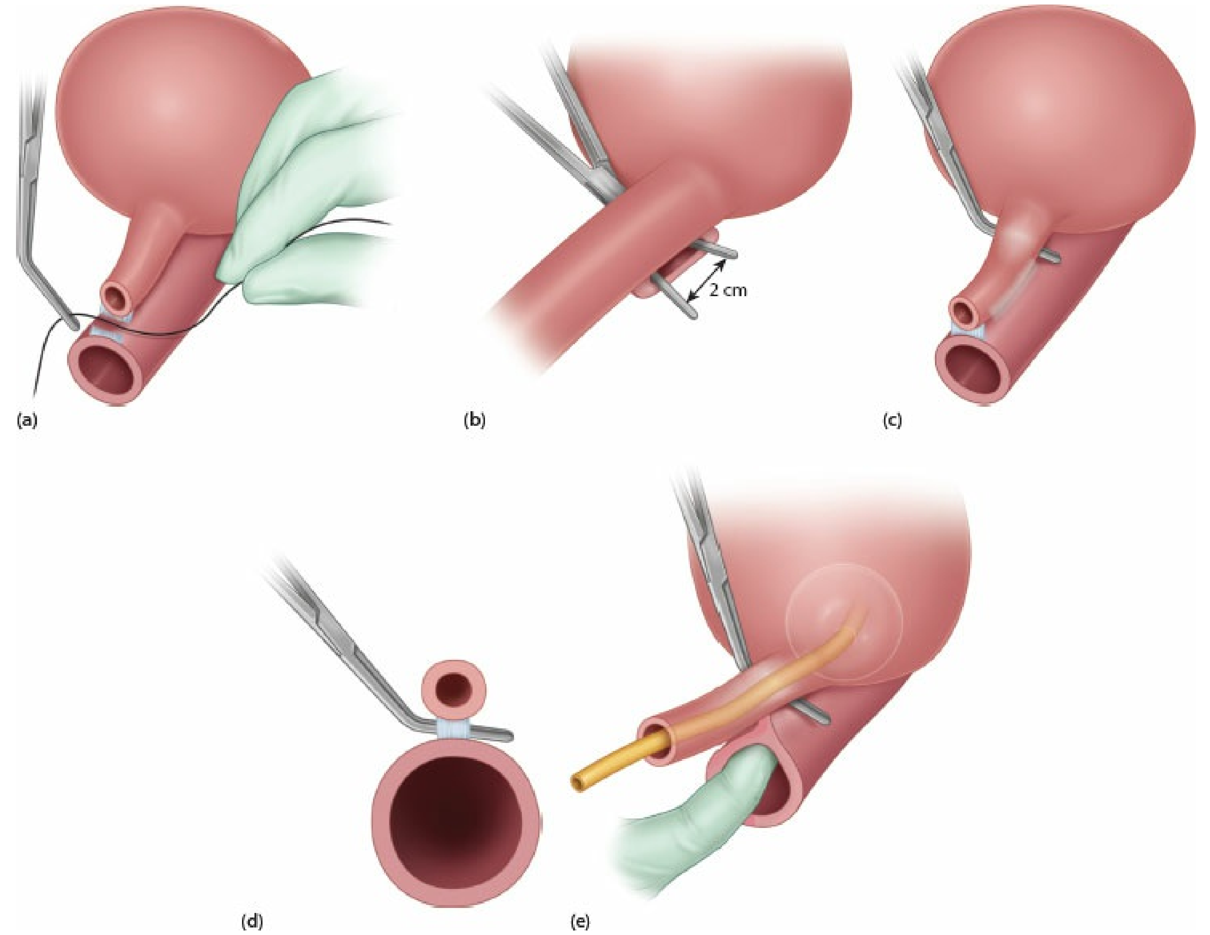

Figure 78.8 (a, b) Insertion of right-angle clamp, (c, d) right-angle clamp in place, and (e) clamp, catheter and finger in position.

After circumferential dissection of the bladder neck has been completed, the cuff sizer is used; the larger size is selected in cases of nonstandard measurement. The appropriate cuff is drawn around the bladder neck with a right-angle clamp and positioned so that the locking button lies on the opposite side from the labia majora in which the pump is to be placed (Figure 78.8).

The appropriate pressure-regulating reservoir is chosen as previously described. The balloon is placed on the same side as the labium majora where the pump will be placed. The system is primed and filled as previously described. A subcutaneous tunnel is created from the suprapubic incision into the labium majora using sharp and blunt dissection. The pump is placed in the labium majora to rest at the level of the urethral meatus with the deactivation button facing anteriorly (outward facing). A Babcock clamp is utilized to fix the pump in place. An absorbable suture can be placed within the tunnel to prevent cephalad migration.

The tubing is then connected as described previously. The cuff is deflated and the device is deactivated. Following hemostasis, the wound is copiously irrigated with antibiotic solution. The abdominal incision is then closed without drainage. The device in place can be seen in Figure 78.9.

The Foley catheter can be withdrawn on the first postoperative day. In cases of accidental or intentional cystotomy, a longer period of catheter drainage is preferred. The device is left in a deactivated position for a period of 6 weeks.

ENDOSCOPIC IMPLANTATION

The AUS in women can also be implanted by either laparoscopic or robot-assisted laparoscopic. The procedure can be performed using either a transperitoneal or an intraperitoneal access depending on patient characteristics and surgeon preferences. The extraperitoneal approach pretends to reproduce the steps of the open procedure, but quite often is difficult because scar tissue of previous pelvic surgery. When using an extraperitoneal approach, the first step consists of approaching the bladder through an incision of the parietal peritoneum from one medial umbilical ligament to other. Anterior and lateral attachments of the bladder have to be incised to expose the bladder neck. When using a transperitoneal approach, an incision of the parietal peritoneum from one medial umbilical ligament to the other is carried out. The endopelvic fascia has to be entered at both sides of the bladder neck, as previously described for the transabdominal implantation. With the help of two surgeon fingers in the vagina, the dissection is performed to visualize the vagina. After releasing the bladder neck, it is important to check the integrity of the bladder. In the case that any accidental injury occurs, management should be the same as to an open implantation. A cuff sizer is used to measure and to select the appropriate cuff size. The balloon and pump are introduced through a mini incision in a similar manner to the transabdominal implantation.

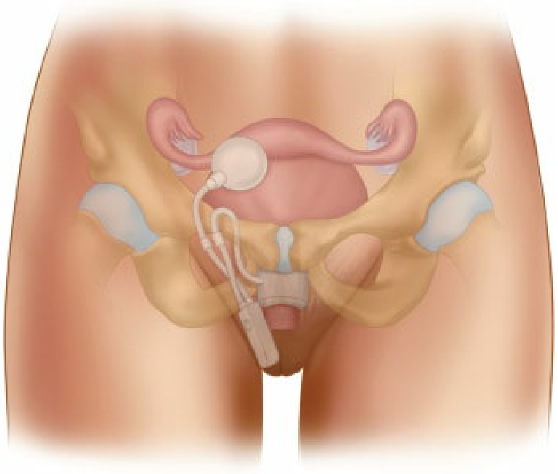

Figure 78.9 Artificial urinary sphincter in place.

COMPLICATIONS

AUS implantation complications include intraoperative injury to the bladder, urethra, or vaginal wall, device failure, erosion, and infection.

When assessing risk factors for explantation including patient age, type and number of prior procedures, time since prior procedure and AUS implantation, and perioperative injury, Costa et al. found only perioperative injury to be contributory. Of 49 patients who had perioperative injuries, 8 explantations resulted, compared with only 4 in the 155 cases that did not have injuries [12]. On a multivariate analysis of a large series of 215 women, Vayleux found that age > 70 years, previous anti-incontinence surgery, and pelvic radiotherapy were risk factors for failure [13]. Surgical technique can minimize major intraoperative complications. Recognized injuries should be repaired primarily under direct visualization with the interposition of well-vascularized tissues if necessary. In many cases, inadvertent injury to the bladder, urethra, or vaginal wall should not preclude implantation of the device. Surgical judgment should be utilized to determine the safety of completing the procedure.

Improvements in the design and manufacture of the device have significantly reduced AUS malfunctions. Device-related issues include fluid loss secondary to tubing fracture at connection sites, cuff leakage at stress points, and kinking of the tubing. Chronic failure may be due to atrophy of the periurethral tissues decreasing the compressive bulk within the cuff, not allowing for pressure to be dispersed evenly around the urethra, resulting in recurrent incontinence. Newly designed cuff backing has addressed this issue; however, it must be considered in cases of failure [14]. Surgical judgment should be used when replacing the malfunctioning portion of the device rather than the whole device. Indications for complete replacement of the device include fluid leakage, which may allow foreign material into the system, or chronic emplacement of the device (more than 3 years) [15].

Device erosion has decreased since the introduction of modified cuff architecture; however, it remains a concern with any foreign body implantation. Significant risk factors for erosions include perioperative injury, incorrect implantation technique, history of prior procedures, and infection [12]. Erosion of the sphincter cuff into the urethra is commonly associated with recurrent incontinence, although urinary tract infection and/or wound surgical site infection may be the first and only symptom. Erosion of the cuff through the vaginal wall is associated with vaginal bleeding and discharge. Erosion of the pressure-regulating reservoir into the bladder is rare, and may present as a urinary tract infection or infection of the device. Pump erosion through the labium majora is diagnosed by direct examination.

Infection or erosion should be treated with explantation of the entire device in the majority of cases. Reimplantation may be considered after 4–6 months. In cases of cuff erosion into the urethra, the placement of an omental flap between the cuff and urethra is recommended at reoperation.

In cases of erosion of the cuff into the urinary tract, salvage of the AUS is not recommended. In the isolated case of erosion of the sphincter tubing through the abdominal skin or erosion of the pump through the labium, aggressive irrigation and debridement of the tissues may make replacement of certain AUS components and wound closure a possibility. When replacement of the pump is necessary, it should be moved to the opposite labium. The device with cuff erosion into the vaginal wall may be salvaged utilizing a Martius flap and vaginal wall closure. Before all salvage attempts, the patient should be counselled as to the high risk of eventual necessity for removal of the complete device.

IMPLANTATION RESULTS

Success rates for implantation of the AUS in female patients are summarized in Table 78.1. The average success rate ranges from 68% in a series of 31 women studied by Donovan et al. [16] to 100% in women studied by Appell [1] and Abbassian [9]. In a large series of 190 patients, Costa et al. reported success rates of 88% and 81.8% in patients with nonneurogenic and neurogenic bladder, respectively [12]. A study comparing AUS and pubovaginal sling in 77 patients with confirmed ISD revealed favorable results for both procedures (84% vs. 91% respectively) [17].

Table 78.1 also includes the published complications from the same series. Infection was seen in 3%–7% of cases. Erosions represented the most common complications, occurring in 7%–29% of cases. Reoperation for cuff malfunction or tubing problems has been as high as 21% in earlier series [18]; however, there is a clear trend toward reduced numbers of device failures due to technological advancements made over the years.

Long-term follow-up data for the AUS in women are sparse. Existing reports indicate mechanical or nonmechanical reasons [3]. In a large series of 344 patients with an average follow-up of 9.6 years, 85.6% of women were continent, 26% had surgical revision of the device, and in 30% the device was explanted [19]. Similar continence rate were found in another series of 55 patients at an average follow-up of 9.3 years [20] (Table 78.2).

Available data on the outcome of the endoscopic implantation suggest a similar outcome, suggesting that laparoscopic or robotic assisted laparoscopic implantation of AUS in women is feasible by surgeons who are very experienced laparoscopically (Table 78.3).

CONCLUSION

The AUS provides uniform circumferential compression of the bladder neck, without changing its position. The AUS is indicated for incontinent women with proven ISD and can be particularly useful in those patients who have undergone previous unsuccessful anti-incontinence procedures. In addition, those women with ISD and a poorly contractile bladder, the AUS may be the initial treatment of choice over the sling due to its lower incidence of prolonged postoperative urinary retention.

The AUS may be placed either with a transvaginal or transabdominal approach. The transvaginal approach affords direct visualization of the difficult dissection of the urethrovaginal plane and the option of a suprameatal incision to allow in the anterior dissection of the urethra. Advantages of the transabdominal approach include lack of a vaginal incision and improved exposure to the endopelvic fascia and anterior bladder neck dissection. Additionally, transabdominal exposure allows the opportunity to perform a deliberate cystotomy to assist in a particularly difficult dissection. The endoscopic implantation of the AUS is feasible, seeming to provide similar outcome in the hands of surgeons who are very experienced in laparoscopy. Regardless of operative approach, emphasis should be placed on meticulous surgical approach as intraoperative complication places the patient at risk for postoperative problems such as infection and erosion with eventual device explantation. The AUS compares well to the success of more traditional procedures for urinary incontinence. The data suggest that placement of the AUS is a safe and effective treatment option for the carefully selected patient with ISD.

Diagnosis and Treatment of Obstruction Following Incontinence Surgery: Urethrolysis and Other Techniques

Stephen Mock, Melissa R. Kaufman, W. Stuart Reynolds, and Roger R. Dmochowski

INTRODUCTION

Stress urinary incontinence (SUI) is a common condition among women. This, in combination with an increase in public awareness, has more and more women actively seeking treatment. Although there are many available treatment options for SUI, the introduction of less morbid anti-incontinence procedures has led to a rise in the utilization of surgery to combat this problem. In particular, the synthetic midurethral sling (MUS) has become popular over the last decade, owing to high efficacy, minimal patient morbidity, and technical simplicity [1]. This in turn has led to an increase in the number of patients having postoperative voiding issues. Postsurgical voiding dysfunction (VD) can be transient and is generally lower than historically reported, but obstruction requiring intervention will still unavoidably occur.

INCIDENCE OF OBSTRUCTION AND VD AFTER STRESS INCONTINENCE SURGERY

The incidence of iatrogenic obstruction and VD varies widely in the literature, ranging from 2.5% to 24%, with the true incidence unknown and likely underestimated for a multitude of potential reasons [2] (Table 79.1). The American Urological Association panel cited a 1%–10% risk of either retention lasting greater than 1 month or requiring intervention after incontinence surgery [3]. In a large review of 1175 TVT (transvaginal tape) procedures, Rardin et al. found 23 (1.9%) women with persistent VD that required sling release. Twenty women had urinary retention or incomplete emptying while three had refractory urgency/urge urinary incontinence (UUI) [4]. In the Finnish nationwide TVT database of 9040 patients, 50 cases (0.6%) of sling release for urinary retention were reported [5].

ETIOLOGY

The risk of iatrogenic obstruction is usually related to technical factors. In a retropubic urethropexy, sutures elevating the bladder neck may be too tight and can cause overcorrection of the urethrovesical angle or “hypersuspension.” Sutures placed too close to the urethra can cause urethral deviation. Excessive periurethral scarring can occur anteriorly between the urethra and the pubis and lead to urethral compression. Sutures placed too distally can cause kinking with obstruction and an inadequately supported bladder neck/proximal urethra with potentially continued stress incontinence. A similar mechanism may occur with transvaginal bladder neck suspension. With suburethral sling procedures, excessive tension on the sling around or under the urethra is usually responsible for obstruction. Sling tensioning, be it fascial or polypropylene, is highly arbitrary with considerable variability between surgeons as to what constitutes an appropriate amount of tension. For a pubovaginal sling (PVS), tensioning may be performed under cystoscopic guidance to determine adequate coaptation of the proximal urethra. This approximately corresponds to a two fingerbreadth width between the rectus fascia and the sutures once tied down. For synthetic MUS, sling tension should be minimal and should easily accommodate a surgical instrument or metallic sound between the sling and the urethra. As a result, small nuances in tension may explain the difference in outcomes and complications reported by different groups [1].

Less commonly, displacement of the sling from its intended position may result in obstruction. Sarnelli et al. showed that patients with obstruction after their surgery had a shorter distance between the pubic symphysis and their sling on ultrasonography. This shorter distance may indicate a more proximal sling or may indicate a tighter sling (one that elevates the urethra more toward the symphysis), either of which may be responsible for the subsequent obstruction [6]. Similarly, based on anecdotal experience on post–sling obstruction, the authors have found that obstructive slings are most likely to be found close to the bladder neck. In addition, the authors have found that progression of anterior and apical pelvic organ prolapse (POP) can cause a nonobstructive sling to become obstructive 10 years or more after placement of the sling. Also, in theory, patients with an altered wound healing cascade, as in the case for keloid formers or those suffering from scleroderma, can result in excessive scarring and lead to obstruction, even in cases where the sling appears to be loosely tied.

Occasionally, postoperative VD is caused by a learned VD or failure of relaxation of the striated urethral sphincter [7]. In these cases, patient education and sometimes biofeedback can be helpful. When the problem persists, botulinum A toxin injection into the urethral sphincter has been reported to be successful [8]. Finally, impaired detrusor contractility may be responsible for a “relative obstruction” after incontinence surgery. Sometimes, this can be diagnosed preoperatively and the patient may be warned of the possibility of VD after surgery.

The pathophysiology of obstructive symptoms is fairly easy to explain, but that of de novo storage symptoms is more complex. However, it is important to remember that a portion of patients who preoperatively have mixed symptoms will have their urge symptoms assume a more prominent and bothersome role once the stress incontinence has been cured postoperatively [9]. Static changes in bladder outlet resistance can occur as a result of a tensioned sling or a “tension-free” MUS with documented increased void times, decreased maximum flow rates (Q_{max}), increased mean detrusor pressure, increased detrusor pressure at maximal flow, increased mean urethral resistance, and elevated postvoid residual (PVR) volumes [1]. Several authors have demonstrated detrusor instability in association with obstruction [10,11]. Chaikin et al. reported an increasing incidence of urge incontinence over time after PVS. They postulated that it was suggestive of the deleterious effects of chronic insidious obstruction as the sling tightens due to the increasing shrinkage over time [12]. It is believed by some that increased detrusor overactivity secondary to obstruction develops due to the acquired parasympathetic denervation sensitivity, while others believe that damage inflicted on the autonomic innervation of the bladder by surgical dissection leads to this without obstruction [13,14]. Others have suggested alterations in cholinergic and purinergic afferent pathways due to obstruction playing an integral role in the development of storage symptoms [15]. Although the exact pathophysiological mechanisms may not be agreed upon, it is clear that de novo storage symptoms do develop in a large number of patients with urethral obstruction.

Table 79.1 Potential Factors for Varying Incidence of Obstruction and Voiding Dysfunction after Stress Urinary Incontinence Surgery

No standardized definition of obstruction in this setting.
Symptoms can range from storage to obstructive.
Patient loss to follow-up.
Patient loss to seeking second opinion.
Patient may elect to remain obstructed rather than undergo further surgery or risk recurrence of incontinence.
Diagnosis during early postoperative period when symptoms can be transient.

IDENTIFYING RISK FOR POSTOPERATIVE VD

Ideally, for both patient selection and informed counseling, risk factors for postoperative VD would be informative, but no definitive conclusions are available. Risk factors cited include prior anti-incontinence surgery [16], concomitant POP surgery [17,18], age [19], elevated PVR volume [20], and $Q_{max} < 20$ mL/s [20]. Wheeler et al. found the only patient characteristic or parameter predictive of voiding trial passage and lack of urinary retention or incomplete emptying following MUS was Q_{max}. A $Q_{max} > 30$ cc/s had a 100% positive predictive value for voiding trial passage. Other characteristics such as prior incontinence procedure, concurrent anterior repair, PVR volume, and other potential predictors were not found to be significantly predictive of voiding trial passage using multivariate analysis in their study [21]. While evidence exists that women who void with no/minimal detrusor pressure or who void primarily with Valsalva maneuvers were more likely to require prolonged catheterization [22,23]; there are conflicting reports [24,25]. In a secondary analysis of the ValUE

(value of urodynamics evaluation) trial, Sirls et al. evaluated the effect of urodynamic testing on clinical diagnosis, treatment plan, and outcomes in women undergoing SUI surgery. Of those who were diagnosed with voiding phase dysfunction preoperatively, there was no change in the odds of self-voiding at discharge or developing postoperative VD [26]. However, these results are confounded by the fact that surgical modification was allowed based on preoperative results, with nearly all modifications making surgery less obstructive, likely undertaken due to the theoretically higher risk of retention in those with detrusor underactivity or acontractility. Additionally, in the SISTEr (stress incontinence surgical treatment efficacy) trial, Lemack et al. found no urodynamic variables were predictive of postoperative VD (defined as need for catheter greater than 6 weeks or surgical intervention to improve voiding) following Burch colposuspension or PVS [27]. Sling approach is another factor possibly associated with sling obstruction. In the TOMUS (trial of MUSs), Richter et al. demonstrated a significantly higher rate of VD requiring surgery (or permanent catheter) after a retropubic sling compared with a transobturator sling (2.7% vs. 0%, $p = 0.002$) [28].

DIAGNOSTIC EVALUATION

No consensus has been reached on the optimal timing of evaluation of a patient with suspected obstruction or VD after a sling procedure, but the single most important piece of clinical information used to determine if urethrolysis is indicated is a clear temporal relationship of VD following incontinence surgery [2]. While transient VD and urinary retention are frequent and expected after many types of anti-incontinence surgery, most cases will resolve within 4 weeks postoperatively. In a study evaluating early postoperative VD in patients after TVT, Burch, and vaginal sling procedures, the return to normal voiding occurred at a mean of 9 (0–90) days after TVT, 5 (2–42) days after Burch and 21 (2–210) after sling procedures [29]. PVS result in less rapid tissue ingrowth and have a high likelihood of resolution of VD by within 3 months [30]. Thereafter, there is a very low probability that any persistent retention will resolve without intervention. As a result, it had been common practice to delay evaluation of the patient with urinary retention or severe storage symptoms for approximately 3 months postoperatively to allow adequate time for obstruction/retention to resolve. Additionally, this time frame is thought to allow for adequate retropubic scarification and fibrosis, which may help minimize the risk of recurrent SUI.

The waiting period advocated for obstruction and retention for more traditional anti-incontinence procedures has been largely abandoned for MUS. In these cases, earlier intervention is suggested when obstruction is suspected [4,16,31]. After MUS, temporary VD has been reported to resolve in 25%–66% of patient in 1–2 weeks [32,33], but due to the tremendous ingrowth of fibroblastic tissue and subsequent immobility of the sling, patients with severe symptoms or urinary retention are less likely to improve after this time period. Considering these facts, early intervention may be warranted but which some believe carry a higher likelihood of resulting in recurrent SUI, though no formal studies or guidelines have been issued [16]. At the other end of the spectrum is the delayed intervention, which may risk success as long-standing symptoms would intuitively seem less likely to respond to relief of obstruction the longer one is obstructed, but this has not been proven conclusively, with some groups showing favorable results with earlier intervention [34,35] while others do not [36]. However, the decision to proceed with workup and possible intervention must be considered early and discussed with the patient as their symptomatology, level of dissatisfaction, and willingness to risk possible recurrence of SUI should guide when it’s done and what is done.

History and Physical Examination

Key points in the history are the patient’s preoperative voiding status and symptoms and the temporal relationship of the lower urinary tract symptoms to the surgery. The type of procedure performed and the number and the type of other procedures done should be elicited. Urodynamic data from before incontinence surgery are useful if available. Finally, it is important to determine if the symptom of stress incontinence persists.

Symptoms related to obstruction lie along a continuum that includes storage and emptying symptoms. The most obvious sign of obstruction is the complete or partial urinary retention, the inability to void continuously, the presence of a slow stream with or without intermittency, or the need to strain to void. Some patients may have more subtle symptoms, including the need to bend forward/change positions to void or recurrent urinary tract infections (rUTI) that are associated with an elevated PVR volume. However, many women will present with predominate storage symptoms of frequency, urgency, and urge incontinence, with or without obstructive symptoms. Carr and Webster reviewed the presenting symptoms in 51 women subsequently undergoing urethrolysis and are as follows: storage (irritative) symptoms (75%), voiding (obstructive) symptoms (61%), de novo urge incontinence (55%), need for intermittent catheterization (40%), rUTI (8%), and painful voiding (8%). Urinary retention as the sole symptom occurred in 24% [37]. More recently, Clifton et al. reported on 93 cases of sling release of which the indication for intervention was retention in 54%, obstructive or urge symptoms in 42%, and rUTI in 4% [38].

A full genitourinary examination should be performed to assess urethral angulation, urethral mobility, vaginal estrogen status, POP, and evidence of mesh extrusion in the vagina. The examination may reveal overcorrection or hypersuspension where the angle of the urethra and urethral becomes more vertical than is normal. When severe, this is usually quite obvious, but can be confirmed by a negative (downward) angle on Q-tip test. A ridge at the point of obstruction may be seen or felt as the Q-tip or cystoscope passes through it. Other findings on physical exam can include nonpliable vagina, foreshortened urethra, or periurethral dimpling. While these signs may help solidify the diagnosis, their absence does not rule it out. Conversely, not all obstructed patients will appear to be overcorrected. Goldman reported seeing a negative angle on cotton swab test in most patients that had PVS but not in those with synthetic MUS [39].

Urodynamics

The inclusion of urodynamics (UDS) as a standard component in the workup of postoperative VD is controversial. This partly stems from the lack of a standardized criterion that reliably characterizes obstruction in women with a high level of sensitivity or specificity. However, a number of investigators have attempted to address this, and several definitions have been proposed and are listed in Table 79.2. We feel UDS is helpful and can provide information on the presence of involuntary detrusor contractions, impaired compliance, or the presence of VD, even in cases of obvious urinary retention. UDS can confirm the diagnosis of obstruction with the classic findings of high-pressure, low-flow voiding dynamics (Table 79.2) but should not exclude a patient from surgical intervention, even if contractility is impaired or absent as many women do not generate a significant contraction on UDS but are obstructed nevertheless. Surface pad electromyography may help identify a lack of pelvic floor relaxation during voiding and diagnose VD. For a patient with mainly storage symptoms but normal emptying, UDS may provide a specific diagnosis that can be helpful in directing therapy, especially if obstruction can be ruled out. On the other hand, Aponte et al. demonstrated that UDS did not change outcomes in those whose primary indication for surgery was urinary retention or increased PVR volume and thus reserve UDS for those who present with mainly storage symptoms [40]. Additionally, patients with nondiagnostic UDS or who failed to produce a detrusor contraction have the same outcome as those with classic high-pressure and low-flow voiding [41], which highlights the critical importance of the temporal relationship between surgery and the onset of VD as an indicator of obstruction.

Table 79.2 Carious Female Bladder Outlet Obstruction Criteria

Author	Year	Parameter
Chassagne et al. [42]	1998	Q_{max} of <15 mL/s and p_{det} Q_{max} of >20 cm H_2O
Nitti et al. [43]	1999	Radiographic evidence of an obstruction between the bladder neck and distal urethra in the presence of a sustained detrusor contraction of any magnitude during voiding
Blaivas et al. [44]	2000	Q_{max} of <12 mL/s and p_{det} Q_{max} of >20 cm H_2O
Lemack et al. [45]	2000	Q_{max} of <11 mL/s and p_{det} Q_{max} of >21 cm H_2O
Defrietas et al. [46]	2004	Q_{max} of <10 mL/s and p_{det} Q_{max} of >25 cm H_2O
Gravina et al. [47]	2007	Q_{max} of <15 mL/s and bladder outlet obstruction index ≥−8

Nitti et al. reported on the utility of adding fluoroscopy to UDS to aid in the diagnosis of female bladder outlet obstruction. In this study, patients were classified as obstructed if there was radiographic evidence of obstruction between the bladder neck and distal urethra in the presence of a sustained detrusor contraction of any magnitude. Fluoroscopy helps localize the site of obstruction and allows for the diagnosis of obstruction even in cases where contractility is impaired as long as the site can be localized. Using this definition, the authors were able to demonstrate significant differences between obstructed and unobstructed cases for the parameters of Q_{max}, p_{det} at Q_{max}, and PVR volume [43]. A wide range of values were seen, which makes assigning specific cutoff values to define obstruction restrictive. More recently, Akikwala et al. compared the contemporary definitions of obstruction and how well they correlated with a clinical suspicion of obstruction and found the fluoroscopic definition to have the highest concordance [48].

There does not appear to be any consistent preoperative parameters that predict success or failure of urethrolysis. For example, Foster and McGuire found that patients with detrusor overactivity had a higher rate of failure [49]. Others have reported similar findings [36,40]. Nitti and Raz found that as the PVR volume increased, so did the rate of failure, but others have not confirmed this correlation [41]. Carr and Webster found that the only parameter predictive of success was no prior urethrolysis [37]. McCrery and Appell reported that no urodynamic parameter was predictive of success or failure of urethrolysis [50]. Neither the presence nor the strength of the detrusor contraction preoperatively, nor pressure flow analysis predicted postoperative outcomes [41].

Endoscopy and Imaging

Cystoscopy may show scarring, narrowing, occlusion, kinking, or deviation of the urethra. As discussed prior, a hypersuspensed urethra that is fixed with poor mobility in the sagittal axis due to the pronounced vertical angulation of the urethra against the pubis is highly suggestive of obstruction, but its absence does not rule it out. The urethra and bladder should be carefully inspected for eroded sutures or sling material and the presence of a fistula that could be other sources of their symptoms. Secondary signs of obstruction, such as bladder trabeculations or diverticula may be seen. In cases where intervention is anticipated, endoscopy should be done routinely, either before surgery or at the time of surgery prior to incision.

Radiographic imaging may be done independent of videourodynamics. A standing cystogram in the anteroposterior, oblique, and lateral positions, with and without straining, assesses the degree of bladder and urethral prolapse and displacement or distortion of the bladder. A voiding cystourethrogram can assess the bladder, bladder neck, and urethra during voiding to determine the narrowing, kinking, or deviation. The lack of midurethral dilation and funneling of the bladder neck would be suggestive. While not mandatory, imaging can be useful in equivocal cases.

In summary, the diagnosis of obstruction is made on the basis of clinical presentation and diagnostic evaluation, depending on the circumstances. A temporal relationship between surgery and the onset of symptoms is the most critical factor in diagnosis. Patients with normal emptying before incontinence surgery who have significant retention or obstructive voiding symptoms after incontinence surgery need little in the way of a diagnostic workup.

MANAGEMENT OF IATROGENIC OBSTRUCTION

Conservative Treatment

Treatment of obstruction and its timing are usually dictated by the degree of bother of symptoms. It is important to remember, in the early postoperative period, VD is common and usually transient. After this time period, conservative measures can be tried. A selective α blocker is a safe and low-risk alternative that can provide some symptomatic relief by augmenting relaxation of the bladder neck with resulting improved voiding and urinary storage in some patients [1]. Patients who are emptying well but have significant storage symptoms may be treated initially with behavioral modification or pharmacotherapy. Besides cholinergic blockade, anticholinergic medications may have local anesthetic properties that may lessen irritation from suture or inflammation. In our experience, these measures are not usually successful when obstruction exists, but can be considered before surgery. CIC is a reasonable option in women who are not very bothered by catheterization and who rather not undergo surgery or fear the risk of recurrent SUI.

The role for urethral dilation in cases of postsurgical obstruction is not clear. There are conflicting reports as seen in Table 79.3. There are also concerns about the potentially traumatic nature of dilation, which could induce scarring of the urethra or predispose to mesh erosion [1]. The cutting of suspension or sling sutures above the rectus has been described anecdotally with variable success.

In those patients that void with Valsalva, physical therapy may aid to help them learn how to relax pelvic floor and avoid straining to void, which may be compounding their problem. In patients with learned VD, some authors have suggested the use of diazepam 2–10 mg orally two to three times per day or baclofen 5–10 mg orally twice per day to aid in relieving urethral or pelvic floor spasm in lieu of or in conjunction with physical therapy [58].

When conservative measures fail, definitive surgical therapy may be required.

Table 79.3 Summary of Series on Treatment of Obstruction after Incontinence Surgery

	n	Time to intervention	Resolution of obstruction (%)	Resolution of irritative voiding symptoms (%)	Overall success[a] (%)	Recurrent SUI[b] (%)	Notes
Urethral dilation							
Karram et al. [16]	28	<6 weeks			82

[a] Success is usually defined as cure or significant improvement in presenting symptoms (resumption of normal bladder emptying for patients in retention, and resolution of symptoms for patients with obstructive symptoms or frequency, urgency, or urge incontinence).

[b] Recurrent SUI is defined as percentage of patients without SUI before urethrolysis who experienced SUI after urethrolysis.

Surgical Intervention

There are numerous ways to free up the obstructed urethra, which vary based on many factors including the type and number of anti-incontinence surgery, prior attempts at urethrolysis, and surgeon and patient preferences. Success rates for various procedures range from 25% to 100% dependent on whether success is defined as the return to normal voiding or resolution of all symptoms (Table 79.3) and appear to be independent of the particular procedure chosen, though no randomized head-to-head surgical trial has ever been performed. The specific risks of surgery, including bladder or urethral injury, persistence of storage symptoms, recurrent SUI, and persistence of obstruction, need to be outlined, and each patient should carefully weigh these risks against the success rates of intervention. In this section, we will describe surgical techniques for the treatment of iatrogenic obstruction in order of invasiveness.

Midurethral Sling Loosening

In women with postoperative urinary retention after PVS, intervention is reserved after a waiting period of at least 3 months since there is a very high likelihood of VD resolution [30]. In contrast, the vast majority of patients are able to empty fairly normally within 72 hours after MUS, but for those who are remain in retention, early intervention prior to tissue ingrowth is recommended. This allows one to perform a minimally invasive procedure, under local anesthesia in an office setting [59] or in the operating room, if greater adjustment is needed or due to patient intolerance. The anterior vaginal wall is infiltrated with local anesthetic and the prior vaginal incision is opened. The MUS is usually easily visualized. The sling is hooked with a right-angle clamp (or a similar instrument). Spreading of the right-angle clamp or downward traction on the sling will usually loosen it (1–2 cm) [31]. This is usually possible if intervention is done by 10 days. The incision is suture closed, and the patient is allowed to attempt to void. The longer one waits, the more scarring occurs and anesthesia and a wider exposure may be necessary.

Transvaginal Sling Incision

The transvaginal incision of a sling has similar results compared with urethrolysis but with decreased morbidity (Table 79.3). Cystoscopy is performed firstly to assess the urethra and rule out erosion or urethral injury, followed by an inverted U or midline incision to expose the area of the bladder neck and proximal urethra [60]. As the vaginal flap is dissected off, the sling should be identified above the periurethral fascia. The sling may be encased in scar tissue and thus require careful dissection to identify the sling. If the sling has significant tension on it, it may be especially difficult to identify. Insertion of a cystoscope or sound into the urethra with gentle upward torque improves visualization of the bladder neck and places tension on the sling, allowing for its identification. Once the sling is isolated, it should be separated from the underlying periurethral fascia with sharp or blunt dissection. The dissection may be facilitated by grasping the sling with an Allis clamp on either side of the midline and exerting downward pressure. Care should be taken to avoid injury to the bladder and urethra by beginning the dissection distally, identifying normal urethra then proceeding more proximally until the plane between the sling and urethra is identified. A right-angle clamp can be placed between the urethra and periurethral fascia and the sling. The sling is lifted and cut in the midline (Figure 79.1a). Alternatively, if scarring is dense and the plane between the sling and periurethral fascia cannot be developed easily, the sling can be isolated lateral to the midline, off of the urethra. For practitioners who do not routinely perform this procedure, this lateral approach followed by lateral incision provides a margin of safety in minimizing inadvertent urethral injury. The edges of the sling are then mobilized off the periurethral fascia to, but not through, the endopelvic fascia (Figure 79.1b). Lateral support is preserved because the retropubic space is not entered, and the urethra is not freed from the undersurface of the pubic bone. Typically, synthetic material is excised and autografts/allografts are left in place. Cystourethroscopy should be carried out to rule out urethral or bladder injury. In cases of autologous or biological materials, if the sling cannot be clearly identified, then formal transvaginal urethrolysis (see in the following text) should be performed.

MUS can be isolated and incised in a similar manner. Unlike autologous and biological slings, it is imperative to identify the sling and cut it. Conversion to urethrolysis without specifically cutting the sling may fail to relieve obstruction. Usually, the sling is easily found, and identification can be aided by palpation of the sling. However, sometimes this can be quite difficult, especially in cases where the sling has migrated proximally or has rolled onto itself and created a tight narrow band. In many cases, after the MUS is cut, it retracts away from the urethra. The cut ends can be grasped with clamps and dissection proceeds hugging the sling to minimize injury to underlying tissue. The extent of excision largely depends on the primary indication for MUS removal with some suggesting dissecting to the level of the endopelvic fascia and excising the sling ends [60] while others do not [61]. If sling incision is not successful in relieving obstruction, formal urethrolysis may be carried out.

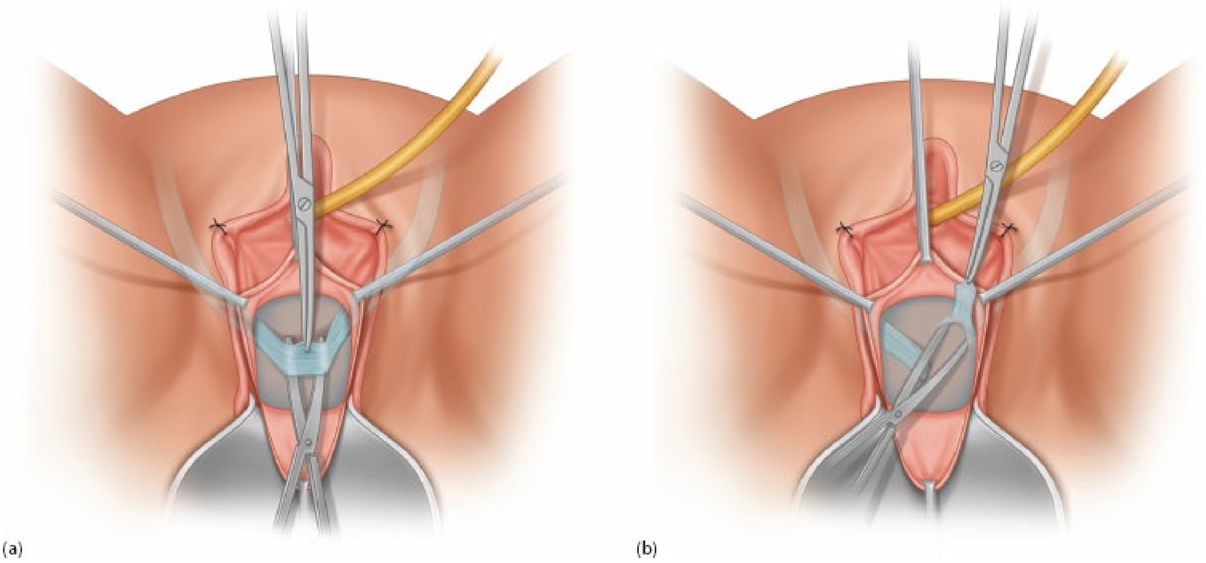

Figure 79.1 (a) After an inverted U or midline incision, the sling is isolated in the midline and incised. A right-angle clamp may be placed between the sling and the periurethral fascia to avoid injury to the urethra. (b) The sling is freed from the undersurface of the urethra toward the endopelvic fascia. Ends may be excised or left in situ. Urethrolysis

The ultimate goal of urethrolysis is to restore mobility and can be accomplished through a retropubic or a transvaginal approach. The approach chosen depends on several factors that include patient presentation, type of initial anti-incontinence surgery, history of prior urethrolysis, and surgeon and patient preference. In general, proceeding from the less morbid transvaginal approach and reserving the retropubic approach for failures is prudent. However, exceptions exist that would favor a retropubic approach as the primary initial procedure such as inadequate vaginal access precluding a transvaginal approach, in cases where the original anti-incontinence surgery was performed transabdominally or associated with bladder perforation, fistula, or other operative complication, after a Burch resuspension, or associated with intravesical mesh exposure, which must be removed. Indeed, Anger et al. did report a higher rate of success with retropubic urethrolysis compared to transvaginal approach for the treatment of obstruction after Burch procedures [62]. This was felt secondary to the inability to reach proximal most sutures transvaginally.

Transvaginal Urethrolysis

In 1984, Leach and Raz described the transvaginal technique of urethrolysis, and though variations have been published since, it is still the most commonly used today [63]. A midline or inverted U incision approximately 3 cm long is made in the anterior vaginal wall extending from the level of the midurethra to 1–2 cm proximal to the bladder neck. Dissection proceeds laterally along the glistening surface of the periurethral fascia to the pubic bone. The retropubic space is entered sharply by perforating the attachment of the endopelvic fascia to the obturator fascia (Figure 79.2a). The urethra is dissected bluntly and sharply off the undersurface of the pubic bone and completely freed proximally to the bladder neck. Some separation of the urethra from the pubis is done blindly with the Metzenbaum scissors (Figure 79.2b). Care should be taken to stay as close to the underside of the pubis as possible, and manual palpation of this plane along with an awareness of the location of the urethral catheter provides a proprioceptive map in this hard-to-visualize space. If an inadvertent injury to the urethra or anterior bladder wall near the bladder neck is caused, primary repair should be attempted and completion of the procedure should be entertained as further bladder or urethral wall damage can occur.

A Foley catheter is left for 2–3 weeks. Fistula formation is minor as the area of perforation is well away from the vaginal incision. Once sufficient space is developed in this plane, the remaining adhesions and scar can be swept down bluntly with an index finger. If suspension sutures are felt, a clamp can be used to bring it into view so it can be cut safely. After this initial mobilization, a right-angle clamp can be placed between the pubic bone and the urethra, and a Penrose drain is placed around the urethra. Downward traction is applied on the Penrose drain to aid visualization and all remaining retropubic attachments are dissected free (Figure 79.3). At this point, the urethra should be freely mobile in all planes, and this can be tested with movement of an intraurethral sound or cystoscope. Cystoscopy should be performed to rule out urethral and/or bladder injury prior to vaginal closure. If injury is noted, a catheter is left in place. If all is intact, the catheter can be removed at the end of the procedure. It is also good practice to assess ureteral integrity by giving intravenous indigo carmine or methylene blue to assure efflux.

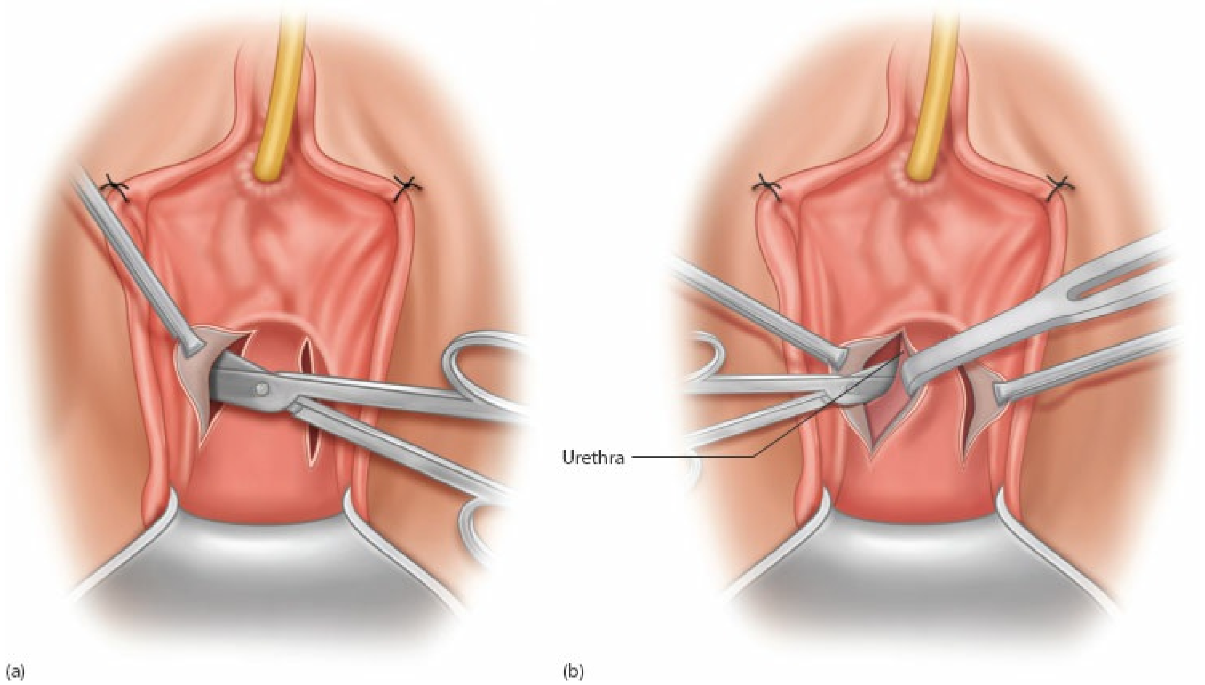

Figure 79.2 Transvaginal urethrolysis. (a) An inverted U incision in the anterior vaginal wall and entrance into the retropubic space. (b) The urethra is sharply dissected off the undersurface of the pubic bone. The endopelvic fascia, periurethral fascia, and vaginal wall are retracted medially to expose the urethra in the retropubic space. (Reproduced from Nitti VW and Raz S, *J Urol*, 152, 93, 1994. With permission.)

If it is difficult to incise the scar tissue or if urethral mobility is still limited, a suprameatal technique has been described, either as part of the traditional transvaginal approach or by itself. In their description, Petrou et al. make an inverted U incision with the apex of the U at the 12 o’clock position and about 1 cm above the urethral meatus. Allis clamps are used to retract both edges of the incision. With tension on the upper edge, the perineal membrane is perforated and all attachments, scar, and sutures between the pubic bone and urethra are incised sharply with scissors. An index finger can be followed along the underside of the pubis into the retropubic space. With a sweeping motion directed laterally and posteriorly, obstructing bands can be identified and either bluntly or sharply freed. The arms of the sling or suspending sutures are encountered with lateral dissection and should be divided sharply. Once done, urethral mobility is assessed and if adequate, cystoscopy is performed to rule out inadvertent injury prior to vaginal incision closure [64]. Because lateral dissection is limited, potential advantages of this approach include preservation of the lateral endopelvic fascia and urethropelvic ligament, which allows for continued urethral support, thus theoretically decreasing the risk of recurrent SUI. Clitoral denervation is a potential complication limiting its wider application.

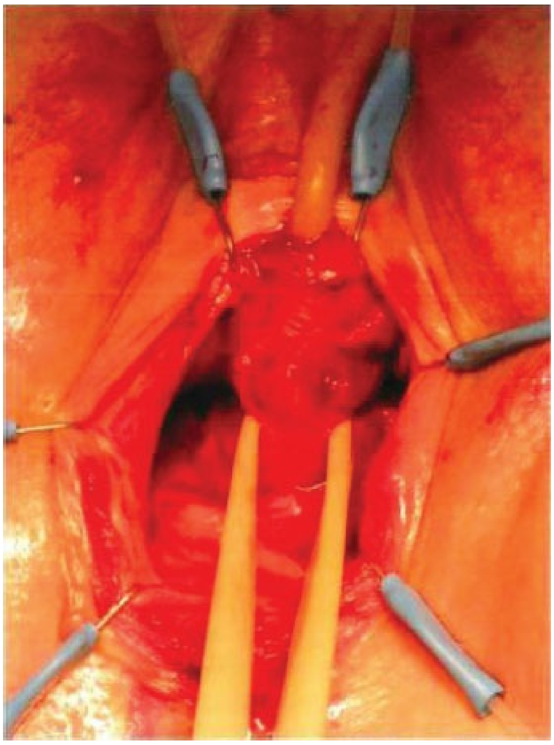

Figure 79.3 Intraoperative photo after completed urethrolysis. A Penrose drain has been placed around the urethra, isolating it from the pubic bone.

In cases of extensive urethrolysis or coexistence of SUI with obstruction, resupporting the urethra at the time of urethrolysis has been introduced, though this remains controversial. In many of the original descriptions of urethrolysis, patients underwent resuspension irrespective of the presence of preoperative SUI. Resuspension poses the risk of persistent obstruction and if symptoms do not resolve, it is difficult to determine whether this situation resulted from inadequate urethrolysis or resulted from the secondary resuspension. Additionally, outcome studies have demonstrated a similar risk of recurrent SUI [2]. There is also evidence that patients can be salvaged with transurethral collagen injections should SUI recurs [65]. As a result, it is our practice to attend to the presenting complaint of obstruction and address recurrent SUI at a later date should it occur.

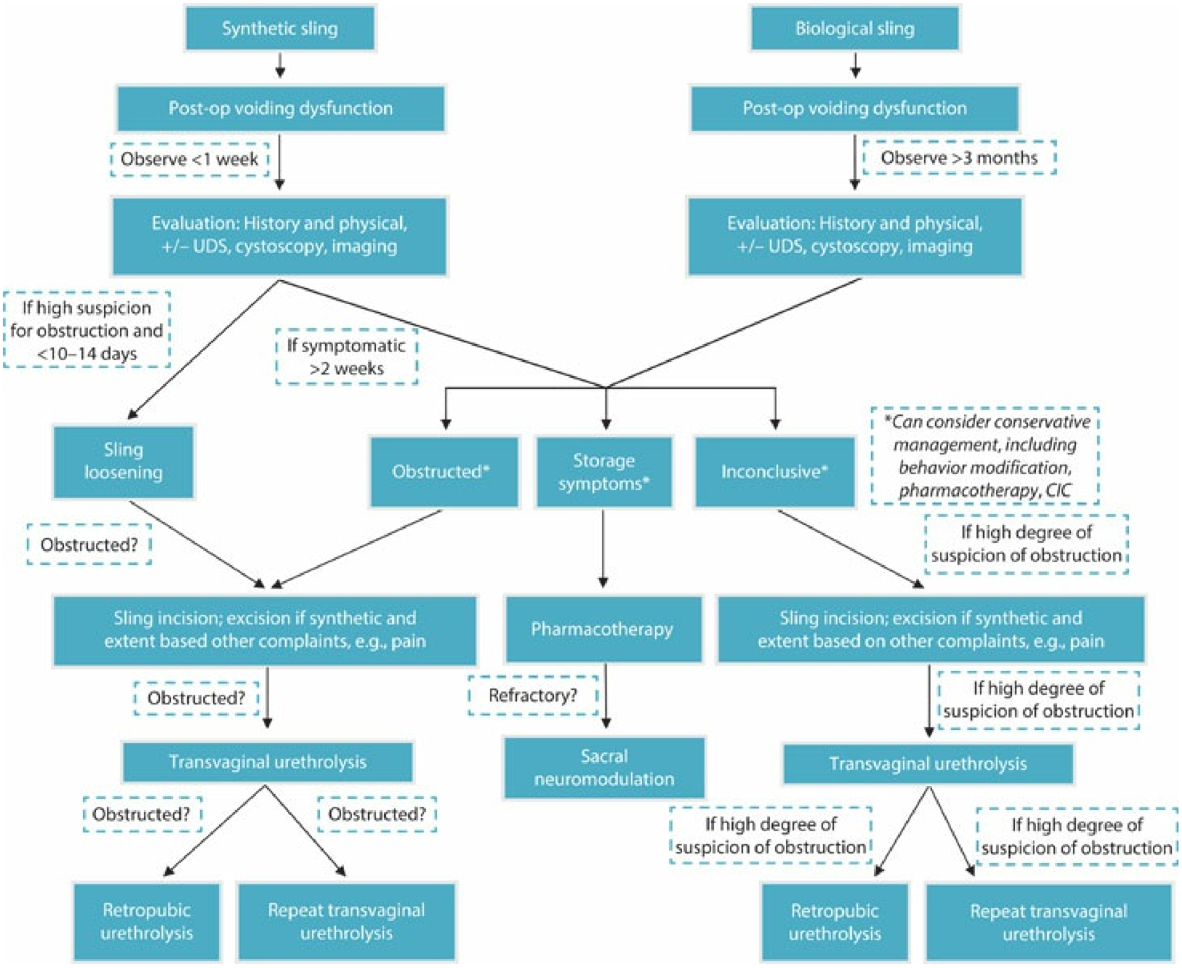
Retropubic Urethrolysis

The patient is placed supine on the operating table with the legs slightly spread apart to allow for manual vaginal access. Either a Pfannenstiel or low midline incision is made. The rectus fascia and muscle are opened in the midline to the level of the pubic symphysis. The retropubic space is developed and exposed. Any visible and palpable suspension sutures are cut and all attachments and scar between the urethra and pubis are incised sharply. Complications can be minimized by keeping the tips of the scissors up against the pubic symphysis during sharp dissection. Careful attention is paid to the location of the Foley catheter to avoid inadvertent bladder or urethral injury. If bladder injury occurs, prior to repairing it, it may be helpful to leave the bladder open until the dissection is complete to give a constant sense of where the bladder is, with respect to the scar tissue. The index finger of the surgeon’s nondominant hand placed into the vagina helps identify the boundaries of the vagina in relation to the urethra and urethrovesical junction. At the end of the dissection, the urethra, bladder neck, and anterior vaginal wall should be mobile and free from the overlying pubic bone. It should be possible to pass fingers through the abdominal wound, under the pubis, and see your fingers pushing the vaginal skin out in the distal vagina.

In cases of severe scarring, it may be necessary to mobilize laterally as far as the ischial tuberosities, creating a paravaginal defect. This defect should be repaired by reapproximating the paravaginal fascia to the fascia of the obturator internus along the arcus tendineus. The paravaginal repair sutures are left untied. An omental flap can be brought down and fixed between the pubis and urethra so that recurrent scarring is minimized [37]. The paravaginal repair sutures are then tied and the abdomen is closed. Cystoscopy is performed to rule out urethral injury and confirm efflux of indigo carmine from the ureteral orifices.

Failed Urethrolysis

Failure of urethrolysis may be due to persistent or recurrent obstruction, inadequate initial lysis, detrusor overactivity, impaired detrusor contractility, or learned VD. Recurrent obstruction may result from periurethral fibrosis and scarring, or intrinsic damage to the urethra that has occurred as a consequence of the urethrolysis surgery. When obstruction persists, it is reasonable to attempt a repeat urethrolysis. Scarpero et al. reported on the efficacy of repeat urethrolysis in 24 women who failed initial urethrolysis and remained in urinary retention. Both transvaginal and retropubic approaches were chosen depending on the clinical situation. Obstruction was cured in 96%, but storage symptoms completely resolved in only 12% and were improved and required medication in 69%. SUI recurred in 18% [66]. In another series, repeat urethrolysis resulted in cure of obstructive symptoms in 72% and storage symptoms in 59% [50]. These data clearly support aggressive repeat urethrolysis in the face of initial failure, at least for retention and incomplete emptying. In general, if an aggressive transvaginal urethrolysis fails, then a retropubic approach may be considered. In cases where the aggressiveness of the initial transvaginal procedure is unknown, or if only a sling incision was performed, then a repeat transvaginal approach may be appropriate. Consideration should also be given to the use of a Martius labial fat pad flap as an interposition layer to decrease recurrent fibrosis and provide some urethral support. The flap is divided midway along its longitudinal axis to allow for circumferential coverage of the urethra, effectively supporting the undersurface and retropubic surface of the urethra [67].



Synthetic sling
Biological sling
Post-op voiding dysfunction
Post-op voiding dysfunction
Observe <1 week
Observe >3 months
Evaluation: History and physical, +/– UDS, cystoscopy, imaging

Figure 79.4 Treatment algorithm.

Residual and refractory storage symptoms after urethrolysis may be treated with sacral neuromodulation after obstruction has been ruled out, and the treating physician feels that the likelihood of residual/recurrent obstruction is low. Starkman et al. found a >50% reduction in symptoms in 75% of patients they treated with this modality. In the 75% of patients that responded, 100% were able to stop all antimuscarinics [68]. However, if there is any concern for residual obstruction or inadequate initial urethrolysis, then a repeat urethrolysis should be considered. The treatment algorithm flowchart summarizes the diagnosis and treatment approach (Figure 79.4).

CONCLUSION

It is indeed a challenging prospect to treat the patient with significant irritative and obstructive features after performing an operation for incontinence. While keeping in mind the patient’s symptoms and goals, the physician must use careful decision making when assessing, diagnosing, and treating obstruction. Fortunately, the various urethrolysis techniques are highly successful for restoring efficient voiding. Though progress has been made, improved methods of identifying those at risk for obstruction, diagnosing obstruction, and treating troublesome irritative voiding symptoms are warranted.

80 Complications of Stress Urinary Incontinence Surgery

Véronique Phé and Emmanuel Chartier-Kastler

INTRODUCTION

According to the International Continence Society, stress urinary incontinence (SUI) is defined as “the complaint of involuntary leakage on effort or exertion, or on sneezing or coughing” [1]. SUI is responsible for major disability in many women. The prevalence of SUI is difficult to estimate, but possibly as high as 50% [2] depending on the definition of urinary incontinence adopted and the age group studied. This prevalence is probably underestimated. According to the 2012 update of the International Consultation on Incontinence guidelines, the surgical treatments of SUI may include the use of pubovaginal slings, suburethral slings, colposuspension, and artificial urinary sphincters. Recently, adjustable continence therapy (ACT®) balloons have been introduced as a minimally invasive option. The guidelines do not define a clear priority among these options. However, various efforts have been made to reduce the morbidity associated with these procedures.

SUI surgery is a functional surgery, which requires a careful patient selection and evaluation to improve surgical outcomes and decrease failure and complications rate. Before undergoing an SUI surgery, the risk of potential complications should be carefully assessed and addressed with the patients. Complications may occur during and after the procedure, and it is essential to identify high-risk patients and minimize risk from surgery before the procedure. Thus, it is necessary to inform and counsel the patients concerning the operative risks commonly attributed to general anesthesia including intubation, myocardial infarction, cerebrovascular accident, and deep vein thrombosis. As may be anticipated, mortality increases with advancing age and the presence of medical comorbidities.

Increased awareness regarding the numerous management options for SUI has produced heightened interest in determining standards for outcomes measures, including the reporting of surgical complications [1,3,4]. Recent attention to the potential complications of mesh implantation from the Food and Drug Administration has certainly heightened awareness in the urologic community to reporting of complications (http://www.fda.gov/cdrh/safety/102008-surgicalmesh.html).

This chapter will focus on the complications of the surgical modalities used for SUI, namely, not only midsuburethral sling procedures, colposuspension, and pubovaginal slings but also artificial urinary sphincter, ACT, and periurethral injections.

COMPLICATIONS OF MIDSUBURETHRAL SLINGS

Due to minimal invasiveness, retropubic tension-free vaginal tape (TVT) is widely used in the treatment of SUI associated with urethral hypermobility, with a high success and low complication rates since it has been described by Petros and Ulmsten [5]. This procedure has been recently challenged by transobturator tapes (TOT) and mini-slings (regardless if they are retropubic or transobturator) [10–12]. Long-term data about midsuburethral slings are only now becoming available. Comparison between transobturator slings (TVT-O or TOT) show equal effectiveness with slightly lower cure rates than TVT [12]. Recent randomized controlled studies and meta-analysis studies did not support routine use of mini-slings in clinical practice [10,11].

The significant reported complications of midsuburethral sling procedures include bladder and urethral injuries, bleeding, de novo urgency, voiding dysfunction, bladder and urethral erosion, vaginal extrusion, urinary tract infections, pain, and dyspareunia. There is some difficulty in summarizing the published complications of midsuburethral slings data due to the lack of standardization of definitions and differences in reporting methods between studies. The reported complication rates ranged from 4.3% to 75.1% for TVT and 10.5% to 31.3% for TOT [4]. The incidence of complications varies with operative experience, procedure, and center reporting, and there is a learning curve that requires further delineation [6].

Intraoperative Complications

Bladder and Urethral Injuries

Bladder perforation during needle passage of TVT is not uncommon, with reported rates of 0.7%–24% [7,8]. Previous anti-incontinence surgery and surgeon experience were reported as potential risk factors for perforation [9]. In an update meta-analysis, the risk of bladder perforation during TOT approach is lower than TVT procedure [10]. The outside-in techniques seem to be more risky than the inside-out technique although the difference is not statistically significant [11].

In case of bladder perforation when recognized intraoperatively, repositioning the tape is mandatory and without any short- or long-term consequence. Most of the authors recommend a 2- or 3-day bladder catheterization with a Foley catheter [12]. But the benefit of an extended bladder catheterization in case of bladder perforation has not been demonstrated as opposed to a 24-hour bladder drainage. Failure to recognize intravesical needle passage of sling can lead to hematuria, irritative bladder symptoms, pelvic and urethral pain, fistulas, recurrent urinary tract infections, and a return to the operating room. Given the ease, speed and availability of cystoscopy, and the potential for serious complications if perforation is overlooked, cystoscopy could be recommended in all midsuburethral sling procedures [13]. Technique (use of a 70° lense) and training to it is of major interest in the case of TVT practice.

Urethral injuries are uncommon during midsuburethral sling procedures [14]. If urethral injury is noted at midsuburethral sling placement, the procedure should be aborted and the urethra closed with multiple layers.

Vaginal Perforation

Vaginal perforation has been reported to be less frequent in a TVT procedure (0%–1.5%) than in TOT (0%–10.9%) [4,13]. This complication occurs significantly more often in outside-in procedure than in inside-out procedure [15]. This complication is likely due to an insufficient vaginal dissection for outside-in TOT procedure and to a wrong needle trajectory in inside-out TOT procedure. In case of perforation, the vagina has to be closed immediately and the sling can be placed.

Finally, two types of vaginal perforation may be described:

- Laterally in the culs-de-sac during a TOT procedure
- Medially as a mid- to long-term complication at the incision level (TOT and TVT)

This last condition may be more described as a vaginal extrusion than a vaginal perforation (see the “Vaginal Extrusion” section).

Hemorrhage

The occurrence of hemorrhage ranges from 0.7% to 8% [3,7] without any statistical difference between TVT and TOT [13]. Intraoperative bleeding from the vaginal dissection can usually be controlled with direct pressure on the paraurethral and retropubic areas and then followed by vaginal packing. Greatly increased bleeding that results in a retropubic hematoma usually arises from a blinded venous injury during needle passage, and up to 2.8% may require transfusion [16]. Vascular injuries involving large arteries such as the external iliac, femoral, obturator, epigastric, and inferior vesical have been reported and have been responsible for at least one mortality [17]. Accordingly, arterial injuries must be managed immediately by laparotomy or angioembolization. Arterial perforation during TVT procedure may be avoided by a good patient’s installation (legs down) and a retropubic introduction of the ancillary, always close to the midline and parallel to it, avoiding any lateral movement.

Bowel Perforation

The literature reported few bowel perforations during TVT procedure (less than 1%) [16]. To our knowledge, there are no published cases of bowel perforation with TOT techniques. A review of the Food and Drug Administration Manufacturer and User Facility Device Experience database revealed seven deaths that occurred after TVT placement as of 2004, of which six were associated with bowel injury [17]. Patients with a history of abdominal or pelvic surgery are at a greater risk for bowel injury because of adhesions in the retropubic space and pubic symphysis.

Postoperative Complications

Vaginal Extrusion

Reported rates of vaginal extrusion ranged from 0% to 1.6% [18,19]. A meta-analysis of polypropylene midsuburethral slings revealed a possible trend toward increased extrusion after the transobturator approach (OR 1.5, 95% CI 0.51–4.4) [20]. Several reasons may account for this finding including atrophic, scarred, or compromised vaginal mucosa. Potential risk factors for extrusion related to surgery include inadequate closure of vaginal tissue, infection, mesh rejection, and unrecognized vaginal injury during needle passage. Patients with vaginal extrusion may present with vaginal discharge, vaginal pain, dyspareunia, or sling palpable. However, patients may also be asymptomatic [21]. Most cases occur in the first few months after surgery but they can also occur later. In the case of small vaginal extrusion, spontaneous healing can be expected in 6–12 weeks [22]. If conservative management fails or the erosion is greater than 1 cm (Figure 80.1), the sling may be excised with vaginal closure.

Bladder Erosion

Bladder erosion occurs 4–11 months after surgery and can lead to recurrent urinary tract infections, overactive bladder symptoms, pelvic pain, and hematuria [14,21]. Then a cystoscopy should be performed. The resection of the sling by cystoscopy is not recommended [14,21,23]. A resection of the sling combining an abdominal and a vaginal approach is generally performed [14,24] (Figure 80.2).

Prevention of this complication may be done with a good training to the technique, checking during cystoscopy that the ancillary has not been inserted inside the detrusor muscle (moving it, the detrusor must not move with). In case of any doubt, the surgery must be repeated after removal of the ancillary and/or mesh.

Urethral Erosion and Injury

Urethral erosions are rare (0.3%). They may be caused by a poor surgical technique that could damage the integrity of the urethral tissue, excessive tension placed on the sling or local infection. Poorly estrogenized tissue, previous vaginal surgery, or a history of pelvic radiation may also contribute. Postoperative symptoms of erosion include overactive bladder symptoms, urethral or pelvic pain, recurrent urinary tract infections, urinary retention, and hematuria. Management of these symptoms includes complete excision of the eroded part of the synthetic sling and urethroplasty.

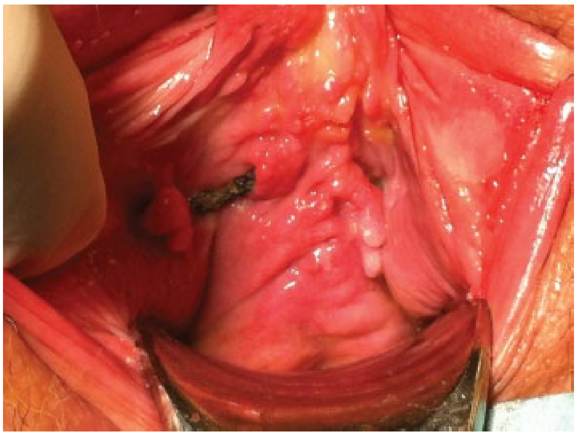

Figure 80.1 Vaginal extrusion caused by a midsuburethral tape.

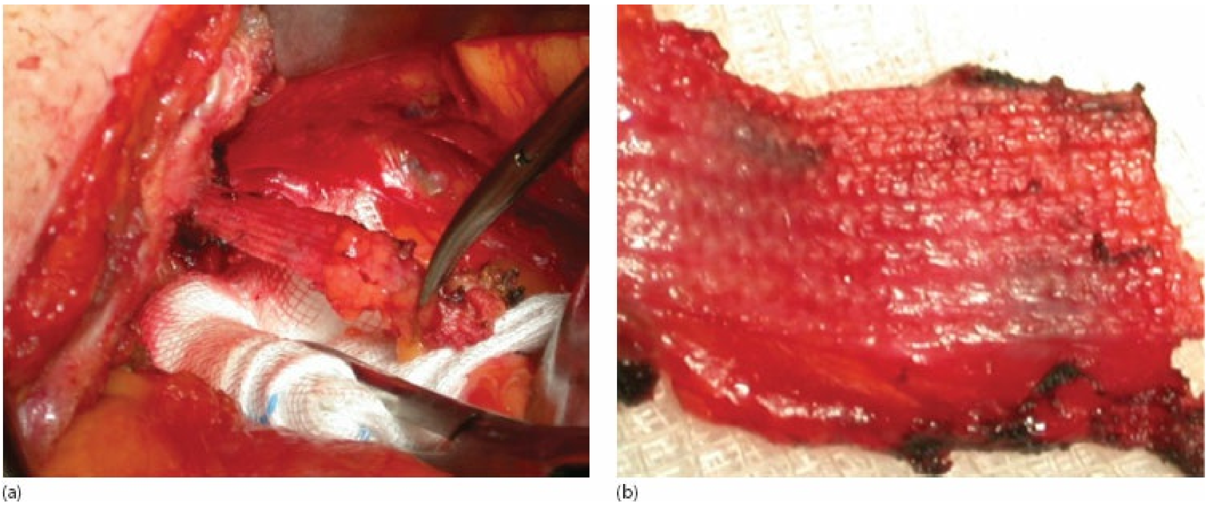

Figure 80.2 (a, b) Resection of tension-free vaginal tape by an abdominal approach.

De Novo Urgency

The onset of de novo urgency and its possible treatment is one of the most clinically relevant and largely debatable postoperative complications of midsuburethral slings. Previous studies reported de novo urgency rates ranging from 4% to 33% after TVT [12,19]. Discrepancies can be related to the different definitions and questionnaires used to collect overactive bladder symptoms, different demographic characteristics of the women included, and different concomitant surgical procedures associated with TVT. Furthermore, the prevalence of urgency symptoms is known to increase with age. This phenomenon is thought to result from a combination of mild obstruction and urethral irritation caused by the sling. Bladder irritability caused by undiagnosed pelvic hematoma has been proposed as well. Elevation of the bladder neck may also be a contributing factor and has been demonstrated on transperitoneal ultrasound after TVT [25]. There is no significant difference in de novo urgency between TVT and TOT [10]. After excluding reversible causes such as extrusion and obstruction, anticholinergic medications are the mainstay of current therapeutic interventions. In the case of urgency refractory to medical therapy and in the absence of any clinically significant obstruction, alternative therapy such as sacral neuromodulation and botulinum toxin A injections may be considered.

Voiding Dysfunction

TVT may lead to bladder outlet obstruction [20]. Consequently, patients can complain of a slow or intermittent urine stream with a significant post-voiding residual volume and recurrent lower urinary tract infections. The reported rates of postoperative obstruction range from 1.9% to 19.7% [9,26]. Postoperative maximum stream flow is significantly decreased [27]. There are no significant differences in postoperative urinary retention between retropubic and transobturator approaches [10]. Moreover, urinary tract infections in case of chronic obstruction can increase from 8% during the first year after surgery to 44% during the fifth year [28]. In a patient with immediate postoperative retention or incomplete bladder emptying, indwelling or intermittent self-catheterization should be tried because resolution is commonly spontaneous [18]. If improvement is not seen within 4 weeks, early sling lysis should be considered. Studies revealed that this was required in 0.1%–7% of cases [26,29]. Some authors recommended total resection of the TVT as first-line treatment by an abdominal approach in order to obtain more satisfying results [30].

Urinary Tract Infections

Urinary tract infection is less commonly reported than some other postoperative complications. Moreover, the definition of urinary tract infections and how it is diagnosed is often not clear. In comparative prospective studies, urinary tract infections were reported in 7.4%–13% of women undergoing TVT or TOT procedures, without any statistically significant differences [7,26]. In the case of recurrent urinary tract infections, voiding dysfunction and urethral or bladder erosions should be investigated.

Groin and Thigh Pain

A meta-analysis revealed that groin and thigh pain was more common in patients who underwent a transobturator (inside-out) approach (OR 8.8, 95% CI 2.6–29.5) [20]. A randomized controlled study revealed that 16% of women in the transobturator (inside-out) arm had groin pain compared to 1.5% of those in the TVT arm, which led to an increased need for analgesia in the transobturator group [7]. Both of these findings were statistically and clinically significant. Groin pain after TVT-O tended to persist longer than that after TVT. The etiology of this pain is not yet clear but may be of neurological origin. Injuries to nerves such as the obturator have been reported but are rare (less than 1%) [26,31,32]. In the case of persistent pain, some authors recommended resection of the sling [33].

Dyspareunia

Postoperative dyspareunia has not routinely been prospective reported. In a prospective observational study of 300 women who underwent a TVT-O procedure, 1.3% reported new onset dyspareunia [34]. The authors attributed this finding to posterior migration of the tape, which could be palpated close to the anterior vaginal fornix. Then all women were treated successfully by cutting the tape in the midline. Further prospective studies should be conducted to address this end point because many women with SUI are sexually active.

COMPLICATIONS OF COLPOSUSPENSION

Open abdominal retropubic procedures for urinary incontinence were widely performed till the turn of the century when the use of synthetic midsuburethral slings gained in popularity. In Novara's meta-analysis, midsuburethral slings were followed by significantly higher cure rates than Burch colposuspension, considering success rates evaluated according to any definition of continence. With regard to complication rates, bladder perforation was significantly more common after midsuburethral slings, whereas the risk of pelvic hematoma, urinary tract infections, storage lower urinary tract symptoms, voiding lower urinary tract symptoms, and reoperation were similar between the two surgical treatments. A randomized controlled study on 344 patients with SUI who were randomized to TVT or Burch colposuspension [35] reported, at a 24-month follow-up, that TVT was followed by higher rates of intraoperative complications (mainly bladder and vaginal perforations), whereas operation times, blood loss, analgesic requirements, postoperative complications, and catheterization were greater in the colposuspension group. Reoperation rates for urinary incontinence were similar in both arms (1.8% after TVT vs. 3.4% after colposuspension, $p = 0.48$), but surgical procedures for pelvic organ prolapse were more common after colposuspension (0% vs. 4.8%, $p = 0.0042$).

COMPLICATIONS OF PUBOVAGINAL SLINGS

The pubovaginal sling is an efficient procedure in the long run. Indeed, the 10-year range of success rates of this surgery has been reported to be between 55% and 70% [36]. However, the technique is invasive and followed by significant risks of de novo storage symptoms (3%–23%) and voiding dysfunction (up to 11% with 1.5%–7.8% long-term self-catheterization) [36]. Although currently considered the gold standard for transvaginal sling procedures, recent studies have revealed some of these materials may encapsulate rather than integrate [37,38]. In a comparative analysis (Stress Incontinence Surgical Treatment Efficacy Trial [SISTEr]), 655 women with SUI were randomized to undergo either Burch colposuspension or autologous fascia pubovaginal sling with success defined as no self-reported SUI, a negative stress test, and lack of retreatment [38]. Although the pubovaginal sling group performed significantly better than the Burch colposuspension (66% vs. 49% success), the pubovaginal sling group experienced a substantially increased number of postoperative issues including urinary tract infections, voiding dysfunction, urge incontinence, and a need for surgical revision.

Randomized controlled trials comparing midsuburethral tapes and pubovaginal slings had similar efficacy in terms of both overall and subjective continence rate [10]. With regard to complication, the risk of intraoperative bladder perforation were significantly lower in the pubovaginal sling group; pelvic hematoma was similar in the two procedures. However, midsuburethral tapes were followed by a significantly lower risk of storage symptoms and reoperation. The prevalence of voiding dysfunction was similar in the two procedures.

COMPLICATIONS OF ARTIFICIAL URINARY SPHINCTER (AMS 800®, AMERICAN MEDICAL SYSTEM, MINNEAPOLIS, UNITED STATES)

Artificial urinary sphincter is the treatment of female severe SUI with intrinsic sphincter deficiency, most often after failure of other surgical treatments and as a “last treatment.” This surgery is only performed by experienced and trained teams [39,40] due to the technical difficulties related to the short female urethra or a history of local surgery responsible for the morbidity of this operation [41].

Intraoperative Complications

In case of bladder injury, localizing precisely the injuries by opening the bladder dome allows to repair and does not prevent from implanting the device if correctly repaired [40,42]. It is of trained center expert opinion that any injury at the level of the bladder neck or posterior urethral portion indicates not to implant the device. Any bladder injury far away from the bladder neck, either involuntary or voluntary done as an eye control of dissection, do not contraindicate implantation of the cuff.

Vaginal injury is rare and leads to stop the procedure when it is located posteriorly to the bladder neck and/or urethra, in front of cuff placement. Any vaginal injury (lateral on cul-de-sac) may not stop the surgery and must be carefully repaired. The cuff may be inserted except in any other intraoperative complication.

Postoperative Period

Postoperative acute urinary retention can occur and leads to a new indwelling catheter insertion for at least 48 hours [40]. Usually, it is of interest to let a catheter until day 5 or 6 to decrease recatheterization rate. The overall early postoperative morbidity is 6% [43].

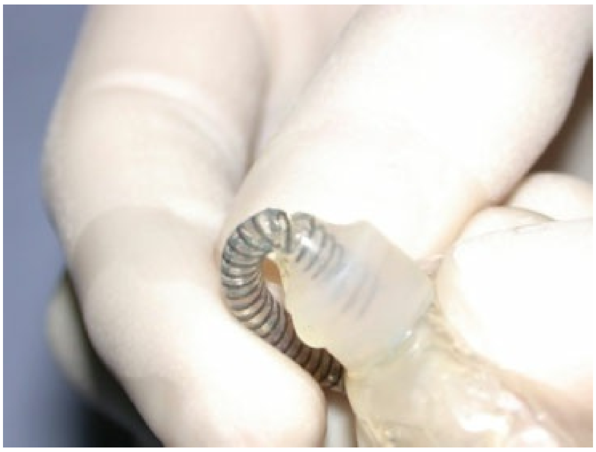

Figure 80.3 Artificial urinary sphincter tube perforation.

The main long-term complications of an artificial urinary sphincter is explantation of the device in 3%–50% of cases due to infection and/or erosion [43–45] and the need for revision of the device in 13%–63% of cases [43].

The major reported risk factors for explantation are aging, previous anti-incontinence procedures, a delay between the previous procedure and sphincter implantation, perioperative complications, and pelvic irradiation [43,46–48].

Few studies have focused on the survival of the device [39,40,49–51]. The revision rates after 5 years reported in the literature range from 13% to 63%. Most of revisions were due to the mechanical failure of the pump, balloon, cuff, or connections (Figure 80.3). Discrepancies between series may also be related to the medical histories of irradiation among the women [44], the number of previous anti-incontinence procedures before the insertion of the artificial urinary sphincter [39], or learning curves and the surgeon’s experience. The artificial urinary sphincter is supposed to have an average life span of 10 years. After 15 years, the survival rates are significantly lower [40]. According to the American and European Guidelines, the exact indication and the optimum timing for artificial urinary sphincter implantation in women are not clear [52,53]. A group of experts attempted to clarify and optimize indication and technique [41].

COMPLICATIONS OF ADJUSTABLE CONTINENCE THERAPY BALLOONS

The balloons named ACT (Uromedica, United States) are a recent treatment modality of female UI and are indicated in a specific population of patients: difficult situations of primary or secondary failure of treatment for urethral hypermobility by midsuburethral sling or patients unsuitable for artificial urinary sphincter placement (e.g., women over the age of 80 with cognitive impairments and motor disabilities) [54]. But the place of this therapy in the decision tree for female urinary incontinence management has not been clearly defined at this moment in international guidelines [52]. The main reason is related to the paucity of long-term prospective data.

Only eight studies were published between 2007 and 2013, evaluating the efficacy and complications of treatment for female UI by ACT balloon [55–61]. During the procedures, no major complications were reported. Most intraoperative complications are urethral or bladder perforations, observed in 3%–17% of cases. It is worth noting that the 17% perforation rate was reported in the study by Chartier-Kastler published in 2007 [55], which was the first nationwide, multicentered, prospective, controlled study evaluating treatment for female SUI by ACT balloon and therefore corresponded to the early experience with this type of management in France. The most recent studies have reported intraoperative perforation rates between 3.7% and 4.5%. Perforation does not necessarily lead to cancel the procedure.

Postoperative complications, during the first year, includes urethral erosion (2%–15%), cutaneous erosion of the port (3%–7.5%), balloon migration (6.5%–17.5%), device infection (0.6%–8.9%), balloon dysfunction (0.6%–6%) (Figure 80.4), inefficacy of treatment or even worsening of incontinence (2.5%–11.7%), dysuria or acute urinary retention (1.5%–6.8%), and de novo urgency (10.5%) [58]. Migration can lead to explantation ± reimplantation. The explantation rate ranged between 18.7% and 30.8% [57,61]. The risk factors for explantation of ACT balloons have not been clearly identified in women. Other reported complications are less frequent: labial hematoma, labial infection, urinary infection, de novo urgency, dyspareunia, dysuria, pain, and discomfort. They are not always reported in the different studies. ACT balloons appear to be a minimally invasive treatment of female SUI. The balloons are easily adjusted percutaneously to enhance efficacy. Complications are usually mild and can be easily managed. The need for explantation does not preclude repeat implantation. Additional follow-up will determine the long-term durability of this device.

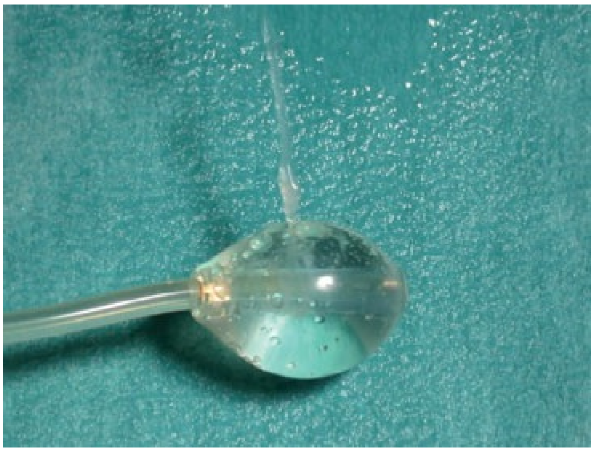

Figure 80.4 Adjustable continence therapy balloon perforation.

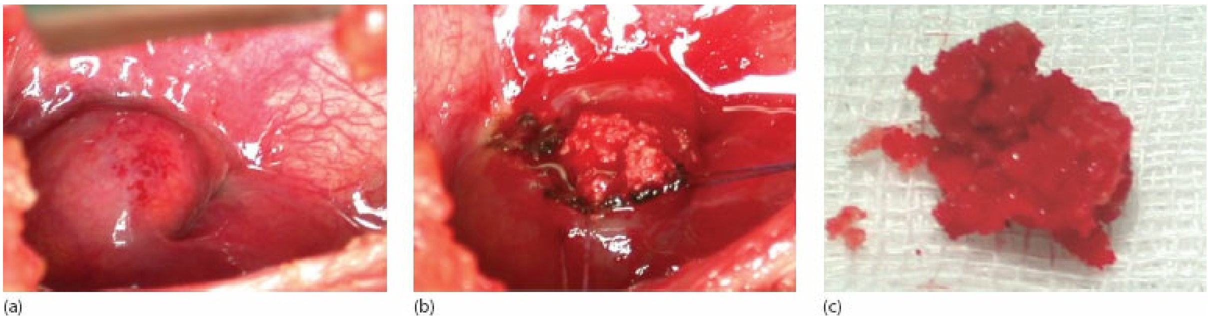

Figure 80.5 (a–c) Bulking agent protrusion in the bladder.

COMPLICATIONS OF PERIURETHRAL INJECTIONS

Bulking agents have historically demonstrated disappointing long-term success rates [62,63]. There are currently no data in the literature in support of the use of periurethral injections as first-line treatment for SUI. Only limited data are available concerning comparison of the various techniques. Periurethral injections can sometimes have lasting effects, but repeated injections may be necessary [64,65]. Periurethral injection is associated with few complications and adverse effects. Potential local side effects include urinary tract infection, urinary retention, local pain, pseudo-abscess formation, and urethral erosion. Distant effects as a result of particle migration are generally site specific and include pulmonary embolism. The incidence of urinary retention following the procedure ranges from 15% to 25% [66–68]. This usually resolves within 24–48 hours.

De novo urgency has been reported as high as 39% [66,69]. In case of persistent obstruction, resection of the implanted material may be performed [70] (Figure 80.5). In conclusion, this technique can be used because of its good benefit/risk balance in frail patients, previously operated patients, and patients refusing surgery. But the results are considerably inferior to other techniques.

STANDARDIZED CLASSIFICATION OF COMPLICATIONS

All complications listed earlier were reported by authors without any standardization, leading to probable underestimated rates of complications. To adequately assess results of a specific SUI surgery and counsel patients regarding the options, outcomes must be measured and quantified in a standard and consistent manner to permit purposeful conclusions. The International Urogynecological Association and the International Continence Society recognized the increasing use of prostheses (meshes) and grafts in female pelvic floor surgery [71]. They proposed a standardized terminology and classification. The classification was developed to be sensitive to all possible physical complications involving the use of a prosthesis or graft in a female pelvic floor surgical procedure. Complications were classified according to three aspects: category, time, and site. Indeed, complications involving the use of meshes, tapes, and grafts in female pelvic floor surgery need to involve the following viewpoints of (1) local complications, (2) complications to surrounding organs, and (3) systemic complications. A key advantage of a standardized classification is that all parties involved in female pelvic floor surgery including surgeons, physicians, nurses, allied health professionals, and industry will be referring to the same clinical issue. The standardized classification may certainly be helpful to report complications in long-term studies evaluating long-term follow-up of SUI surgeries.

CONCLUSIONS

Surgical interventions for SUI are widely employed with substantial success and low morbidity and mortality. Careful counseling allowing realistic patient expectations with regard to complications will set a benchmark from the perspective of the most important outcome, namely, patient satisfaction.

Surgery for Urogenital Prolapse

81 Classification and Epidemiology of Pelvic Organ Prolapse

Steven E. Swift

INTRODUCTION

The study of pelvic organ prolapse (POP) is one area of medicine that seems so intuitive but in actuality is replete with anecdotal evidence, case series, and very little hard science. Most of this stems from the lack of a scientifically validated and universally agreed upon definition of the disease state of "pelvic organ prolapse." A classification system to codify pelvic organ support has been defined and has gained international recognition. However, while it accurately describes the degree or stage of pelvic organ support, it does not classify it into normal versus abnormal or "prolapse." This is akin to having a blood pressure cuff to measure blood pressure but no definition as to what represents normal versus hypertension. Until we can define the disease, we cannot properly identify its etiology or make any statements regarding therapy, prognosis, or natural history. Therefore, all of the scientific literature regarding POP should be viewed with caution, paying particular attention to how POP is described and defined. Despite the current state of affairs, studies into the classification and epidemiology of POP are moving forward as the scientific community has recognized the problems and is addressing them via research protocols.

CLASSIFICATION OF PELVIC ORGAN SUPPORT

The aforementioned title specifically does not use the term "prolapse" but instead uses "support" as none of the current POP classification systems attempts to define "prolapse." Instead, they only address where the vaginal walls or structures extend anatomically without making any reference as to what is normal versus abnormal or "prolapsed."

The history of classification systems for pelvic organ support extends back into the nineteenth century, with a new system appearing every generation or so, but with no system ever attaining widespread acceptance as the "gold standard" [1–7]. Several of these systems are diagramed in Figure 81.1. Over the last decade, the POP quantification (POPQ) system has gained international recognition as the "gold standard" for classifying pelvic organ support, and it is the first and only system to gain recognition by most of the major societies that study pelvic organ support defects: the International Continence Society (ICS), the American Urogynecologic Society (AUGS), and the Society of Gynecologic Surgeons [8]. It is also one of the few systems to be extensively studied with several reports in the literature documenting excellent inter- and intraexaminer reliability [9–11]. Two other classification systems that have been studied include the Baden and Walker "half-way" system and a simplified POP classification (S-POP) system. The Baden and Walker "half-way" system has been around for decades and has gained some widespread notoriety. In a recent survey of the literature on POP, it was the second most commonly employed classification system behind the more popular POPQ system [10,12]. The S-POP system is a simplified version of the POPQ that has been studied in a large international multicentered trial [13]. It was shown to have very good intra- and interexaminer reliability and had good intersystem association with the POPQ [14].

Currently, there is only one internationally recognized classification system for codifying pelvic organ support—the POPQ. It has proven itself to be a reliable system, and it is the system that should be employed in research regarding pelvic organ support. The Baden and Walker "half-way" system remains a common system in clinical practice, and this may stem from its ease of use; however, it should not continue to supplant the POPQ in research studies and the scientific literature [10].

PELVIC ORGAN PROLAPSE QUANTIFICATION SYSTEM

While the POPQ system is recognized as the standard for describing pelvic organ support, it has not resolved all of the questions regarding POP. First, while it is a good system for codifying pelvic organ support, like its predecessors, it does not establish any diagnostic criteria for POP. In addition, while it is the only universally recognized system, it has yet to gain universal acceptance in research or clinical practice. Despite being initially described and published in 1996, as of 2003, it still only appeared in about 30% of the literature regarding pelvic organ support defects and, as of 2006, is only used clinically by about 40% of the members of the societies (ICS, AUGS) that acknowledge it as the recognized scientific standard for describing pelvic organ support [12,15].

There are many reasons why the POPQ system has not gained widespread clinical use, but the most commonly cited reasons are the following: (1) not used by colleagues, (2) too time-consuming, and (3) too confusing [15]. There is some validity to these concerns, but there are also some misconceptions. If only 40% of the members of the ICS and AUGS use it in their clinical practice, it would be surprising to find that other health-care providers outside of these societies had embraced the POPQ in their clinical practice. While there is no literature on how the system is used outside of the field of urogynecology, there is a study of 54 obstetrics and gynecology house officers and students who were trained to use the system. When specifically queried, only 1 of 54 reported seeing or using the system outside of their urogynecology rotation [16]. Concerns about taking too much time to complete are unwarranted as it only takes 2–3 minutes to complete the examination, even in neophytes [9].

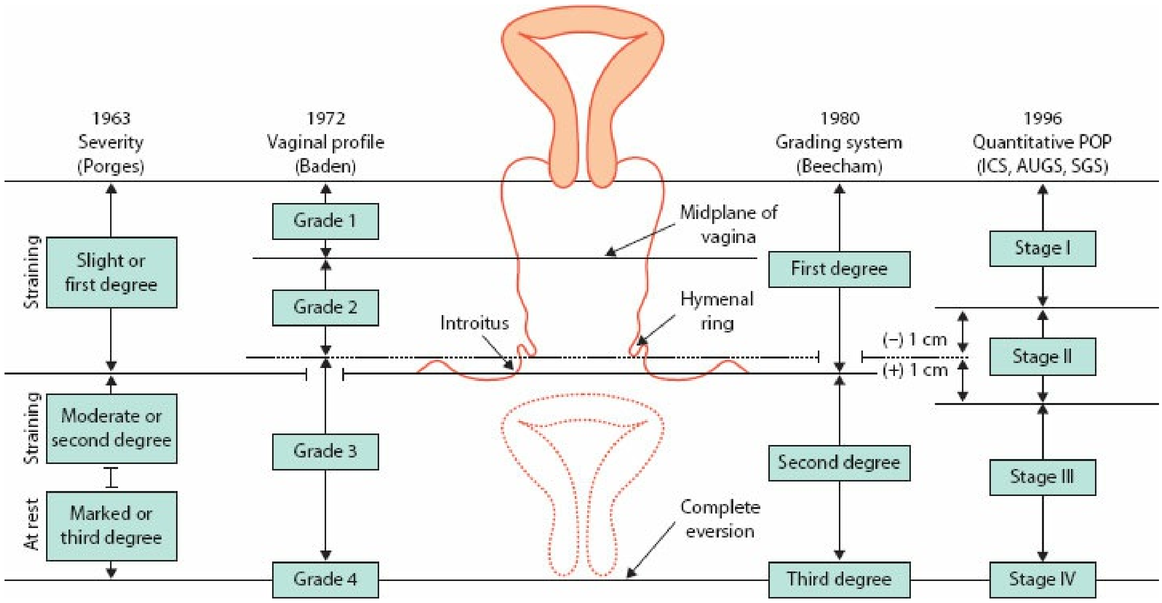

Figure 81.1 Comparison of the four most commonly used pelvic organ prolapse grading systems. AUGS, American Urogynecologic Society; ICS, International Continence Society; SGS, Society of Gynecologic Surgeons.

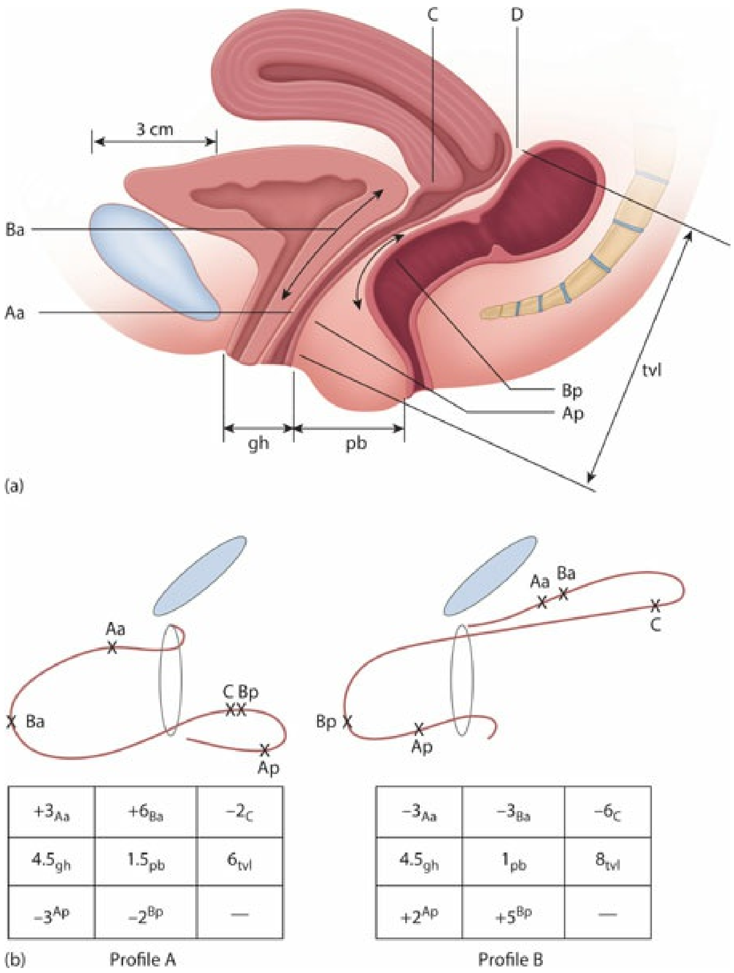
Performing the Pelvic Organ Prolapse Quantification Examination

The POPQ examination takes nine measures of the position of midline vaginal structures (Table 81.1). All of the measurements are in centimeters relative to the hymeneal ring. The remnant of the hymeneal ring is used as the reference point because it is a fixed and easily identified landmark, as opposed to the introitus, which is a nonstandardized anatomic structure (it is defined as the “entrance into the vagina”). All of the points recorded during the examination, with the exception of total vaginal length, are measured with the subject performing a Valsalva or a deep cough. Structures that lie above the hymeneal ring are recorded as negative, whereas structures that prolapse beyond the hymeneal ring are recorded as positive (both recordings in half centimeters) (Figure 81.2). Any structure that descends to the level of the hymeneal ring is recorded as 0 cm. Nine measurements are taken during the examination: two from the anterior vaginal wall, two from the apex of the vagina, two from the posterior vaginal wall, and one each recording the genital hiatus, perineal body, and the total vaginal length at rest (see Table 81.1). These points are depicted diagrammatically in Figure 81.2; note also the two diagrams representing a large anterior segment defect with some apical descent (Profile A) and a large posterior defect (Profile B). The nine points may be recorded in a convenient manner using a three-by-three grid as noted in the figure. Any rigid measuring device—such as a marked wooden Pap smear spatula, ruler, or engraved instrument—may be used.

Table 81.1 Sites Measure in the Quantitative Pelvic Organ Prolapse Examination

Point	**Description**
A anterior (Aa)	A point on the anterior vaginal wall 3 cm above the hymeneal ring
B anterior (Ba)	Most dependent or distal point on the anterior vaginal wall segment between A anterior and point C or the cuff if subject is status posthysterectomy
C	Anterior lip of the cervix or the cuff if subject is status posthysterectomy
A posterior (Ap)	A point on the posterior vaginal wall 3 cm above the hymeneal ring
B posterior (Bp)	Most dependent or distal point on the posterior vaginal wall segment between A posterior and point D or the cuff if subject is status posthysterectomy
D	Posterior fornix (this space is left blank in the subject who is status posthysterectomy)
Genital hiatus (gh)	Middle of external urethral meatus to posterior hymeneal remnant
Perineal body (pb)	Posterior hymen to middle of anal opening
Total vaginal length (tvl)	Hymeneal ring to vaginal apex



Profile A

$+3_{Aa}$	$+6_{Ba}$	-2_{C}
4.5_{gh}	1.5_{pb}	6_{tvl}
-3^{Ap}	-2^{Bp}	—

Profile B

-3_{Aa}	-3_{Ba}	-6_{C}
4.5_{gh}	1_{pb}	8_{tvl}
$+2^{Ap}$	$+5^{Bp}$	—

Figure 81.2 (a) The nine points recorded for the pelvic organ prolapse classification system. Terms are defined in Table 81.1. (b) Profile A represents a large anterior wall defect with some apical descent; Profile B represents a large posterior defect. Note the grid system used for recording the nine points.

For descriptive purposes, an ordinal staging system is used whereby the prolapse stage is defined by the vaginal structure that demonstrates the greatest degree of prolapse (Table 81.2). An easy method of remembering this staging system involves understanding stage II. Any vaginal structure that descends such that the leading edge is at or between 1 cm above and 1 cm past the hymeneal ring is stage II. If the vaginal structure or leading edge has some movement but remains above –1 cm, it is stage I, and any structure or leading edge that descends beyond +1 cm is stage III up to complete eversion, which is stage IV. Stage 0 is no descent of any vaginal segment.

At a practical level, an efficient method of performing the examination consists of placing a bivalve speculum in the vagina and measuring apical descent using the posterior blade of the speculum to measure anterior and then posterior structures, and then measuring the perineal structures. Further information regarding the performance of the POPQ examination, including a videotape, is available at the AUGS website (www.augs.org).

Table 81.2 Staging of Pelvic Organ Prolapse

Stage	**Description**
0	No descensus of pelvic structures during straining.
I	The leading surface of the prolapse does not descend below 1 cm above the hymeneal ring.
II	The leading edge of the prolapse does not extend from 1 cm above the hymen to 1 cm through the hymeneal ring.
III	The prolapse extends more than 1 cm beyond the hymeneal ring, but there is not complete vaginal eversion.
IV	The vagina is completely everted.

One aspect of this system that may be awkward, or even an anathema, to adherents of prior systems is the strict avoidance of terms such as cystocele, rectocele, or enterocele. The rationale behind this seemingly dogmatic practice is to avoid erroneous assumptions regarding the prolapsing organs. Since the vagina is relatively opaque, it is not possible to identify which organ is on the other side of the epithelium. It is often difficult even for experienced observers to discriminate between a high rectocele and a pulsion enterocele. Furthermore, patients who have had prior reconstructive pelvic surgery may have gross alterations in their vaginal axis, which result in unusual patterns of prolapse (e.g., anterior enterocele after sacrospinous ligament suspension). Another change from previous systems is the avoidance of staging the individual vaginal segments, i.e., a patient having a stage II cystocele and stage III rectocele. Instead, the patient is given one overall stage; for example, the previously noted patient would be described as having a POPQ stage III examination.

Simplified Pelvic Organ Prolapse Quantification System

In response to concerns regarding the clinical utility of the POPQ, the International Urogynecological Association sets up a task force to develop a more user-friendly system for classifying pelvic organ support. They also wanted a system that would demonstrate good association with the POPQ such that clinicians could use the user-friendly version in their clinical practice but take advantage of scientific literature using the standard POPQ. Out of this task force was developed the S-POP. The S-POP is basically the ordinal staging of the POPQ applied to each segment of the vaginal wall (anterior, posterior, apex, and cervix) without the need for nine separate measures. This idea stemmed from observations that several investigators were already reporting on simple ordinal staging for pelvic organ support without taking the nine measurements [11]. The S-POP is just a codification of applying what many investigators were already proposing.

Performing the Simplified Pelvic Organ Prolapse Quantification Exam

The technique for performing the simplified POPQ exam is as follows. Patients are asked to empty their bladder prior to the exam. The subject is then placed in the dorsal lithotomy position. Once the subject is positioned for examination, they are instructed to forcefully perform Valsalva or to cough—if the clinician feels the Valsalva is inadequate.

The four areas to be examined and staged include the anterior and posterior vaginal walls, the apex/cuff, and the cervix. If a subject was status posthysterectomy, then only three measurements are taken: the anterior and posterior vaginal walls and the cuff scar/apex. For the exam of the anterior and posterior vaginal wall segments, a disarticulated Graves speculum or two fingers of the examiner are employed as a retractor. For examination of the anterior vaginal segment, the speculum or fingers are placed into the vagina and the posterior vaginal wall is retracted to allow for full visualization of the anterior vaginal wall. A point or rugal fold approximately 3 cm proximal to the urethral meatus on the anterior vaginal wall is identified. The patient is then instructed to perform Valsalva or cough in a forceful fashion and where that point or rugal fold previously identified descends in relation to the hymenal remnants is noted and recorded as the stage of the anterior vaginal wall (noted in the following under staging). The posterior segment is examined in a similar fashion. The point chosen to represent the posterior vaginal segment is identified in a similar fashion retracting the anterior vaginal wall. The only difference is the point is approximately 3 cm proximal to the hymenal remnants instead of the urethral meatus. The cervix is evaluated by placing a speculum in the vagina and directly observing its descent during a Valsalva or cough to determine its stage in relation to the hymenal remnants. Care should be taken to make certain that the cervix is not inadvertently supported by the speculum during the exam. The vaginal apex or cuff scar is visualized in a similar fashion. If the cervix, apex, or cuff scar descends beyond the hymenal remnants with Valsalva or cough, then a speculum is not necessary. If the subject has a cervix, then the vaginal apex or posterior fornix is described separately from the cervix.

The staging system for each segment is as follows:

Stage I: Prolapse where the given point remains at least 1 cm above of the hymenal remnants during Valsalva or forceful cough

Stage II: Prolapse where the given point descends an area extending from 1 cm above to 1 cm below the hymenal remnants (Figure 81.3)

Stage III: Prolapse where the given point descends greater than 1 cm past the hymenal remnants but does not represent complete vaginal vault eversion or complete procidentia uteri (Figure 81.4)

Stage IV: Complete vaginal vault eversion or complete procidentia uteri

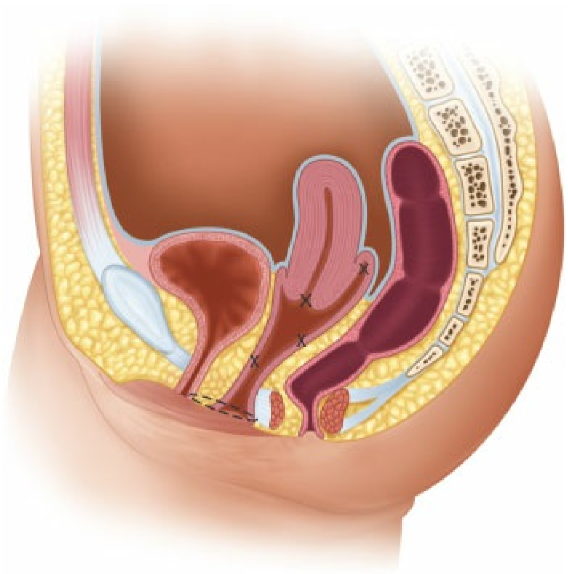


Figure 81.3 The four points measured for the simplified pelvic organ prolapse classification exam. Note the dotted line representing the hymenal remnants.

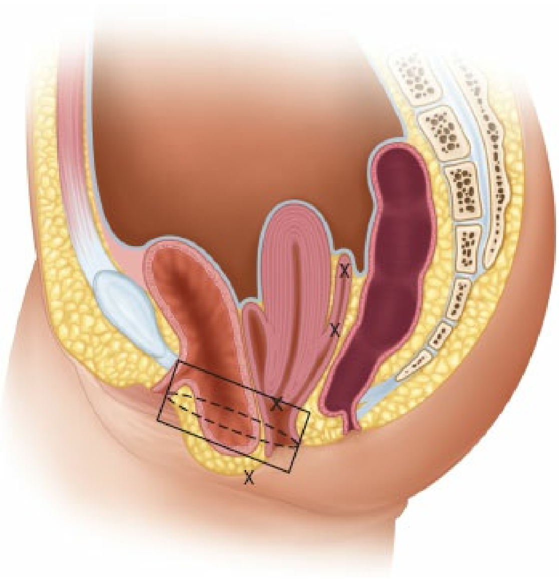

Figure 81.4 Simplified pelvic organ prolapse classification (S-POP) stage III anterior vaginal wall prolapse, stage II cervical support, and stage I apex and posterior vaginal wall support. Note the dotted line representing the hymenal remnants and the box representing S-POP stage II.

No specific measuring devices need to be used. The examining clinician can approximate the 1 cm above or below the hymenal remnants defining stage II. The subjects are assigned an overall stage as the highest value among the four segments, and each segment is assigned an individual stage.

Assigning individual stages to the various vaginal segments while not part of the POPQ is a standard clinical practice. In addition, the task force that developed the simplified POPQ felt that a stage 0 was not necessary since it is asymptomatic and not different enough from stage I to warrant a separate classification stage.

EPIDEMIOLOGY OF PELVIC ORGAN PROLAPSE

The National Institutes of Health (NIH) consensus conference recognized that without a standard validated definition of POP there could be little progress in studying the disease and its treatment. They noted that currently there are no clinically or scientifically validated definitions and felt that any proposed definition should take into account both a subject's anatomy and their symptoms [17]. Despite the lack of knowledge on which to base a rational definition for POP, the NIH defined POP as ≥POPQ stage II exam.

Subsequent to the NIH consensus conference, there have been several published studies examining the distribution of pelvic organ support in various general female populations [18–25]. However, only four studies have looked at general populations of a significant age range employing the POPQ system [18–20,26]. From the distribution of these four studies as plotted in Figure 81.5, it can be seen that POPQ stage II support represents between 30% and 50% of the populations studied. However, it is doubtful that POP is this prevalent; therefore, the NIH definition may be too broad. Only 2%–11% of the subjects in these studies have stage III and IV examinations, which is more consistent with current estimates on the percent of subjects undergoing surgical treatment for this condition. There is an 11% lifetime risk of undergoing surgical correction of POP, and the incidence of surgery for POP/incontinence is 22.7 per 10,000 [27,28].

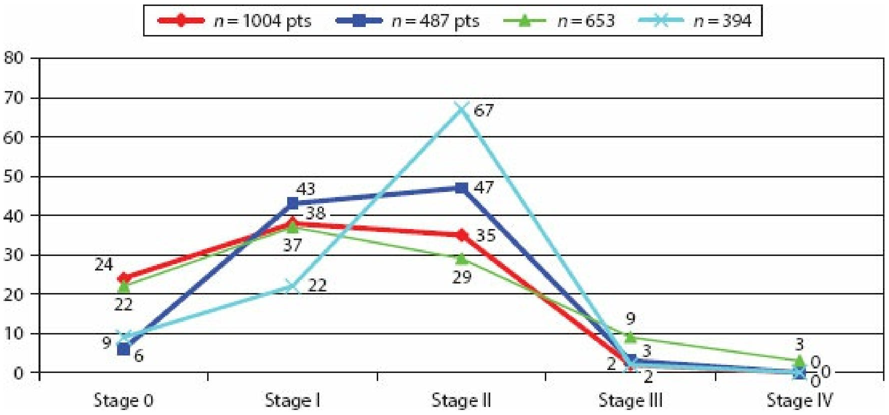

Figure 81.5 Percent of subjects in each pelvic organ prolapse quantification stage in three studies of general female populations. *n* is the number of subjects examined in each study. (*n* = 487: From Swift SE, *Am J Obstet Gynecol*, 183, 277, 2000; *n* = 1004: From Swift SE et al., *Am J Obstet Gynecol*, 192, 795, 2005; *n* = 653: From Slieker-ten HMCP et al., Distribution of pelvic organ prolapse in a general population: Prevalence, severity, etiology and relation with the function of pelvic floor muscles, Abstract Presented at the *Joint Meeting of the ICS and IUGA*, August 25–27, 2004, Paris, France; *n* = 394: From Trowbridge ER et al., *Am J Obstet Gynecol*, 198, 548.e1, 2008.)

POP is a disease with essentially no mortality and only minimal morbidity; however, it is a condition that greatly impacts the quality of life. Therefore, symptoms play a central role in defining at what point a patient goes from “normal” pelvic organ support to “abnormal” POP. Most studies demonstrate that there is a very weak (if any) correlation between symptoms and advancing degrees of POP with the exception of the symptom of a bothersome vaginal bulge [29–33]. In the few studies that correlated POPQ stage with symptoms, it appears that symptoms begin to significantly increase once the leading edge of the vaginal wall extends to or just beyond the hymen [19,28]. Therefore, a reasonable definition of POP may be protrusion of any vaginal segment to or beyond the hymen in symptomatic patients. If one carefully reads the literature, this definition, while not recognized, is slowly becoming the standard. A recent review article has suggested that we should define the disease and outcomes regarding management strategies using composite scores based on objective and subjective findings [34].

ETIOLOGY OF PELVIC ORGAN PROLAPSE

As previously noted, there is no currently accepted definition of POP; therefore, each study into its pathophysiology is left to employ its own definition. Generally, the literature defines prolapse in one of two ways—either anatomically by examination or by surgical admission for corrective surgery. The concern regarding surgical admissions is that they miss those patients that manage their prolapse conservatively; the concern regarding anatomic descriptions is that no two studies use the same anatomic cutoffs [19,21,23,25,27,35–39]. A list of epidemiological studies and their definitions is provided in Table 81.3. This plethora of definitions makes it difficult to evaluate trends in the literature into the various etiologies and can lead to conflicting results. This portion of the chapter will examine the various proposed etiologies of POP, bearing in mind that the frequently conflicting results stem from the various definitions employed in each study.

The only universally accepted risk factor for POP is the increasing age. Regardless of the definition used, this factor is always identified as a risk for prolapse, and most estimates suggest that there is roughly a doubling in the risk of prolapse with every completed decade of life [18,19,25,35]. The other proposed pathophysiologies for POP are many but for the most part involve two types of insult: either the acute damage that occurs with pregnancy or the chronic insults from conditions that lead to continuous intermittent increases in intra-abdominal pressure. In addition, other areas that have been investigated include prior pelvic surgery and genetic factors.

Effect of Pregnancy

The relationship between pregnancy and POP has been extensively studied and is mentioned in almost every treatise on this subject. It is assumed that as the fetal vertex passes through the birth canal, there is direct damage to the nerves, fascia, and muscle that leads to eventual relaxation of the pelvic floor musculature and POP. While it is generally recognized that any parity is associated with an increased risk of prolapse, what role the delivery mode plays is more controversial [18–21,23,33–36,38]. Specifically, can one delivery mode (i.e., cesarean section) provide protection against prolapse? The majority of the literature supports the notion that increasing parity increases the risk of POP [18,19,21,33,36]. Studies suggest that anywhere from a 4- to an 11-fold increase in the risk of prolapse is dependent on parity, with increasing parity imparting greater risk [19,21,35].

However, the literature on the mode of delivery is mixed. When women who delivered only by cesarean section were compared to women who had any vaginal delivery, the data are inconclusive and do not suggest a protective effect [19]. The data on instrumented vaginal delivery are sparse, and in one study forceps delivery was not identified as a risk factor for the development of prolapse [36]. In addition, there is one study suggesting that episiotomy protects against prolapse [37].

The data regarding infant weight are more consistent, with most studies demonstrating an increase in prolapse with increasing fetal weight; delivery of a macrosomic infant carries the greatest risk [19,23,35,36].

Table 81.3 Definitions of Pelvic Organ Prolapse from the Various Epidemiological Studies

Author	**Definition**
Jorgensen et al. [39]	Surgical admission for surgery to correct prolapse
Olsen et al. [27]	Surgical admission for surgery to correct prolapse
Mant et al. [21]	Surgical admission for surgery to correct prolapse
Chiaffarino et al. [36]	Baden and Walker stage II and greater
Marchionni et al. [37]	Baden and Walker stage II and greater
Samuelsson et al. [23]	Presence of any cystocele, rectocele, uterine descent, or absence of the urethrovesical crease
Gruel and Gruel [38]	Any vaginal relaxation to the introitus (roughly equivalent to Baden and Walker stage II and greater)
Swift et al. [35]	POPQ stage III prolapse
Hendrix et al. [25]	Stage I or greater prolapse by a unique system defined for this study (stage I is defined as in the vagina)
Swift et al. [19]	Leading edge at –0.5 cm above the introitus or greater (some POPQ stage II and all stage III and IV)

Pregnancy and macrosomia are consistently identified as risk factors for POP, but whether cesarean delivery or avoidance of an operative vaginal delivery can protect against POP remains a topic of debate with no clear evidence to support or refute this supposition.

Modifiable Lifestyle Risk Factors

There are several opinions regarding how to counsel patients in ways to prevent POP. Factors such as occupations that require a lot of lifting, together with obesity and smoking, all contribute to POP, and modifying or removing these insults will reduce the risk.

The data on occupation, as a risk for prolapse, stem from an article published in 1994 on nursing assistants in Denmark. The investigators noted a 60% increased risk of surgery to correct POP and herniated lumbar disks in nursing assistants over the general population [39] and felt this was due to the excess heavy lifting of patients inherent in their job description. Since then, two large studies have incorporated job description into their data collection [19,36]. Both found that manual workers and housewives had a slightly increased risk of prolapse over women who classified themselves as professionals.

Obesity is another risk factor commonly quoted for POP. It is felt that the increasing weight from abdominal adipose tissue increases the pressure on the intra-abdominal organs, leading to pelvic floor weakness and prolapse. Here, the literature is divided, with several studies suggesting it as a risk factor [19,21,25,27,37] and several studies finding no association [23,35,37].

Smoking is the final modifiable risk factor often associated with POP. Again, the data are mixed, with several studies suggesting that current smokers are at risk [21,25,27], two showing no relationship

[23,36], and one study suggesting smoking has some protection against POP [19].

Among the lifestyle or modifiable etiologies, the only factor that demonstrates a consistent relationship with an increased risk of POP is job description, with those individuals engaged in more manual labor having a greater risk of prolapse.

Medical Illnesses

Other areas that are commonly discussed and implicated as being etiologies of POP are chronic medical or congenital illnesses that result either in increased intra-abdominal pressure or in microvascular disease and poor-quality collagen. The relationship between chronic illness and prolapse has been investigated in large epidemiological studies with mixed results. It would seem intuitive that those illnesses associated with chronic recurrent increases in intra-abdominal pressure, constipation, and chronic obstructive pulmonary disease (COPD) would increase the risk of POP. Constipation is an illness that can be difficult to define; however—when evaluated—it appears consistently related to an increase in prolapse [25,40].

Two studies evaluated COPD and neither noted it as a risk for prolapse [27,35]. In one of these studies, the number of subjects with COPD was very small, and in the other the pelvic organ, prolapse was defined by surgical admission so the data could be questioned. However, when taken with data on smoking, there does not appear to be a strong relationship between pulmonary disease and prolapse.

Medical illnesses that lead to long-term damage to the microvasculature and peripheral neuropathies, such as hypertension and diabetes mellitus, have been suggested as a potential cause of POP. However, as with many etiological studies, the results are mixed. In one large study, the presence of any chronic illness was not associated with an increased incidence of prolapse [19]; in another study, only hypertension was identified as a risk factor [35].

There are also a few studies in women with collagen vascular diseases, such as Marfan and Ehlers–Danlos syndrome, which suggest that these patients are at an increased risk of prolapse [41,42]. However, again the data are somewhat conflicting, and this may stem from the lack of any definition of prolapse in these studies.

Race

There is a long history of observational data to suggest that women of certain racial groups are at a greater or lesser risk of POP. There are early anecdotal reports of African-American and “Chinese” women having a very low risk of POP in comparison to Caucasian women [43–45]. While it can be difficult to classify women into race (with the Tiger Woods phenomenon), it appears that African-American women having a slightly decreased risk of prolapse when compared to their Caucasian counterparts and Hispanic women have an increased risk over Caucasian women [19,25,35]. The data on Asian women in these trials are too sparse to draw any conclusions.

Menopausal Status and Hormone Replacement Therapy

The association between menopausal status, hormonal therapy, and POP is a very complicated issue. First, women who are menopausal tend to be older than their premenopausal counterparts, and, as pointed out earlier, increasing age is probably the greatest risk factor for POP. In addition, women who take hormone replacement therapy (HRT) may not have taken it consistently since menopause and can be on any of a myriad of dosing schedules, further complicating any comparative studies. The majority of the studies suggest that postmenopausal women are at greater risk; however, when a multiple logistic regression analysis takes age into account, menopausal status becomes nonsignificant, suggesting that it may be the age factor more than the decreased estrogen levels that places the woman at risk for prolapse [19,25,35,36].

In these same studies, when the role of HRT was evaluated in menopausal women, the results are even less clear. One study suggested that past use decreases risk but not current use, another suggested no difference between ever and never using HRT, and one suggested that postmenopausal women with current use had a risk equal to that of premenopausal women. It should be noted that, while HRT may not protect menopausal women from developing prolapse, it has never demonstrated a negative effect.

Prior Pelvic Surgery

This is another area where it is difficult to determine if there are any significant relationships. First, it is known that up to 30% of women who undergo surgery for POP will require a second procedure to correct recurrent prolapse [27]. Therefore, subjects who have had prior prolapse surgery have many of the underlying conditions that put them at risk for prolapse, and using this as a risk factor is similar to noting the increased risk of cancer in patients undergoing treatment for cancer. Conversely, many patients who have undergone a hysterectomy had it done to correct POP, as pelvic relaxation is the third most common indication for hysterectomy in the United States [46]. Therefore, many of these patients have already been treated for prolapse and many will have been treated successfully. However, when hysterectomy is evaluated, most studies suggest that it does expose patients to an increased risk of POP [21,23,35,37]. When the hysterectomy was done specifically for prolapse, it increases the risk even more [37]. The mechanism behind this phenomenon may be the disruption of the normal apical supports of the vagina in subjects with otherwise good support. This emphasizes the need to be ever mindful of providing strong attachment of the cardinal and uterosacral ligament complex to the vaginal cuff at the time of hysterectomy. In subjects who have undergone prior prolapse surgery, there appears to be upwards of a fivefold increase in their risk of developing POP [35].

Family History

This is one area where we have almost no data; however, this may be of central importance when we counsel patients about other modifiable risk factors. There is one study where subjects who had undergone surgery for prolapse were asked about any family history of other relatives undergoing similar surgery [36]. The authors noted that there was an increased risk of POP surgery if a patient’s mother or sister had undergone prolapse surgery.

Natural History of Pelvic Organ Prolapse

This is an area of study with almost no data. There is one good study that evaluated the effect of no treatment on subjects with minimally symptomatic POP followed over time. The 64 women who were followed had minimally symptomatic prolapse (95% had POPQ stage II and stage III) and declined pessary or surgical management. They were followed on average for 16 months and in approximately 80% there were no changes in their POPQ examinations. Of the 64 women, 20% eventually elected an intervention, but this study demonstrated that no intervention is an acceptable therapeutic option in minimally symptomatic subjects and that patients generally do not experience rapid progression of prolapse [47].

SUMMARY

While we are still in the infancy of understanding POP, we are moving forward. There is now a growing body of literature regarding the classification and epidemiology of POP incorporating the POPQ and well-described definitions of POP that are beginning to help us understand this complex disease.

Currently, it is difficult to evaluate the pathophysiology of POP because of the lack of a standard definition. This makes the plethora of emerging data difficult to interpret because often we are comparing apples and oranges. There are a few consistencies, with age and pregnancy being acknowledged risk factors for POP. Other factors that probably play a role include obesity, a job with a greater proportion of manual labor and lifting, lack of HRT, hysterectomy, and family history. However, before recommendations can be made regarding preventive strategies, more studies using a consistent definition are required.

82 Anterior Vaginal Wall Prolapse

Mark D. Walters and Matthew D. Barber

INTRODUCTION

Anterior vaginal prolapse occurs commonly and may coexist with disorders of micturition. Mild anterior vaginal prolapse often occurs in parous women but usually presents few problems. As the prolapse progresses, symptoms may develop and worsen, and treatment becomes indicated. The anterior vaginal wall is the most common segment of the vagina to prolapse and the segment that is most likely to fail in the long term after surgical correction. This chapter reviews the anatomy and pathology of anterior vaginal prolapse, with and without stress incontinence, and describes methods of surgical repair.

ANATOMY AND PATHOLOGY

Anterior vaginal prolapse (cystocele) is defined as pathological descent of the anterior vaginal wall and overlying bladder base. According to the International Continence Society (ICS) standardized terminology for prolapse grading [1], the term “anterior vaginal prolapse” is preferred as “cystocele.” This is because the information obtained at the physical examination does not allow the exact identification of structures behind the anterior vaginal wall, although it usually is, in fact, the bladder. The ICS grading system for prolapse is discussed in detail in Chapter 81.

The etiology of anterior vaginal prolapse is not completely understood, but it is probably multifactorial, with different factors implicated in prolapse in individual patients. Normal support for the vagina and adjacent pelvic organs is provided by the interaction of the pelvic muscles and connective tissue [2]. The upper vagina rests on the levator plate and is stabilized by superior and lateral connective tissue attachments; the midvagina is attached to the arcus tendineus fasciae pelvis (ATFP) (white lines) on each side [3]. Pathological loss of that support may occur with damage to or impairment of the pelvic muscles, connective tissue attachments, or both.

Nichols and Randall described two types of anterior vaginal prolapse: distension and displacement [4]. Distension was thought to result from overstretching and attenuation of the anterior vaginal wall, caused by overdistension of the vagina associated with vaginal delivery or atrophic changes associated with aging and menopause. The distinguishing physical feature of this type was described as diminished or absent rugal folds of the anterior vaginal epithelium caused by thinning or loss of midline vaginal fascia. The other type of anterior vaginal prolapse—displacement—was attributed to pathological detachment or elongation of the anterolateral vaginal supports to the ATFP. It may occur unilaterally or bilaterally and often coexists with some degree of distension cystocele, with urethral hypermobility or with apical prolapse. Rugal folds may or may not be preserved.

Another theory ascribes most cases of anterior vaginal prolapse to disruption or detachment of the lateral connective tissue attachments at the ATFP, resulting in a paravaginal defect and corresponding to the displacement type discussed earlier. This was first described by White in 1909 [5] and 1912 [6] but disregarded until reported by Richardson et al. in 1976 [7]. Richardson described transverse defects, midline defects, and defects involving isolated loss of integrity of the pubourethral ligaments. Transverse defects were said to occur when the “pubocervical” fascia separated from its insertion around the cervix, whereas midline defects represented an anteroposterior separation of the fascia between the bladder and vagina. A contemporary conceptual representation of vaginal and paravaginal defects is shown in Figure 82.1 [8].

There have been few systematic or comprehensive descriptions of anterior vaginal prolapse based on physical findings and correlated with findings at surgery to provide objective evidence for any of these theories of pathological anatomy. In a study of 71 women with anterior vaginal wall prolapse and stress incontinence who underwent retropubic operations, DeLancey [9] described paravaginal defects in 87%

on the left and 89% on the right. The ATFP were usually attached to the pubic bone but detached from the ischial spine for a variable distance. The pubococcygeal muscle was visibly abnormal with localized or generalized atrophy in over half of the women.

Improvements in pelvic imaging are leading to a greater understanding of normal pelvic anatomy and the structural and functional abnormalities associated with prolapse. Magnetic resonance imaging (MRI) holds great promise, with its excellent ability to differentiate soft tissues and its capacity for multiplanar imaging. The pelvic organs, pelvic muscles, and connective tissues can be identified easily with MRI. Various measurements can be made that may be associated with anterior vaginal prolapse or urinary incontinence, such as the urethrovesical angle, descent of the bladder base, the quality of the levator muscles, and the relationship between the vagina and its lateral and apical connective tissue attachments. Aronson et al. [10] used an endoluminal surface coil placed in the vagina to image pelvic anatomy with MRI and compared four continent nulliparous women with four incontinent women with anterior vaginal prolapse. Lateral vaginal attachments were identified in all continent women. In Figure 82.2, the “posterior pubourethral ligaments” (bilateral attachment of ATFP to posterior aspect of the pubic symphyses) are clearly seen. In the two subjects with clinically apparent paravaginal defects, lateral detachments were evident (Figure 82.3). More recent studies based on MRI analysis and computer modeling suggest that apical support abnormalities are at least as important as, if not more important than, paravaginal defects; the degree of apical decent can explain about half of anterior wall descent [11]. This supports studies that used clinical examination with pelvic organ prolapse quantification (POPQ) that also demonstrates a strong correlation between anterior and apical vaginal support ($r = 0.89$) [12]. Other factors, such as levator ani muscle impairment, levator avulsion, greater anterior wall length, and widened urogenital hiatus, also contribute to anterior vaginal prolapse [13–15].

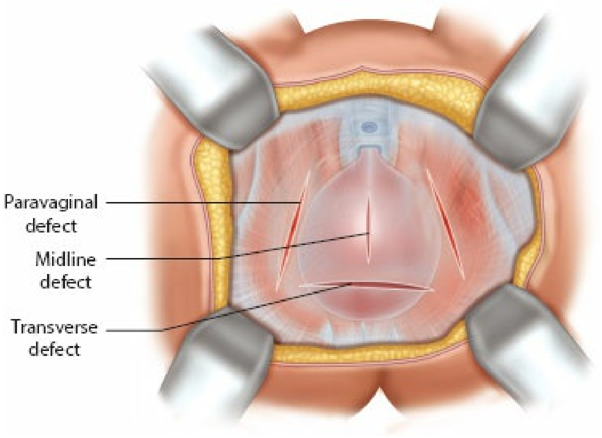

Figure 82.1 Three different defects can result in anterior vaginal wall prolapse. Lateral or paravaginal defects occur when there is a separation of the pubocervical fascia from the arcus tendineus fasciae pelvis, midline defects occur secondary to attenuation of fascia supporting the bladder base, and transverse defects occur when the pubocervical fascia separates from the vaginal cuff or uterosacral ligaments. (Reproduced from Karram MM, Vaginal operations for prolapsed, in Baggish MS and Karram MM, eds., *Atlas of Pelvic Anatomy and Gynecologic Surgery*, Saunders, Philadelphia, PA, 2001. Figure 82.3 Axial T1-weighted image from a 57-year-old woman, para 5, with stress urinary incontinence. The paravaginal detachment (arrow) is seen at the level of the urethrovesical junction. v, anterior vaginal wall; p, posterior pubic symphysis; u, urethra; o, obturator internus muscle; c, endovaginal coil; r, rectum; l, levator ani musculature. (Reproduced from Aronson MP et al., *Am J Obstet Gynecol*, 173, 1702, 1995. With permission.)

Anterior vaginal prolapse commonly coexists with stress urinary incontinence. Some features of pathophysiology may overlap, such as loss of anterior vaginal support with bladder-base descent and urethral hypermobility; other features, such as sphincteric dysfunction, may occur independent of vaginal and urethral support. The pathophysiology of stress incontinence is covered more fully in Chapter __.

EVALUATION

History

When evaluating women with pelvic organ prolapse or urinary or fecal incontinence, attention should be paid to all aspects of pelvic organ support. The reconstructive surgeon must determine the specific sites of damage for each patient, with the ultimate goal of restoring both anatomy and function.

Patients with anterior vaginal prolapse complain of symptoms directly related to vaginal protrusion or of associated symptoms such as urinary incontinence or voiding difficulty. Symptoms related to prolapse may include the sensation of a vaginal mass or bulge, pelvic pressure, low back pain, and sexual difficulty. Stress urinary incontinence commonly occurs in association with anterior vaginal prolapse. Voiding difficulty may result from advanced prolapse. Women may require vaginal pressure or manual replacement of the prolapse in order to accomplish voiding, or they may relate a history of urinary incontinence that has since resolved with worsening of their prolapse. This can occur with urethral kinking and obstruction to urinary flow; women in this situation are at risk for incomplete bladder emptying and recurrent or persistent urinary tract infections and for the development of de novo stress incontinence after the prolapse is repaired.

Physical Examination

The physical examination should be conducted with the patient in the lithotomy position as for a routine pelvic examination. The examination is first performed with the patient supine. If physical findings do not correspond to symptoms or if the maximum extent of the prolapse cannot be confirmed, the woman is reexamined in the standing position.

The genitalia are inspected, and if no displacement is apparent, the labia are gently spread to expose the vestibule and hymen. The integrity of the perineal body is evaluated, and the approximate size of all prolapsed parts is assessed. A retractor or Sims speculum can be used to depress the posterior vagina to aid in visualizing the anterior vagina. After the resting examination, the patient is instructed to strain down forcefully or to cough vigorously. During this maneuver, the order of descent of the pelvic organs is noted, as is the relationship of the pelvic organs at the peak of straining.

It may be possible to differentiate lateral defects, identified as detachment or effacement of the lateral vaginal sulci, from central defects, seen as midline protrusion but with preservation of the lateral sulci, by using a curved forceps placed in the anterolateral vaginal sulci directed toward the ischial spine. Bulging of the anterior vaginal wall in the midline between the forceps blades implies a midline defect; blunting or descent of the vaginal fornices on either side with straining suggests lateral paravaginal defects. Studies have shown that the physical examination technique to detect paravaginal defects is not particularly reliable or accurate. In a study by Barber et al. [16] of 117 women with prolapse, the sensitivity of clinical examination to detect paravaginal defects was good (92%), yet the specificity was poor (52%) and, despite an unexpectedly high prevalence of paravaginal defects, the positive predictive value was poor (61%). Less than two-thirds of women believed to have a paravaginal defect on physical examination were confirmed to possess the same at surgery. Another study by Whiteside et al. [17] demonstrated poor reproducibility of clinical examination in detecting specific anterior vaginal wall defects. Thus, the clinical value of determining the location of midline, apical, and lateral paravaginal defects remains unknown. Although valuable for research, the value of MRI for the clinical evaluation of anterior vaginal prolapse has yet to be demonstrated.

Anterior vaginal wall descent usually represents bladder descent with or without concomitant urethral hypermobility. In 1.6% of women with anterior vaginal prolapse, an anterior enterocele mimics a cystocele on physical examination [18]. Other uncommon conditions, such as large suburethral diverticulum or anterior vaginal cysts or myomas, can also mimic anterior vaginal prolapse.

Diagnostic Tests

After a careful history and physical examination, few diagnostic tests are needed to evaluate patients with anterior vaginal prolapse. A urinalysis should be performed to evaluate for urinary tract infection if the patient complains of any lower urinary tract dysfunction. Hydronephrosis occurs in a small proportion of women with prolapse; however, even if identified, it usually does not change management in women for whom surgical repair is planned [19]. Therefore, routine imaging of the kidneys and ureters is not necessary.

If urinary incontinence is present, further diagnostic testing is indicated to determine the cause of the incontinence. Urodynamic (simple or complex), endoscopic, or radiologic assessments of filling and voiding function are generally indicated only when symptoms of mixed incontinence, pain, or voiding dysfunction are present. Even if no urologic symptoms are noted, a full-bladder cough stress test should be done with the prolapse reduced, and voiding function should be assessed to evaluate for completeness of the bladder emptying. This usually involves a timed, measured void, followed by urethral catheterization or bladder ultrasound to measure postvoid residual urine volume.

If surgery to repair the prolapse is planned, it is important to check urethral function after the prolapse is repositioned. Women with severe prolapse may be paradoxically continent because of urethral kinking; when the prolapse is reduced, urethral dysfunction may be unmasked with occurrence of incontinence (occult stress incontinence) [20]. A pessary, vaginal retractor, or vaginal packing can be used to reduce the prolapse before office bladder filling or electronic urodynamic testing. If urinary leaking occurs with coughing or Valsalva maneuvers after reduction of the prolapse, the urethral sphincter is probably incompetent, even if the patient is normally continent. This is reported to occur up to two-thirds of women with stage III or IV prolapse. In this situation, the surgeon should consider adding an anti-incontinence procedure in conjunction with anterior vaginal prolapse repair [21]. If stress incontinence is not present even after reduction of the prolapse, an anti-incontinence procedure probably still decreases the rate of postoperative urinary incontinence but results in more complications, voiding dysfunction, and higher cost [21,22]. A validated, individualized computer prediction model for de novo stress incontinence after prolapse surgery is available [23].

SURGICAL REPAIR TECHNIQUES

Anterior Colporrhaphy

The objective of anterior colporrhaphy is to plicate the layers of vaginal muscularis and adventitia overlying the bladder (“pubocervical fascia”) or to plicate and reattach the paravaginal tissue in such a way as to reduce the protrusion of the bladder and vagina. Modifications of the technique depend on how lateral the dissection is carried, where the plicating sutures are placed, whether apical support is added, and whether additional layers (natural or synthetic grafts) are placed in the anterior vagina for extra support.

The operative procedure begins with the patient supine, with the legs elevated and abducted and the buttocks placed just past the edge of the operating table. Antibiotics should be given within 60 minutes of incision to achieve minimal inhibitory concentrations in the skin and tissues by the time the incision is made. This typically means a first-generation cephalosporin (cefazolin) or combination regimens (500 mg metronidazole and 400 mg ciprofloxacin) if the patient has an allergy to penicillin [24]. In general, all patients undergoing vaginal prolapse surgery are at moderate risk for thromboembolic events and require a prevention strategy [25]. Low-dose unfractionated heparin (5000 units every 12 hours), low-molecular-weight heparins (e.g., 40 mg enoxaparin or 2500 units of dalteparin), an intermittent pneumatic compression device, or a combination of these are recommended. Either form of heparin should be started 2 hours before surgery and the compression stockings placed on the patient in the operating room before incision. These treatment approaches should be continued until the patient is ambulatory.

The abdomen, vagina, and perineum are sterilely prepped and draped, and a 16 Fr Foley catheter with a 10 mL balloon is inserted for easy identification of the bladder neck. A weighted speculum is placed into the vagina. Hemostatic solutions (such as 0.5% lidocaine with 1:200,000 epinephrine) or saline may be injected below the epithelium along the midline of the anterior vaginal wall, to decrease bleeding and to aid in dissection. If a vaginal hysterectomy has been performed, the incised apex of the anterior vaginal wall is grasped transversely with two Allis clamps and elevated. Otherwise, a transverse or diamond-shaped incision is made in the vaginal epithelium near the apex. A third Allis clamp is placed about 2 cm below the posterior margin of the urethral meatus and pulled up. If a midurethral sling is to be done, then the incision is only made to the bladder neck; a separate incision is made for the sling. Additional Allis clamps may be placed in the midline between the urethra and apex. A scalpel is used to open the anterior wall in the midline. Alternatively, the points of a pair of curved Mayo scissors are inserted between the vaginal epithelium and the vaginal muscularis, or between the layers of the vaginal muscularis, and gently forced upward while being kept half opened/half closed (Figure 82.4a and b). Countertraction during this maneuver is important to minimize the likelihood of perforation of the bladder. The vagina is incised in the midline, and the incision is continued to the level of the midurethra (or bladder neck if a sling is being done). As the vagina is incised, the edges are grasped with Allis or T-clamps and drawn laterally for further mobilization. Dissection of the vaginal flaps is then accomplished by turning the clamps back across the forefinger and incising the vaginal muscularis with a scalpel or Metzenbaum scissors, as shown in Figure 82.4c. An assistant maintains constant traction medially on the remaining vaginal muscularis and underlying vesicovaginal adventitia. This procedure is performed bilaterally until the entire extent of the anterior vaginal prolapse has been dissected; in general, the dissection should be carried further laterally with more advanced prolapse. The spaces lateral to the urethrovesical junction are sharply dissected toward the ischiopubic rami. It is also important to use sharp dissection to mobilize the bladder base from the vaginal apex as shown in Figure 82.5.

If the patient does not suffer from stress urinary incontinence, plicating sutures at the urethrovesical junction could be placed to augment posterior urethral support and to help ensure that stress incontinence, if not present at the time of operation, does not develop postoperatively. Although it may help to prevent de novo stress incontinence, it can also lead to voiding difficulty after surgery. Vesical neck plication was used to treat mild stress urinary incontinence in the past but is no longer done for that indication. Once the vaginal flaps have been completely developed, the urethrovesical junction can be identified visually or by pulling the Foley catheter downward until the bulb obstructs the vesical neck. Repair should begin at the urethrovesical junction, using No. 0 delayed absorbable suture. The first plicating stitch is placed into the periurethral endopelvic fascia and tied (Figure 82.6a). One or two additional stitches are placed to support the length of the urethra and urethrovesical junction.

In a standard anterior colporrhaphy, stitches using No. 2-0 or 0 delayed absorbable sutures are placed in the vaginal tissue (muscularis and adventitia) medial to the vaginal flaps and plicated in the midline without excessive tension. Depending on the severity of the prolapse, one or two rows of plication sutures or a purse-string suture followed by plication sutures are placed (Figure 82.6b). The vaginal epithelium is then trimmed from the flaps bilaterally, and the remaining anterior vaginal wall is closed with a running No. 2-0 subcuticular or locking suture.

Anti-incontinence operations are often performed at the same time as anterior vaginal prolapse repair to treat coexistent stress incontinence, although this practice is somewhat controversial and varies in different geographic regions. Suburethral bladder neck sling placement may also improve the cure rate of the prolapse [26]. Bladder neck suspension procedures (pubovaginal sling procedures or retropubic colposuspension) effectively treat mild anterior vaginal prolapse associated with urethral hypermobility and stress incontinence. More advanced anterior vaginal prolapse will not be treated adequately and, in these cases, anterior colporrhaphy or anterior vaginal mesh repair should be performed, often in conjunction with a colpopexy procedure and a midurethral sling. Surgical judgment is required to perform the bladder plication tightly enough to reduce the anterior vaginal prolapse sufficiently, yet preserve some mobility of the anterior vagina. If anterior colporrhaphy is combined with a sling procedure (midurethral or bladder neck), the cystocele should be repaired before the final tension is set for the sling. Randomized trials support concurrent placement of a midurethral sling at the time anterior vaginal prolapse surgery even in continent women in order to prevent de novo stress urinary incontinence after surgery [22]. A midurethral sling, such as a tension-free vaginal tape or transobturator sling, is best done through a separate midurethral incision after the cystocele repair is complete.

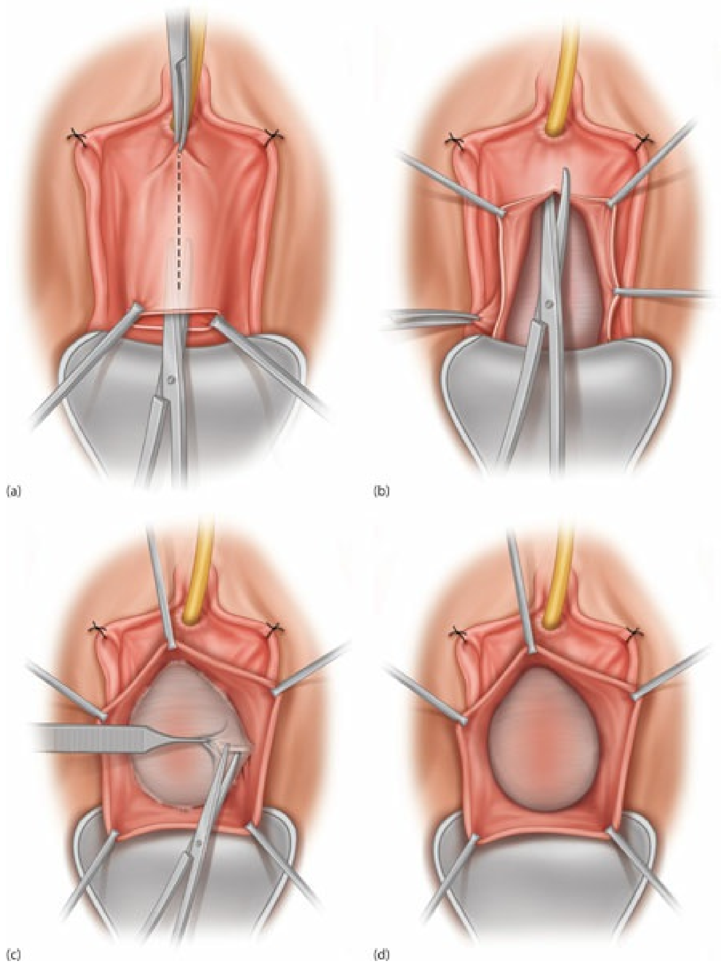

Figure 82.4 Cystocele repair: (a) initial anterior vaginal wall incision is at midline, (b) the incision is extended to the level of the proximal urethra, (c) sharp dissection and traction on the bladder facilitate dissection of the bladder off the vaginal wall, and (d) mobilization of the cystocele off the vaginal wall is completed. Anterior Prolapse Repair with Grafts

A prosthetic material can be used to provide support in the anterior vagina. This can be done in a number of ways and the surgical techniques continue to evolve. Graft materials may include synthetic absorbable grafts (e.g., polyglactin 910 mesh), synthetic permanent meshes (e.g., polypropylene), and biological materials. Biological materials that have been used include autografts of harvested rectus fascia and fascia lata, human allografts including fascia lata and dura mater, and xenografts such as porcine dermis, porcine small intestinal submucosa, and bovine pericardium. In 2010, approximately 25% of surgeries for pelvic organ prolapse in the United States included transvaginal placement of biologic or synthetic mesh. Many surgeons use transvaginal graft placement in an attempt to increase the efficacy and durability of their surgical repair. For anterior prolapse, studies have demonstrated improved anatomic outcomes after transvaginal placement of permanent synthetic mesh when compared to anterior colporrhaphy without mesh (“native-tissue repair”) [27]. However, this comes at the expense of an increased rate of complications unique to synthetic mesh placement including longer operating time and higher blood loss, vaginal mesh exposure or extrusion, mesh erosion or perforation into an adjacent organ (bladder, urethra, or rectum), and vaginal mesh contraction with associated pain and dyspareunia [27]. Concerns over increased adverse events from transvaginal mesh placement led to two separate FDA notifications. In October 2008, the FDA issued a Public Health Notification (PHN) to inform clinicians and patients of adverse events related to urogynecological use of surgical mesh and to provide recommendations on how to mitigate risks and counsel patients. In July 2011, the FDA provided an updated PHN on urogynecological surgical mesh and reported that the complications of mesh used transvaginally are not rare.

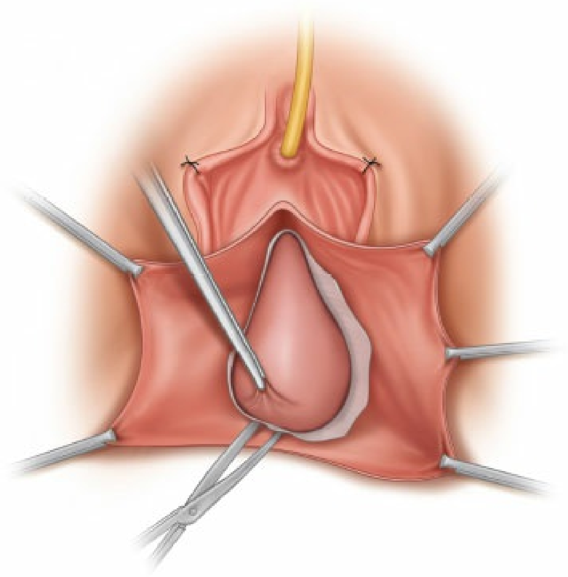

Figure 82.5 Cystocele repair. Sharp dissection is used to mobilize the bladder base from the vaginal apex during anterior colporrhaphy.

When considering the use of transvaginal mesh for anterior prolapse, surgeons and patients must balance improved anatomic support of the anterior vaginal wall against the cost of the devices and increased complications such as mesh erosion, exposure, or extrusion, pelvic pain, groin pain, and dyspareunia. In a joint Committee Opinion published in December 2011, the American Urogynecologic Society and the American College of Obstetrics and Gynecology recommended that pelvic organ prolapse vaginal mesh repair should be reserved for high-risk individuals in whom the benefit of mesh placement may justify the risk, such as individuals with recurrent anterior prolapse or with medical comorbidities that preclude more invasive and lengthier open and endoscopic procedures [28]. They also noted that surgeons placing vaginal mesh should undergo training specific to each device and have experience with reconstructive surgical procedures and a thorough understanding of pelvic anatomy.

Prior to considering treating the anterior vaginal prolapse with graft or mesh, patients should undergo a thorough informed consent process including discussion of risks, benefits, and both surgical and nonsurgical alternative treatments. Surgeons considering mesh use are encouraged to review the FDA's recommendations to health-care providers for pelvic organ prolapse (http://www.fda.gov/MedicalDevices/ProductsandMedicalProcedures/ImplantsandProsthetics/UroGynS

There are several situations where mesh use is contraindicated. Many surgeons would not consider the use of mesh in a patient who has had a previous mesh complication. Mesh augmentations should not be used in pregnant women or women who are contemplating future pregnancy, as the vaginal mesh does not stretch significantly. In patients who have had pelvic radiation, mesh placement is not recommended because of the risk of poor wound healing. Similarly, preexisting local or systemic infection is a contraindication for vaginal mesh placement, particularly nonabsorbable synthetic mesh. Many surgeons would not recommend the use of nonabsorbable synthetic mesh if colorectal surgery is being performed concurrently. Chronic steroid use, smoking, uncontrolled diabetes mellitus, or other causes of a compromised immune system can impair wound healing, and many would consider these conditions to be relative contraindications to vaginal mesh placement. Pelvic pain syndromes such as endometriosis, vulvodynia, interstitial cystitis, fibromyalgia, and dyspareunia should be evaluated preoperatively to allow for comprehensive counseling as to the best surgical and nonsurgical form of treatment.

Currently, there are three general categories of transvaginal mesh or graft placement options for the management of anterior vaginal prolapse: (1) self-tailored mesh, (2) commercially available trocar-guided mesh kits that use a transobturator approach, and (3) commercially available mesh kits that use a transvaginal fixation method rather than a trocar (nontrocar kits). No matter what placement option is used, the general surgical approach to treat anterior vaginal wall prolapse is fixation of mesh to the ATFP or the coccygeus muscle. The initial incision for anterior vaginal mesh placement usually involves significant hydrodissection and a deeper colpotomy incision than usually performed for a traditional native-tissue anterior colporrhaphy so that the perivesical space is entered. The mesh is spread laterally toward the ATFP proximally and distally and, in many of the newer nontrocar kits, attached apically to the sacrospinous ligament. Despite the lack of evidence that any one placement technique is best in managing a patient’s symptoms, most experts would agree on some basic perioperative tenets:

- The bladder should be drained with a transurethral catheter.
- A well-estrogenized vaginal wall is preferred prior to surgery. (We use intravaginal estrogen cream daily [0.5–1.0 g/day] for at least 2–3 weeks preoperatively.) A vaginal pessary should be removed 1–2 weeks prior to surgery to limit vaginal epithelium irritation.

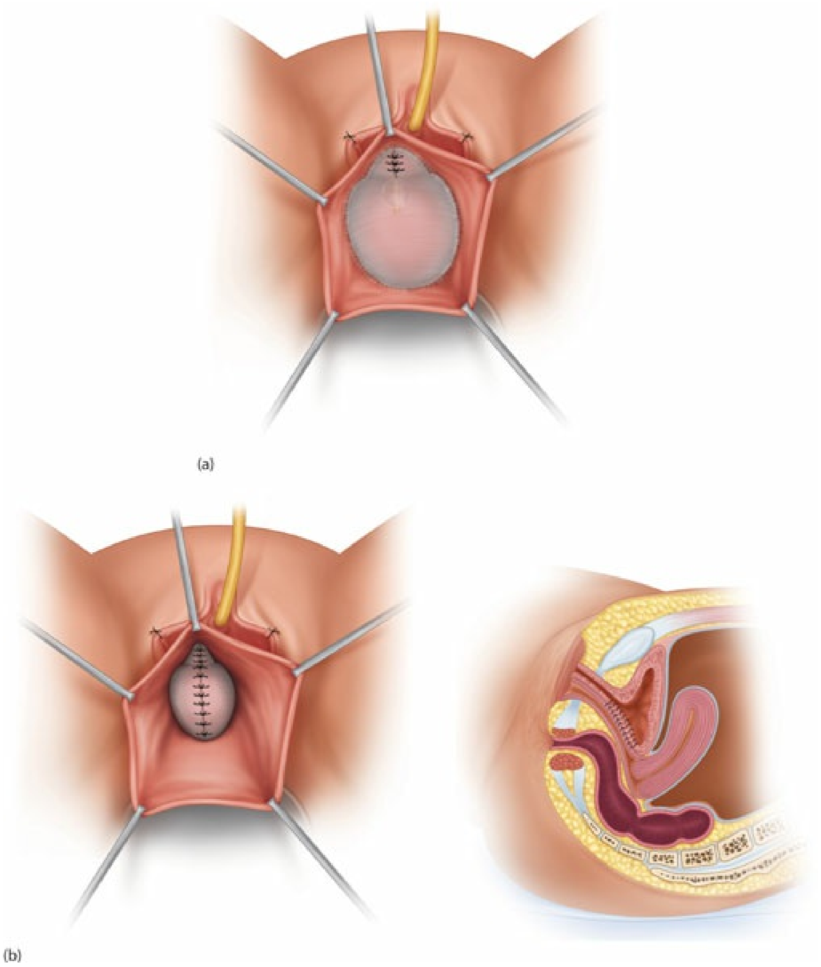

Figure 82.6 Cystocele repair. (a) Kelly plication sutures have been placed and tied, plicating the pubocervical fascia across the midline at the level of the bladder neck. (b) The bladder base has been plicated. Inset: preferential support of the bladder neck when compared to the bladder base. (Reproduced from Karram MM, Vaginal operations for prolapsed, in Baggish MS and Karram MM, eds., *Atlas of Pelvic Anatomy and Gynecologic Surgery*, 2nd edn., Saunders, Philadelphia, PA, 2001. With permission.)

- All patients require perioperative prophylactic antibiotics and efforts to prevent venous thromboembolic events, as noted earlier.
- Avoid making inverted “T-shaped” incisions from a concurrent hysterectomy and colporrhaphy, if possible.

- Exposure of the correct vesicovaginal space is performed with hydrodissection of 20–80 mL of 0.5% lidocaine with 1:200,000 epinephrine, dilute Pitressin (20 units in 60–100 mL of saline), or normal saline. The correct space for dissection is found using a “loss of resistance” technique similar to that used by an anesthesiologist placing an epidural. A wheal or blanching illustrates incorrect intraepithelial placement of the fluid. Hydrodissection in the correct plane will create a fluid bubble in the avascular vesicovaginal and rectovaginal spaces.
- As opposed to an anterior colporrhaphy where the vaginal epithelium and muscularis are split for plication, the mesh should be placed underneath the vaginal muscularis. It is vital that the surgeon perform a full-thickness dissection deep into the vesicovaginal and rectovaginal spaces to avoid erosion of the mesh postoperatively. Proper hydrodissection, as described earlier, facilitates the identification of the proper dissection plane.
- It is unknown whether or not the bladder wall should be plicated in the midline below the graft.
- Loosely place the graft because the mesh can contract by up to 20% following placement, compromising vaginal length and caliber. Allow enough room for Mayo scissors to be easily placed between the mesh and the vagina. Also, ensuring that the mesh is placed flat and with minimal tension will improve fibroblast growth and minimize complications of pain or erosion.
- The vaginal epithelium should not be trimmed. The colpotomy incision is closed utilizing a nonlocking continuous absorbable suture.
- Cystourethroscopy with assessment of urine flow from both ureters should be performed routinely after anterior mesh placement to identify potential urethral, bladder, or ureteral injury.

Self-Tailored Mesh Placement

Self-tailored mesh can be customized by the surgeon to match the size and shape of each patient’s individual pelvic anatomy. Mesh is cut into a trapezoid multiarmed shape for compartment augmentation and fixed to sacrospinous ligaments, obturator fascia, ATFP, and/or the distal bladder neck (Figure 82.7). This type of surgery requires a strong set of vaginal surgical skills as it involves dissections similar to sacrospinous ligament fixation, iliococcygeus suspension, uterosacral suspension, and vaginal paravaginal defect repair. No studies have compared standard repair techniques using self-tailored mesh with other mesh placement techniques.

Trocar-Based Mesh Kits

Trocar-guided devices can be used to suspend mesh by passing needles through the transobturator and/or ischiorectal fossa. Trocar-based mesh kits were the first commercially available transvaginal mesh products and included Anterior Prolift® (Ethicon, Somerville, NJ), Perigee® (American Medical Systems, Minnetonka, MN), and Avaulta® (CR Bard, Murray Hill, NJ). While these three products are no longer marketed by their respective companies in the United States, some trocar-based kits are still available in the United States and worldwide. In general, the technique for placement of these products is similar. First, a weighted speculum, self-retaining retractor, or Deaver retractors are placed in the vagina. Allis clamps are positioned at the urethrovesical junction for traction and 1 cm distal to the vaginal apex. The bladder can be palpated between the two Allis clamps. As opposed to an anterior colporrhaphy in which the vaginal epithelium and muscularis are split for plication, the mesh is placed underneath the muscularis to maintain a thickened vascularized epithelium in order to minimize mesh exposure or erosion. To enter this potential space, the surgeon injects a dilute vasopressin solution or 0.5% lidocaine with 1:200,000 epinephrine underneath the vaginal muscularis as noted earlier to facilitate dissection and minimize blood loss. Irrigation may help during the dissection, as the defect is a glistening white line. A sagittal colpotomy incision is made between the Allis clamps long enough to admit two fingers comfortably. Next, countertraction along the entire incision line is achieved with either the serial Allis clamps or a self-retaining retractor. The vaginal epithelium and full-thickness muscularis are dissected away from the bladder defect. Sharp and blunt dissection of the bladder is then performed while keeping the muscularis and epithelium on the vaginal flaps. As this dissection plane is advanced superiorly, loose areolar tissue is encountered until the ischial spine, ATFP, and, depending upon the kit, the sacrospinous ligaments are exposed. A number of different trocar types are available including helical-shaped trocars similar to those for transobturator slings and flexible straight trocars. Cutaneous incisions that are 4–7 mm in length are made over the appropriate locations for the obturator foramen and/or gluteus trocars. When placing multiple mesh arms through the transobturator space, the superior and inferior puncture sites should be at least 3 cm apart so the mesh can lay flat. Two fingers placed into the vagina can retract the colon, elevate the bladder, and minimize deviation of the trocar tip with direct palpation. For anterior compartment mesh, the surgeon immediately identifies the incoming trocar passing through the ATFP. The prosthesis is loosely placed in a "tension-free" manner. A finger should be kept inside the vagina whenever tensioning the graft. This provides countertraction and splints the tissue at the points of fixation. Stay sutures can be used to help the mesh lay flat against the vagina. If the surgeon conserves the uterus, then permanent sutures can be placed into the cervical stroma to stabilize the mesh. Cystoscopic and rectal examinations before, during, and after each portion of the surgery can be helpful. Once adequate hemostasis is obtained, the vaginal epithelium is closed with a continuous nonlocking stitch of delayed absorbable suture. Placing a lubricated vaginal pack may minimize bleeding and keep the mesh flat during healing. After desired tensioning, all ends of the mesh arms should be trimmed below the surface of the skin and the incisions closed. Concurrent procedures, such as a midurethral sling, should be done through a separate vaginal incision at this time.

Nontrocar Mesh Kits

The nontrocar or "single-incision" mesh kits have become increasingly popular and largely replaced trocar-based kits. The products avoid the potential complications associated with blind trocar passage through the transobturator space and ischiorectal fossa and allow mesh fixation via direct visualization. Additionally, most currently available nontrocar kits provide apical fixation to the sacrospinous ligaments bilaterally as well as anterior vaginal support. The technique for the nontrocar kits begins similarly to the technique for trocar-guided kit placement. After the vesicovaginal space is dissected, pertinent fixation points are identified including the ischial spines, ATFP, and sacrospinous ligaments. For apical fixation, the surgeon palpates the location of interest then identifies the sacrospinous ligament at least 2 cm medial to the ischial spine. The ligament is penetrated using the surgeon's device of choice. The Uphold kit uses the Capio transvaginal suture-capturing device (Boston Scientific®, Marborough, MA) to secure the mesh arms to the sacrospinous ligaments. Alternatively, the Elevate system (American Medical Systems, Minnetonka, MN) uses self-fixating appendage tips delivered by vaginal trocars to the same site (Figure 82.8). The ATFP mesh arms provide lateral fixation. An index finger placed into the vagina palpates the ATFP from the ischial spine to the posterior pubis. The mesh can be passed through the upper third of the ATFP using the same fixation methods. With the Uphold device, there are no ATFP arms to implant, and a sutured anterior colporrhaphy is often performed prior to mesh placement. The mesh arms are slowly and individually adjusted to a loose tension, and then the mesh is sutured flat. Cystoscopy with visualization of ureteral flow is performed to ensure integrity of the bladder and ureters. The colpotomy is closed and the vagina packed as described earlier.

Vaginal Paravaginal Repair

The aim of paravaginal defect repair for anterior vaginal prolapse is to reattach the detached lateral vagina to its normal place of attachment at the level of the ATFP. This can be accomplished using a vaginal or retropubic approach. Retropubic surgeries such as the Burch colposuspension are discussed in Chapter __.

The preparation for vaginal paravaginal repair begins as for an anterior colporrhaphy. Marking sutures are placed on the anterior vaginal wall on each side of the urethrovesical junction, identified by the location of the Foley balloon after gentle traction is placed on the catheter (Figure 82.9a). In patients who have had a hysterectomy, marking sutures are also placed at the vaginal apex. If a culdeplasty or apical suspension procedure is being performed, the stitches are placed but not tied until completion of the paravaginal repair and closure of the anterior vaginal wall. As for anterior colporrhaphy, vaginal flaps are developed by incising the vagina in the midline and dissecting the vaginal muscularis laterally. The dissection is performed bilaterally until a space is developed between the vaginal wall and retropubic space. Blunt dissection using the surgeon's index finger is used to extend the space anteriorly along the ischiopubic rami, medially to the pubic symphysis, and laterally toward the ischial spine. If the defect is present and dissection is occurring in the appropriate plane, one should easily enter the retropubic space, visualizing retropubic, and paravaginal adipose tissue. The ischial spine can then be palpated on each side. The ATFP coming off the spine can be followed to the back of the symphysis pubis. After dissection is complete, midline plication of the bladder adventitia can be performed, either at this point or after placement and tying of the paravaginal sutures (Figure 82.9b and c).

On the lateral pelvic sidewall, the obturator internus muscle and the ATFP are identified by palpation and then visualization. Retraction of the bladder and urethra medially is best accomplished with the Breisky–Navratil retractor, and posterior retraction could be provided with a lighted right-angle retractor. Using No. 0 nonabsorbable or delayed absorbable suture, the first stitch is placed around the tissue of the white line just anterior to the ischial spine. A Capio device (Boston Scientific, Natick, MA) works well to facilitate suture placement. If the white line is detached from the pelvic sidewall or clinically not felt to be durable, then the attachment should be to the fascia overlying the obturator internus muscle. The placement of subsequent sutures is aided by placing tension on the first suture. A series of three to six stitches are placed and held, working anteriorly along the white line from the ischial spine to the level of the urethrovesical junction (Figure 82.9d). Starting with the most anterior stitch, the surgeon picks up the edge of the periurethral tissue (vaginal muscularis or pubocervical fascia) at the level of the urethrovesical junction and then tissue from the undersurface of the vaginal flap at the previously marked sites. Subsequent stitches move posteriorly until the last stitch closest to the ischial spine is attached to the vagina nearest the apex, again using the previously placed marking sutures for guidance. Stitches in the vaginal wall must be placed carefully to allow adequate tissue for subsequent midline vaginal closure. After all the stitches are placed on one side, the same procedure is carried out on the other side. The stitches are then tied in order from the urethra to the apex, alternating from one side to the other. This repair is a three-point closure involving the vaginal epithelium, vaginal muscularis and endopelvic fascia (pubocervical fascia), and lateral pelvic sidewall at the level of the ATFP (Figure 82.9e and f). There must be tissue-to-tissue approximation between these structures. Suture bridges must be avoided by careful planning of suture placement. Vaginal tissue should not be trimmed until all the stitches are tied. The vaginal flaps are trimmed and closed with a running subcuticular or interlocking delayed absorbable suture.

Cystoscopy

Cystoscopy with visualization of ureteral flow is usually performed after cystocele repair, especially if slings or apical suspension procedures are also being performed. The purpose is to ensure that no sutures or mesh have been placed in the bladder and to verify patency of both ureters. The rate of ureteral obstruction after simple anterior colporrhaphy is only 0.4% [29], but the rate increases with the addition of some types of apical suspension. Intraoperative release of the offending sutures almost always releases the obstruction without further sequelae.

Results

The main indication for surgical repair of anterior vaginal prolapse is to relieve symptoms when they exist or as part of a comprehensive reconstructive pelvic procedure for multiple sites of pelvic organ prolapse with or without stress urinary incontinence. Few studies have addressed the long-term success of surgical treatments for anterior vaginal prolapse. While the majority of studies evaluating anterior vaginal prolapse repairs are uncontrolled series, an increasing number of randomized surgical trials have been done in recent years. Success rates vary considerably depending upon the outcome measure used to define success. Historically, most studies evaluating the treatment of pelvic organ prolapse have focused exclusively on anatomic success without considering other important areas such as symptoms, vaginal compliance, quality of life, or socioeconomic outcomes. For an individual patient, the most important outcome of a surgical procedure is the relief of her symptoms and improvement in her quality of life, yet until recently these areas have largely been ignored. Reported success rates for native-tissue anterior colporrhaphy range from 37% to 100% with most cohorts reporting success rates greater than 80%.

In 2001, Weber et al. [30] studied three variations of anterior colporrhaphy using a prospective randomized study design and a strict definition of success (Aa and Ba points at –3 or –2 cm; stage 0 or I). Standard anterior colporrhaphy resulted in 30% of patients with an optimal or satisfactory anatomic result; anterior colporrhaphy with polyglactin 910 mesh overlay had 42% optimal or satisfactory result and ultralateral plication under tension a 46% optimal or satisfactory result. No difference was seen in anatomic or functional outcomes and most patients reported satisfaction with their symptom improvement. The low success rates found in the trial are used as evidence that anterior colporrhaphy should be augmented by either synthetic mesh or another approach used (e.g., sacrocolpopexy) for treatment of anterior vaginal prolapse. More recently, Chmielewski et al. [31] reanalyzed the data from this trial using more clinically relevant definitions of success and reported considerably better outcomes with only 10% of subjects developing anatomic recurrence beyond the hymen, 5% of subjects developing symptomatic recurrence, and less than 1% having another surgery for prolapse at 23 months follow-up. In general, it appears that native-tissue anterior colporrhaphy commonly results in asymptomatic anterior vaginal descent to within 1 cm of the hymen (POPQ stage 2); however, prolapse beyond the hymen, development of symptomatic prolapse (e.g., vaginal bulging symptoms), and reoperation for recurrent prolapse are uncommon events in the first 2–3 years after surgery. Long-term results of anterior colporrhaphy are largely unknown, although Gotthart et al. [32] reported only 13 reoperations for prolapse (2.9%) after 10 years in 456 patients who had vaginal hysterectomy and colporrhaphy. The median interval from the first surgery to the second was 5.5 years.

No randomized trials have been performed evaluating the efficacy of paravaginal defect repair for the treatment of anterior vaginal prolapse. Single-center uncontrolled case series suggest good anatomic results for both open retropubic (success rate 75%–97%) and vaginal (success rate 67%–100%) approaches [33,34]. However, the vaginal approach appears to be associated with high risk of hemorrhage, with one series reporting a 21% blood transfusion rate [33]. Few data are available on the efficacy or safety of the laparoscopic or robotic paravaginal defect repair.

Two studies evaluated the use of absorbable polyglactin 910 mesh to augment anterior colporrhaphy and reported mixed results. The Weber et al. trial [30] described earlier found no benefit, while a randomized trial by Sand et al. [35] found a 75% success rate 1 year after surgery in those receiving absorbable mesh compared with a 57% success in those receiving native-tissue anterior colporrhaphy. Based on the 2012 Cochrane meta-analysis of trials comparing biological graft overlay to anterior colporrhaphy and trials comparing biological graft to permanent synthetic graft, the review concluded that overall use of a biological graft overlay is associated with a lower risk of anatomic failure than anterior colporrhaphy alone (failure rate: anterior colporrhaphy 25% versus biological graft 14%; RR 1.44 [95% CI 1.20–2.63]) but with no difference in subjective cure or improvement in quality of life [36]. Not all trials included in the meta-analysis demonstrated anatomic benefit for biological grafts over native-tissue repair. Given the different characteristics of many of the biological grafts, it seems likely that the results will vary depending upon the specific biological graft used; however, no head-to-head comparisons have been performed.

At least six randomized trials have compared the efficacy of mesh augmentation with polypropylene to native-tissue anterior colporrhaphy for the treatment of anterior vaginal prolapse [27]. Altman et al. [37] published the largest of these studies in 2011. In this multicenter study, 389 women with stage II or greater anterior vaginal prolapse were randomized to Anterior Prolift (n = 186) or anterior colporrhaphy

($n = 182$). Of note, prolapse surgery was performed in the anterior compartment only; concomitant prolapse surgery for the other compartments or for incontinence was excluded. At 1 year, the success rate, defined as POPQ point Ba $< \mp 1$ and absence of vaginal bulge symptoms, was significantly greater after the mesh repair (61%) as compared to colporrhaphy group (35%). The subjective success rate was also significantly greater after the mesh repair (75% versus 62%, $p = 0.008$) as compared to the native-tissue repair, while no difference was detected on validated pelvic floor questionnaires (Urinary Distress Inventory) between the groups. The Prolift mesh procedure was associated with greater morbidity including longer operating time, greater blood loss, and higher rate of intraoperative cystotomy (3.5% versus 0.5%), greater rates of postoperative de novo stress urinary incontinence (12.3% versus 6.0%), and higher combined reoperation rates for stress incontinence, prolapse, and mesh exposure (6% versus 0.5%). De novo dyspareunia was seen in 7.3% after the mesh surgery as compared to 2% after anterior colporrhaphy ($p = 0.07$); however, no difference was detected in overall postoperative sexual function. Reoperation for mesh exposure occurred in 3.2% after the Anterior Prolift in this trial; the overall rate of mesh exposure was 11.5% [27,37].

A 2012 Cochrane review [36] concluded that the use of permanent synthetic mesh for anterior prolapse repair was associated with a decreased anatomic failure rate when compared to anterior colporrhaphy alone (14% versus 49%; RR 3.50, 95% CI 2.71–4.52), but no differences are found in the reoperation rate for prolapse or for improvement in quality of life measures. While the trial by Altman et al. [37] demonstrated improved subjective outcomes with the use of transvaginal mesh, this was not demonstrated in the other trials. However, because of the large size of the Altman study, the Cochrane meta-analysis concluded decreased subjective failure with transvaginal mesh in the anterior wall (17% versus 28%; RR 1.62, 95% CI 1.22–2.14) [36]. Of note, the use of mesh in the anterior vaginal wall appeared to predispose to prolapse in the apical and posterior segments in these trials compared to native-tissue repair. The Cochrane reviewers also found that anterior vaginal mesh placement was associated with greater operating time, greater blood loss, and a tendency for more cystotomies and de novo stress urinary incontinence. Also, the overall rate of reoperations including reoperation for recurrent prolapse, de novo stress incontinence, or mesh exposure was almost two times higher after anterior vaginal mesh than native-tissue repair (10.2% vs. 5.8%) [36].

Vaginal mesh erosions can be a particularly difficult problem and a small but significant number require reoperation for mesh removal due to chronic discharge, bleeding, pain, and other serious complications [38]. The average rate of mesh exposure reported in the literature in the first year after transvaginal mesh placement for pelvic organ prolapse is 10.9%. More than half of the women who experience erosion or exposure from nonabsorbable synthetic mesh after transvaginal placement require surgical excision in the operating room with some women requiring multiple operations. Creation of thicker vaginal flaps with an attached fibromuscularis, limiting vaginal trimming, and avoiding inverted "T" colpotomy incisions or concurrent vaginal hysterectomy probably decreases the mesh erosion rate.

It is worth emphasizing that the great majority of clinical trial evidence available for anterior transvaginal mesh placement involves using trocar-based mesh products that are no longer commercially available in the United States. In recent years, there has been a significant shift toward the nontrocar-based mesh kits for which there are currently few data. Moore et al. [39] performed a prospective multicenter cohort of 60 women receiving Anterior Elevate® (American Medical Systems, Minnetonka, MN) for anterior vaginal prolapse. They reported an anatomic success rate of 92% and a mesh exposure rate of 0%. Vu et al. [40] reported a retrospective analysis of the Uphold system for the treatment of anterior/apical prolapse that included 115 women including 53 who underwent a hysteropexy and reported an anatomic recurrence rate of 5% and a mesh exposure rate of 2.3%. Similarly, Rivaux et al. reported a case series of 59 patients who underwent Uphold hysteropexy and reported a 93% anatomic success rate and 3.5% mesh exposure rate at 12 months [41]. As of the writing of this chapter, no clinical trials comparing nontrocar-based mesh kits for anterior vaginal prolapse have been published.

Risk factors for failure of anterior vaginal prolapse repair have not been specifically studied separate from studies of total prolapse. Vaginal prolapse in general recurs with increasing age and length of follow-up, but the actual frequency is unknown and tends to vary with different definitions of prolapse. Recurrence of anterior prolapse is more likely to occur with more severe initial prolapse and probably with transvaginal, compared to abdominal, repairs [42]. Recurrence may represent a failure to identify and repair all support defects, or weakening, stretching, or breaking of patients' tissues, as it occurs with advancing age and after menopause. Sacrospinous ligament suspension of the vaginal apex, with exaggerated retrosuspension of the vagina, may predispose patients to recurrence of anterior vaginal prolapse; however, a recent clinical trial comparing sacrospinous ligament fixation to uterosacral ligament suspension did not demonstrate a difference in anterior recurrence between these two apical procedures [43]. Other characteristics that may increase chances of recurrence are genetic predisposition, subsequent pregnancy, heavy lifting, chronic pulmonary disease, chronic straining at stool, smoking, and obesity.

Complications

Intraoperative complications are uncommon with native-tissue anterior vaginal prolapse repair. Excessive blood loss may occur, requiring blood transfusion, or a hematoma may develop in the anterior vagina; this is probably more common after vaginal paravaginal repair than anterior colporrhaphy. The lumen of the bladder or urethra may be entered in the course of dissection. Accidental cystotomy should be repaired in layers at the time of the injury. After repair of cystotomy, the bladder is generally drained for 7–14 days to allow adequate healing. Ureteral damage or obstruction occurs rarely (0%–2%), usually with very large cystoceles or with apical prolapse [29,44]. Other rare complications include intravesical or urethral suture placement (and associated urologic problems) and fistulae, either urethrovaginal or vesicovaginal.

Complications unique to synthetic mesh use in the vagina include vaginal mesh exposure or extrusion; mesh erosion or perforation into an adjacent organ including the bladder, urethra, and rectum; and vaginal mesh contraction with associated pain and dyspareunia [45,46]. Complications that can occur with any pelvic reconstructive surgery but that can be made more severe or complicated by the presence of synthetic mesh include bleeding, infection, fistulas, pelvic pain, sexual dysfunction, and dysfunction of the lower urinary and lower gastrointestinal tract. While many of these complications can be managed nonsurgically, a significant proportion will require one or more surgical excision of some or all of the mesh [47]. The incidence of these complications varies from 3% to 39%. A systematic review of 110 studies by Abed et al. [45] found the average rate of graft erosion or exposure to be 10.3% with permanent synthetic grafts and 10.1% after biological grafts. Wound granulation was seen in 7.8%. Approximately, two-thirds of women with a mesh exposure after permanent synthetic mesh placement require some surgery to correct the exposure; in some cases, multiple procedures are required. For a more detailed discussion of incidence and management of mesh or graft complications see Chapter __.

De novo stress incontinence occurs in up to two-thirds of women after anterior vaginal prolapse repair. This risk is higher in women who demonstrate a positive cough stress test with prolapse reduction prior to surgery than those who do not. However, performance of an anti-incontinence procedure such as a midurethral sling or Burch colposuspension decreases this risk whether the preoperative stress test is positive or not [22].

Voiding difficulty can occur after anterior vaginal prolapse repair. This problem may occur more often in women with subclinical preoperative voiding dysfunction, especially if a suburethral plication is done [48]. Treatment is continuous bladder drainage or intermittent self-catheterization until spontaneous voiding resumes, usually within 2 weeks. Urinary tract infections are common (especially with concurrent catheter usage), but other infections such as pelvic or vaginal abscesses are uncommon.

Sexual function may be positively or negatively affected by vaginal operations for anterior vaginal prolapse [49]. Most prospective studies demonstrate that sexual function either does not change or improves in the majority of women after vaginal reconstructive surgery for pelvic organ prolapse; however, worsening sexual function can be seen in some patients. As many as 50% of patients with advanced prolapse report dyspareunia prior to surgery. In general, dyspareunia rates go down after prolapse surgery; however, de novo dyspareunia can be seen, especially if a posterior colporrhaphy is also performed. Vaginal topography, except for perhaps vaginal length, appears to have little relationship with postoperative sexual satisfaction [49]. In a comprehensive study by Kuhn et al. [50] of male and female sexual function after primary repair of vaginal prolapse without the use of mesh, female patients reported improvement in sexual desire, arousal, lubrication, pain, and overall satisfaction, but not orgasm. De novo dyspareunia only occurred in 2 of 70 women. Male partner function improved as well in domains of interest, sexual desire, and overall satisfaction [50]. One prospective comparison of patients undergoing vaginal versus nonvaginal (open or robotic) prolapse repair found that sexual function improved overall after surgery with no difference between groups [51]. Comparisons of sexual outcomes between native-tissue and mesh-augmented repairs have had mixed results with some showing worse sexual function after mesh repairs and others show no difference between the groups. The Cochrane reviewers found no difference in postoperative de novo dyspareunia between native-tissue prolapse repair and those augmented with synthetic or biological grafts [36,52].

83 Enterocele

Kaven Baessler

DEFINITION AND SCOPE

The term “enterocele” is derived from the roots “enter,” meaning intestine, and “cele,” meaning hernia. It is a herniation of the bowel. In general, hernia occurs when a rupture in the smooth muscle or connective tissue allows a bodily structure to protrude. An enterocele is usually referred to as a herniation through or into the vagina typically as a posterior enterocele, which develops in the rectovaginal space (pouch of Douglas or cul-de-sac). The anterior enterocele in the vesicovaginal space is a rare entity [1], which might occur after cystectomy or after hysterectomy [2].

An enterocele is a form of pelvic organ prolapse with the bowel protruding into the vagina. Why and how are etiological and pathophysiological issues which are illustrated in this chapter. Surgical treatment of an enterocele is often concurrent or identical to operations for vaginal vault prolapse. Preventative and therapeutic procedures will be described.

ANATOMY, ETIOLOGY, DEFECTS, AND PATHOPHYSIOLOGY

Normal Anatomy

The important anatomical structures, with regard to enterocele formation, are consistent with normal pelvic organ support mechanisms. An enterocele develops in the pouch of Douglas. Therefore, the pouch of Douglas is an anatomical structure that plays an important and probably predisposing part. The pouch of Douglas is normally closed and does not contain intestine or omentum. In anatomy textbooks, the extent of the pouch of Douglas has traditionally been described as 2–3 cm below the uterosacral ligaments (e.g., Gray’s Anatomy). Histological studies by Uhlenhuth and colleagues have demonstrated that in the fetus the pouch of Douglas may extend to the perineal body [3]. The consecutive fusion of the anterior and posterior peritoneum forms the rectovaginal septum and determines the depth of the pouch of Douglas [3–5]. According to Uhlenhuth, the rectovaginal septum is distinguishable from the “fascial” capsule of the vagina and rectum. In contrast to anatomy textbooks, intra-abdominal measurements of the depth of the pouch of Douglas in young nulliparous women revealed great variations with 25%–75% of the posterior vaginal wall covered with peritoneum [6]. The mean depth of the pouch of Douglas was 49% of vaginal length in nulliparas, 46% in parous women, and was significantly deeper (72%) in patients with posterior vaginal wall prolapse. The mean vaginal length was 10 cm. Age and parity did not have an influence. It would appear that the deep pouch of Douglas is frequently present in young nulliparous women without pelvic organ prolapse, which implies a congenital variation and predisposition [6].

A sophisticated concept of normal pelvic organ support accentuates the imperative role of several factors including integrity of the anterior and posterior endopelvic fascia with intact attachments as well as normal tone, position, and functionality of the levator ani muscle. Normal pelvic floor muscle and fascial structures are required to hold the perineum in place and ensure normal bladder, bowel, and sexual function. It is apparent that fascial defects in the three levels of vaginal support and the posterior compartment may contribute to pelvic organ prolapse including enteroceles [7,8]: the normal pelvic floor tone is essential for the nearly horizontal axis of the vagina, which in turn is necessary to allow for a normal pelvic floor protecting intra-abdominal pressure distribution. These elements might be most important in keeping the pouch of Douglas closed.

Deep Pouch of Douglas as a Predisposing Factor (Figure 83.1)

Principally, a posterior enterocele develops in the pouch of Douglas, which is normally closed. Figure 83.1 illustrates the different characteristics in the development of enteroceles. Intra-abdominal measurements of the depth of the pouch of Douglas have shown that in women with posterior vaginal wall and anterior rectal wall prolapse the pouch of Douglas is significantly deeper and may reach the level of the perineal body [6]. In addition, the anatomy of the pouch of Douglas is considerably different, which is a recognized feature in some studies. In women with severe pelvic organ prolapse, a large or voluminous rectovaginal pouch was a consistent anatomic finding, requiring obliteration during pelvic reconstructive surgery [9–11]. Apart from a mobile vaginal axis and a dehiscence of the levator hiatus, French authors reported a “grande fosse pelvi-périnéale”—a large pelvic pouch—to be the principal lesion in women with enteroceles [12]. Other authors described this phenomenon as an abnormally deep and wide cul-de-sac with a 3D enlargement [13]. Their anatomical observations included a deep and wide rectovaginal pouch and a rectosigmoid colon, which closely follows the sacral curve (Figure 83.2). Although different positions and courses of the sigmoid colon and its mesentery are known [14], systematic descriptions in women with pelvic organ prolapse are scarce. Baessler and Schuessler found 64% of women with enteroceles and all women with anterior rectal wall procidentia to have these features, termed as “grande fosse pelvienne.” A grande fosse pelvienne was also present in 6 of 43 women (14%) in the control group who did not have pelvic organ prolapse. Three of them were nulliparous [15]. Given these findings, it seems reasonable to regard a deep pouch of Douglas as a risk factor for enterocele formation. However, a deep pouch of Douglas does not necessarily result in an enterocele. An enterocele can only develop when other factors open and expose the deep pouch of Douglas.

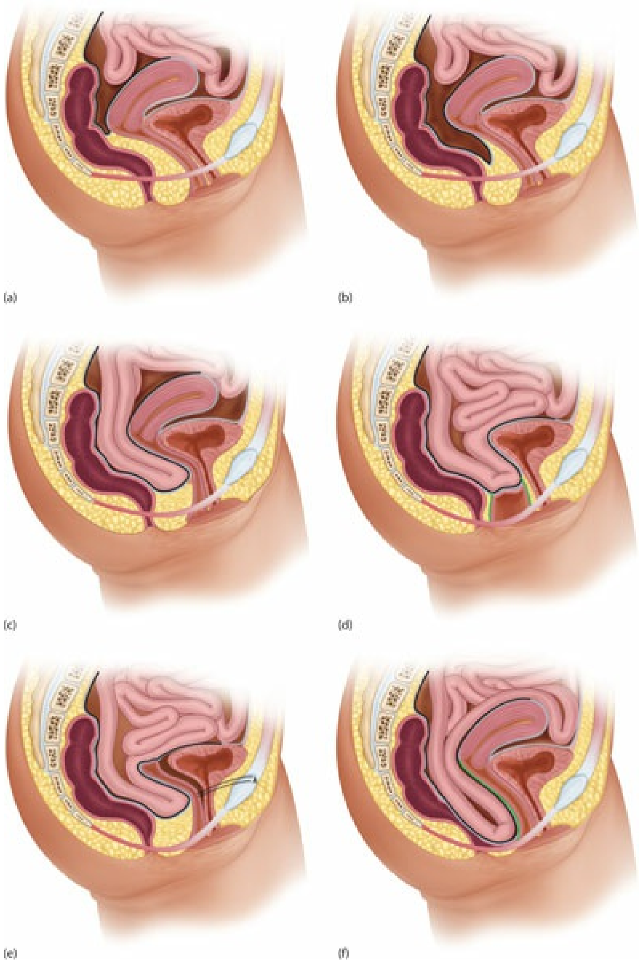

Figure 83.1 The pouch of Douglas—“normal” depth, deep, grande fosse pelvienne. (a) “Normal” pouch of Douglas: the pouch of Douglas covers approximately one-third of the posterior vaginal wall and is closed. (b) Deep pouch of Douglas: peritoneum covers the posterior vaginal wall down to the level of the levator ani. Normal pelvic floor support prevents opening and exposure of the pouch of Douglas. (c) An enterocele has developed in the rectovaginal space displacing the posterior vaginal wall: the vaginal and rectal course is more vertical and the pelvic floor position is lower leaving the pouch of Douglas unprotected. (d) Apical enterocele with separation of the anterior and posterior endopelvic fascia after hysterectomy. (e) Enterocele after Burch

colposuspension with ventral displacement of anterior compartment: the pouch of Douglas was not protected. (f) Enterocele bulging primarily into the rectum: anterior rectal wall procidentia. Intact posterior endopelvic fascia (green line).

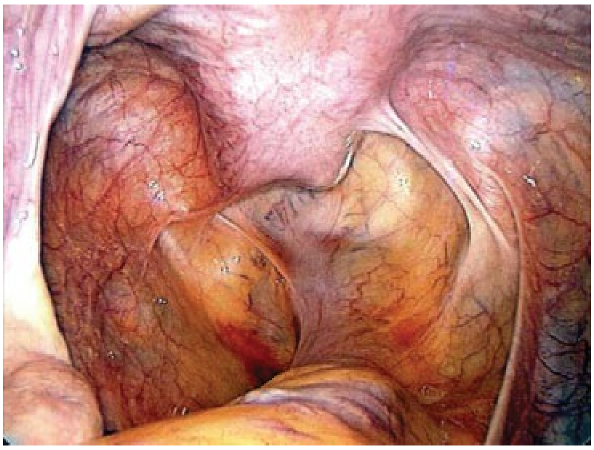

Figure 83.2 Laparoscopic view of a grande fosse pelvienne: note the deep and wide pouch of Douglas, the lack of prominent uterosacral ligaments, and the rectal course close to the sacrum with a short mesentery.

Vaginal Axis

In a woman with normal pelvic organ support, the pouch of Douglas is closed, irrespective of its depth, and lies nearly horizontally between the levator plate and the vagina [16–18]. A recent MRI study measured the mean levator–vaginal angle with a horizontal line at 35°–53° in different ethnic nulliparous populations [19]. It is known that operations that change the vaginal axis can lead to increased prolapse in the “unprotected” area. This is true for the higher incidence of cystoceles after sacrospinous fixations, where the position of the vagina is more posterior and also for the considerate rate of rectoceles and enteroceles after Burch colposuspensions or ventrofixations where the vagina is displaced anteriorly.

A further process that changes the vaginal axis is excessive perineal descent (or descending perineum syndrome), which is often seen clinically in women with significant posterior vaginal wall prolapse (Figure 83.3). A deep pouch of Douglas is likely to accentuate the process of enterocele development once the vaginal axis is changed.

Endopelvic “Fascia”

The integrity of the anterior and posterior endopelvic *fascia* or connective tissue and its attachments is essential for normal pelvic organ support [8]. A defect in the endopelvic *fascia* or insufficiency is necessary for an enterocele to protrude. However, an intact endopelvic connective tissue might only prevent the enterocele from bulging into the vagina but not into the rectum causing an anterior rectal wall procidentia (Figure 83.1f).

It is not entirely apparent whether the endopelvic *fascia* is identical to the rectovaginal septum as the latter can be rather short [20], depending on the depth of the pouch of Douglas. Whole-thickness biopsies of the leading edge of radiologically proven enteroceles showed that in none of the 13 women examined the vaginal epithelium was in direct contact with the perineum and all had a well-defined vaginal wall muscularis [21]. These findings add to the ongoing controversy on whether the *fascia* exists or not. It has been suggested that it is a structure that is artificially created during surgical dissection. This debate is complicated by inconsistent histological studies, some of which do not substantiate the concept of a fascia between the rectum and vagina. However, it might simply be a question of definition: the fascia is a connective tissue usually with smooth muscle cells and it might also contain fatty or areolar tissue [22] (Figure 83.4). Whether the fascia is part of the vagina or rectum or whether it is a separate structure is of scientific but not clinical value. *Fascia* in the clinical sense means connective tissue that has tensile strength and is strong enough to hold sutures and support the underlying organs.

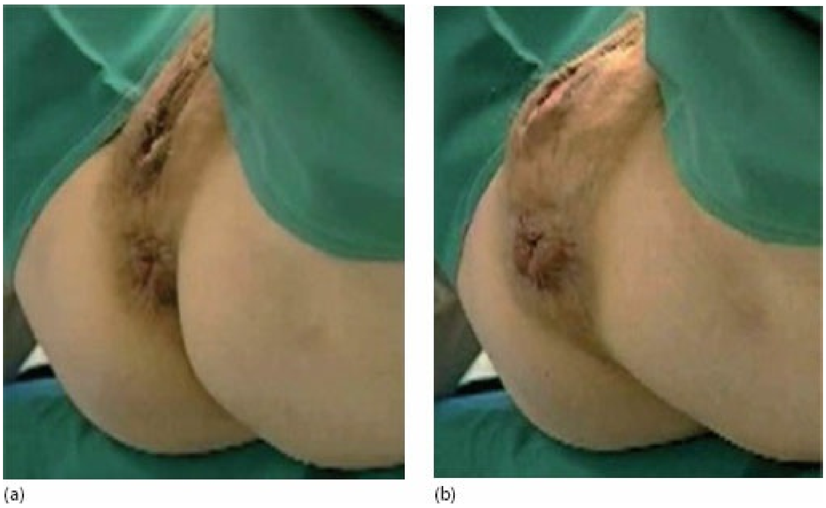

Figure 83.3 Excessive perineal descent. These photos demonstrate a nearly normal position of the perineum at rest (a) but a “ballooning” of the perineum on straining (b). This patient had a large rectoenterocele that did not protrude outside the introitus.

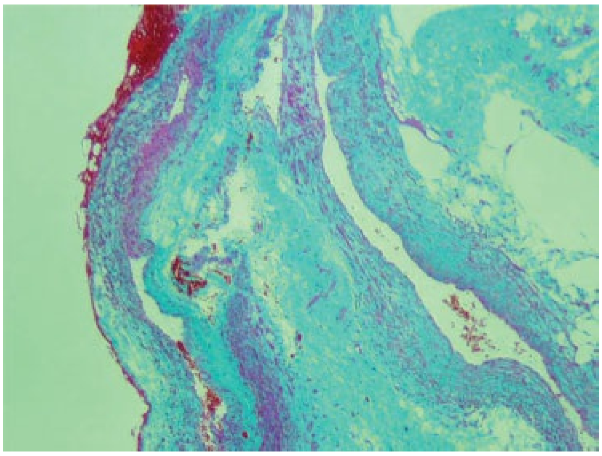

Figure 83.4 The Mallory trichrome stain of a biopsy taken from the tissue used in posterior vaginal wall repairs. The biopsy site was approximately 2 cm below the ischial spine. This stain is used to differentiate fibrous tissue (green) and smooth muscle (red). Note the amount of smooth muscle, organized connective tissue, and areolar tissue. (Courtesy of Dr. Christopher Maher.)

Descending Perineum Syndrome

This syndrome has been described by colorectal surgeons as a “ballooning” of the perineum during straining (Figure 83.3) [23]. Apart from bowel symptoms, which can be similar to complaints of patients with rectoceles or enteroceles, excessive perineal descent of more than 2 cm (measured in relation to the ischial tuberosities) is seen more frequently in women with posterior vaginal wall prolapse [24]. Solitary rectal ulcer, rectal prolapse, and intussusception are common concomitant findings [24,25]. The etiology is unclear, but reduced pelvic floor tone [26] with insufficient perineal and endopelvic *fascial* attachment and a deep pouch of Douglas and sigmoid colon elongation have been discussed. The term “ballooning” is also used to describe an enlargement of the genital hiatus during straining on perineal 3D ultrasound and is associated with pelvic organ prolapse [27].

Pulsion, Traction, Sliding, True, and Congenital: Concepts of Enterocele Development

There are different concepts, and each one of them might be true in an individual patient. The idea of finding a one-fits-all theory is probably in vain. Enteroceles may develop as a *true hernia* with a hernial sac and neck. A defect in the endopelvic connective tissue is then a prerequisite. It is argued that a *traction enterocele* is accompanied by the loss of pelvic organ support [17] and a greater vault descent with normal anatomical connections between the pouch of Douglas and vagina [28,29]. In contrast, according to Nichols and Genadry [17], a *pulsion enterocele* is secondary to increased abdominal pressure, whereas Zacharin states that a pulsion enterocele occurs as a late complication of pelvic surgery like hysterectomies and is associated with a large rectovaginal pouch [28]. However, Zacharin is convinced that the depth of the pouch of Douglas has no bearing on enterocele development. He considers levator incompetence and relaxation of the *fascial* support to be the primary defects. Nichols and Genadry describe *iatrogenic enteroceles* as a sequela to operations that alter the vaginal axis like Burch colposuspension and *congenital enteroceles*, which are associated with an "unusually" deep pouch of Douglas (Figure 83.1e).

In theory, an enterocele can only develop when important anatomical factors change: the vagina becomes more vertical and the (deep) pouch of Douglas opens or the pubocervical and rectovaginal *fascia* are separated. Whether a discrete defect in the endopelvic connective tissue is also required remains a topic for discussion. Therefore, Zacharin's observation of a common deep pouch of Douglas found only in Chinese females corroborates the ones mentioned earlier: their pelvic floor status including tone and support prevents an exposure of the rectovaginal pouch.

Rectal Prolapse

Colorectal surgeons view prolapse with a different attitude but have similar problems defining the pathophysiology of rectal prolapse, which might originate from the pouch of Douglas [30]. Altemeier described three types: type 1 is a false prolapse due to mucosal redundancy, type 2 is an intussusception without an association with the pouch of Douglas, and type 3 is a sliding hernia of the rectovaginal pouch [31]. Enteroptoses, or elongation of the rectosigmoid colon, are considered contributing factors [32]. Similar to vaginal enteroceles, type 3 rectal prolapse develops in the pouch of Douglas and basically is an enterocele bulging into the rectum, sometimes termed anterior rectal wall prolapse (Figures 83.1f and 83.6c).

Further Factors

Old textbooks often quote other factors that might contribute to enterocele formation. Apart from established confounders for pelvic organ prolapse like aging, obesity, and constipation with excessive defecatory straining, connective tissue diseases, parity, and malnutrition especially in war times are also mentioned [33].

Increased intra-abdominal pressure may also play a role as it is associated with increased BMI and leads to a larger genital hiatus [34]. Obesity and constipation have been established as risk factors for pelvic organ prolapse [35–37]. A chylous ascites has been described to accentuate pelvic floor defects and cause an enterocele [38].

EPIDEMIOLOGY

The prevalence of enteroceles is inseparable from other pelvic organ prolapse. Isolated enteroceles may occur after pelvic surgery. The classical example is the development of enteroceles after Burch colposuspension in up to 32% [39–41], which has not been described for suburethral tapes. It has also been recognized that enteroceles and rectal prolapse frequently coexist with other defects of pelvic floor support [42–44].

Specific data on enteroceles from women in the community are scarce. In a prevalence study of 639 women aged 45–85 years using the pelvic organ prolapse quantification of the International Continence Society, only 22% had no prolapse at all, 37% had stage 1, 29% had stage 2, 9% had stage 3, and 3% had complete eversion [45].

SYMPTOMS

As with any other kind of pelvic organ prolapse, an enterocele can cause prolapse symptoms including the feeling of a bulge and a dragging sensation, and it can also interfere with bladder, bowel, and sexual function. Unlike a cystocele or rectocele, an enterocele does not appear to cause any stereotypical and pathognomonic symptoms, and very often symptoms cannot be distinguished from those of any coexisting pelvic organ prolapse. Some women primarily complain of rectal symptoms like fullness and incomplete or difficult bowel emptying; however, in others, the prolapse symptoms are predominant [46]. There might be dyschezia and a frequent, unproductive urge to defecate. Anorectal symptoms and degree of posterior prolapse do not seem to correlate [47,48].

Partial or complete obstruction of the urethra might result in voiding difficulties or retention [49,50]. Dyspareunia, "slackness at intercourse," vaginal dryness, and coital incontinence are frequently reported by women with pelvic organ prolapse [51]. Mainly, a complication of previous pelvic floor surgery and hysterectomy, vaginal rupture, and evisceration has been reported in women with enteroceles [52].

CLINICAL ASSESSMENT AND INVESTIGATIONS

Vaginal and rectal examination with special attention to the endopelvic connective tissue is probably capable of identifying most enteroceles although some studies claim an inferiority of clinical examination to radiological studies [48]. Defects in the endopelvic connective tissue and their location with diminished vaginal rugae are a clue (Figure 83.5). Simultaneous bimanual examination of the tissues between the vagina and rectum under straining or in the standing position usually helps. An enterocele can be located in the anterior vaginal wall where it divides the pubocervical *fascia* in the posterior vaginal wall through the pouch of Douglas or it might separate the anterior and posterior endopelvic *fascia* at the vaginal vault (apical enterocele). Occasionally, peristalsis of the intestine bulging into the vagina establishes the diagnosis. If in doubt and a diagnosis is necessary, intraoperative evaluation during dissection will ascertain the presence or absence of an enterocele. However, perineal ultrasonography has gained popularity and has become the investigation of choice.

Perineal ultrasound may depict an enterocele [53], especially when performed in an upright position. This is its advantage over MRI; it can be performed standing, during straining or coughing, and even during simulated defecation using ultrasound where using gel in the rectum is possible. No opacification is required and the equipment is widely available. In Figure 83.6a, an enterocele descends between the rectum and vagina in a patient after hysterectomy. In a different patient, bulging into the rectum is also noted, explaining the patient's evacuation problems (Figure 83.6b and c). Three-dimensional ultrasound can also produce astounding images (Figure 83.7). Although limited in the evaluation of structures located more proximally, it may provide information on endopelvic connective tissue defects and pelvic floor dynamics (Figures 83.6 and 83.7) and may replace defecography [54,55]. But even with conventional 2D perineal ultrasound, an enterocele can be identified. Rectal ultrasound can also be helpful; sonographic diagnosis of an enterocele was confirmed intraoperatively in 27 of 29 cases in one study [56].

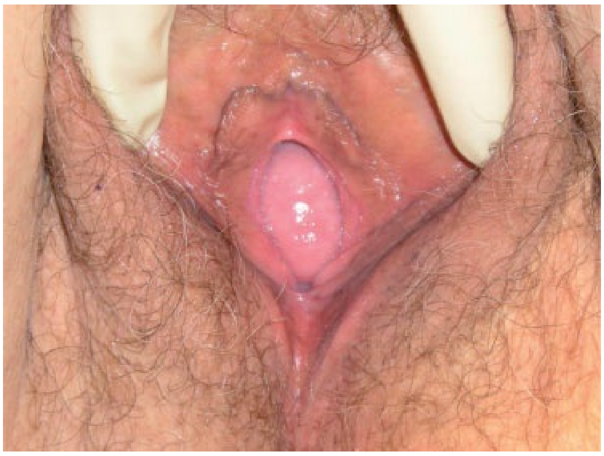

Figure 83.5 A rectoenterocele with diminished vaginal rugae.

Viscerography or fluoroscopic imaging includes the opacification of the bladder, rectum, and vagina with contrast medium. An additional barium meal will show the small bowel on x-ray. Ideally, the investigation is performed dynamically during straining or coughing and comprises defecography. The bowel evacuation gives room and is crucial for some enteroceles to descend. It will also provide further information on bowel emptying, rectal prolapse, or intussusception [47,57] although there are great variations of “normal” findings. Shorvon et al. could demonstrate that rectoceles and intussusception are frequently present in young and asymptomatic women [58]. It is therefore most valuable when the clinician performs the radiological investigations and interprets the findings in context with the symptoms.

Dynamic MRI including defecation MRI provides superb images but has major disadvantages: it is expensive, not widely available, and, at present, performed in the supine position only. Defecation in this situation might be impossible for some patients, and for the diagnoses of enteroceles, it may be inferior to defecating fluoroscopy studies [59]. However, the pictures obtained are remarkable and usually provide an accurate diagnosis (Figure 83.8) [60].

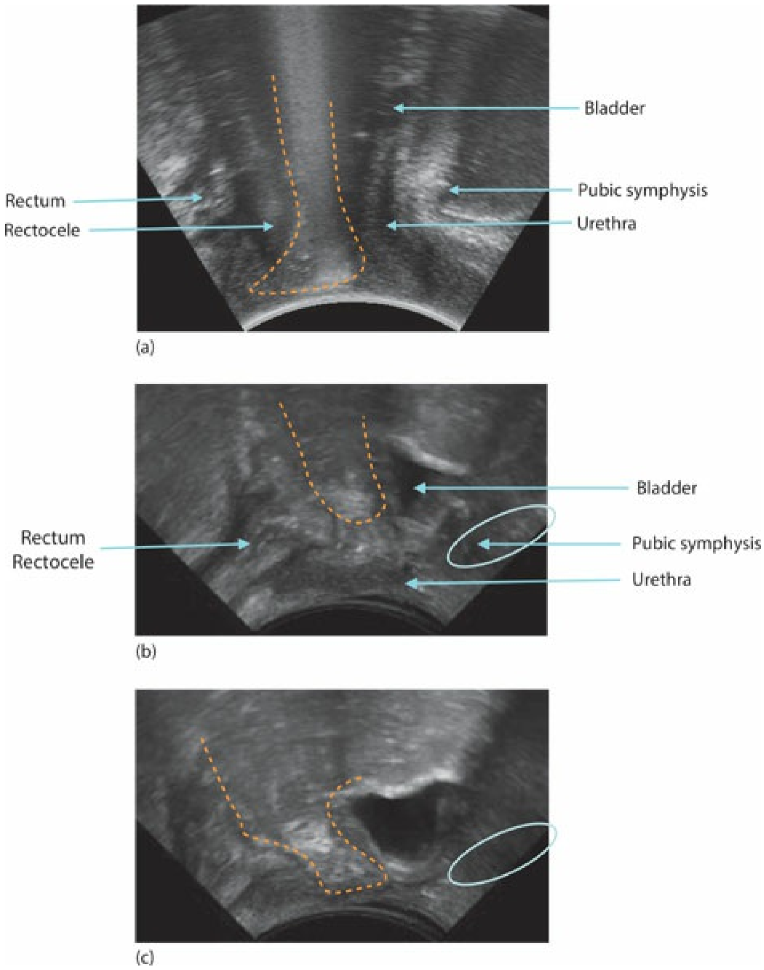

Figure 83.6 (a) Enterocele between the vagina and rectum (dotted line). Note the shadow caused by gas in the bowel. (b) Enterocele between the vagina and rectum at rest (dotted line). (c) On straining, the enterocele descends more not only into the vagina but also into the rectum, causing anterior rectal wall descent.

PREVENTION OF ENTEROCELE

Theoretically, obliteration of the pouch of Douglas and maintaining a normal vaginal axis should prevent enteroceles from developing. Controlled studies assessing prevention of enteroceles are scarce but support modified McCall sutures with reattachment of the uterosacral ligaments to the vaginal vault during hysterectomy [61]. This has long been advocated and several techniques are widely used. At the time of hysterectomy, Cruikshank and Kovac compared three available methods to prevent an enterocele in a randomized controlled trial [62]: obliteration of the pouch of Douglas by suturing the uterosacral ligaments in the midline, called the vaginal Moschcowitz-type operation; the McCall-type culdoplasty, where the uterosacral ligaments are plicated and attached to the vaginal vault and the sutures externalized; and the closing of the peritoneum with a purse-string suture. Up to 3 months postoperatively, all procedures were equally successful (100%). After 3 years, the McCall-type method was found to be superior for enterocele prevention with none of the 32 patients developing a symptomatic enterocele [62].

The prevention of an enterocele after a Burch colposuspension with or without additional pouch of Douglas obliteration by either approximation of the uterosacral ligaments or Moschcowitz-type horizontal purse-string sutures was reported recently [39]. Without Douglas obliteration, postoperative enterocele formation after 3–16 years (mean 9 years) occurred in 19%, whereas after the additional Moschcowitz procedure the incidence was 11% and after uterosacral ligament plication 2%. These differences were significant [39].

Whether extensive distal preparation of the bladder during abdominal hysterectomy with exposure of the pubocervical fascia might contribute to the development of anterior enteroceles is unclear. Also, the utilization of intrafascial hysterectomy might be of value but this has not been assessed systematically. During intrafascial hysterectomy, parts of the endopelvic fascia are maintained in their normal position and plicated over the vaginal vault to prevent separation and subsequent enterocele formation.

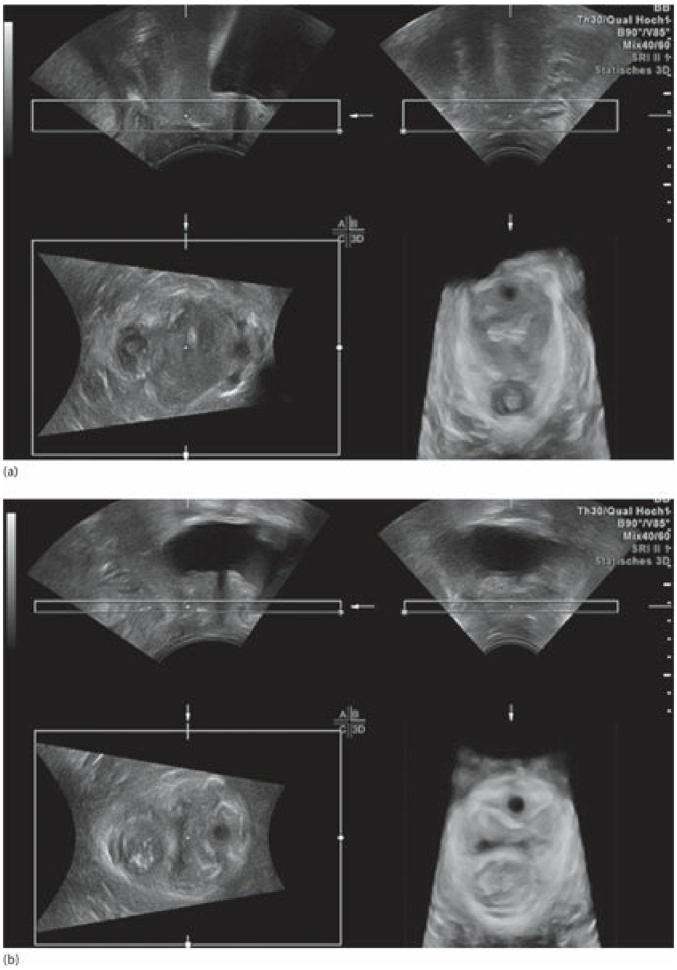

Figure 83.7 Three-dimensional ultrasound. (a) The enterocele between the vagina and rectum can be seen in all three dimensions; the levator is partly damaged but the 3D modulation shows it to be intact in some levels. (b) In comparison, the image shows a rectocele with an intact levator ani, and in the 3D image, the ventral displacement of the posterior vaginal wall is visible.

CONSERVATIVE TREATMENT

Treatment of pelvic organ prolapse depends on the patient's preferences for management, associated symptoms, extent of prolapse, and whether the patient has completed her family. As subjective and objective success and durability of our current surgical prolapse repairs remain limited and the women's longevity is increasing, more patients might ask for conservative options. Conservative treatment of pelvic organ prolapse in general includes the use of pessaries [63] and pelvic floor muscle training [64]. Vaginal pessaries might prevent deterioration of the prolapse and alleviate symptoms of prolapse and are especially useful if there is a long waiting list for surgery [63]. There is an extensive range of mechanical devices available to reduce the prolapse, but literature on success and complications is inadequate especially if isolated enteroceles are considered. Pessaries are an option, and a trial of pessary fitting can easily be performed in clinics and can be managed by educated nurses or continence advisers. In a comparative study, pessaries alleviated pelvic floor symptoms similarly to prolapse surgery [63]. Dissatisfaction with pessary treatment was associated with the development of occult stress urinary incontinence [65].

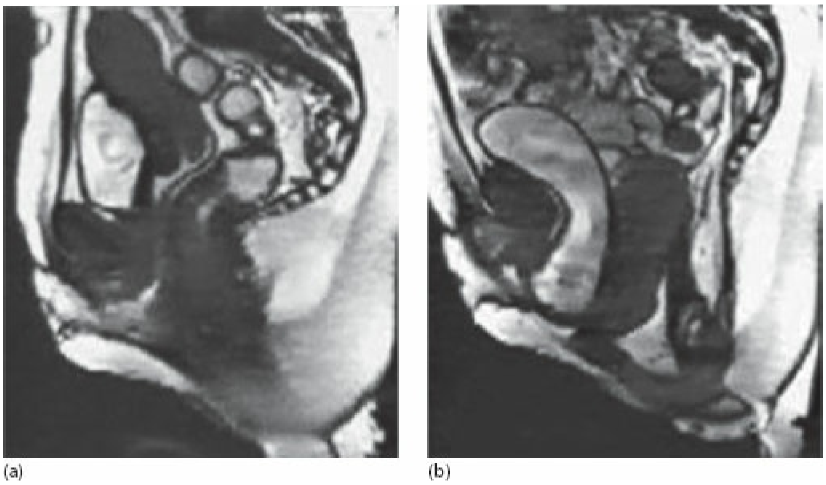

Figure 83.8 Enterocele, considerable pelvic floor and perineal descent, uterine, and bladder prolapse: MRI pictures (a) at rest and (b) during straining.

SURGICAL TREATMENT

There are procedures that only obliterate the pouch of Douglas by plicating the peritoneum like the Moschcowitz or Halban operations or the uterosacral ligaments like the McCall procedure (Figure 83.9). The failure rates are high if there is insufficient pelvic floor support present and an additional solid repair is omitted. Peritoneum alone is not a supportive structure. Therefore, best results might only be achieved when the pouch of Douglas obliteration is combined with surgery to support the vaginal vault or uterus. This can be achieved by native tissue repairs like sacrospinous or uterosacral ligament fixation by using mesh interposition between the vaginal vault and the sacrum (abdominal or laparoscopic sacrocolpopexy) or by vaginal mesh placement (transischiorectal mesh arm placement or direct mesh attachment to the sacrospinous ligament) [66]. An enterocele has been recognized as a risk factor for recurrence of prolapse and for persistence of obstructive symptoms [67,68].

Synthetic mesh is increasingly used in the treatment of posterior vaginal wall prolapse and is meant to reinforce the rectovaginal septum [69]. However, there are few studies that address enteroceles directly. To date, there is no evidence to encourage the use of mesh in the posterior compartment [70]. In the Cochrane review of surgical management of pelvic organ prolapse, the lack of randomized controlled trials for enterocele repair was apparent [70].

The stapled transanal rectal resection for obstructive defecation, rectocele, and/or intussusception has gained popularity although data are limited and ambiguous [71,72].

Operations to Obliterate the Pouch of Douglas

Several horizontal, circular, purse-string-type sutures beginning at the most distal part of the pouch of Douglas/enterocele form the so-called Moschcowitz procedure, which was described by him in 1912 after extensive anatomical studies of rectal prolapse [30]. Although he found it a successful operation in his patients, it has subsequently been associated with a high failure rate and complications like ureteral kinking and small bowel obstruction [73]—although there is a lack of controlled studies. Currently, it is usually used only as an adjunct to major pelvic floor surgery.

Occlusion of the pouch of Douglas as described by *Halban* in his textbook in 1912 includes several sagittal sutures positioned along the pouch in a vertical direction (Figure 83.10) [33]. Although there is less risk for ureteral damage, the ureters should be checked carefully. As with the Moschcowitz operation, this approach has not been studied systematically and is currently performed concomitantly with other pelvic floor surgeries.

Both the Moschcowitz and Halban obliteration were initially described as abdominal procedures but can also be achieved transvaginally or laparoscopically [74,75]. The McCall, Halban, and Moschcowitz procedures and their plentiful variations can be performed prophylactically to obliterate a deep pouch of Douglas or therapeutically to correct an enterocele.

As described earlier in the prevention of enterocele, there are several methods available to close the rectovaginal pouch vaginally but also abdominally. A popular approach is the simple *plication of the uterosacral ligaments* in the midline and the *McCall culdoplasty* with its numerous modifications (Figures 83.9 and 83.10). The principal structure employed is the uterosacral ligament, which is sutured together in the midline with several interrupted stitches or one continuous stitch. Modifications include the incorporation of the vaginal vault or cervix into the sutures. After the suture is passed through the uterosacral ligaments on either side with or without inclusion of the rectosigmoid serosa, it is tied, and the ends are passed through the medial aspect of the upper vaginal wall. Permanent or delayed absorbable sutures should be used although there are no controlled studies to corroborate this. Nonabsorbable sutures should not be passed through the vagina to avoid any sinus formation or abscess. Long-term success rates at 5 and 7 years are very good after the McCall culdoplasty and Douglas obliteration [66,76,77].

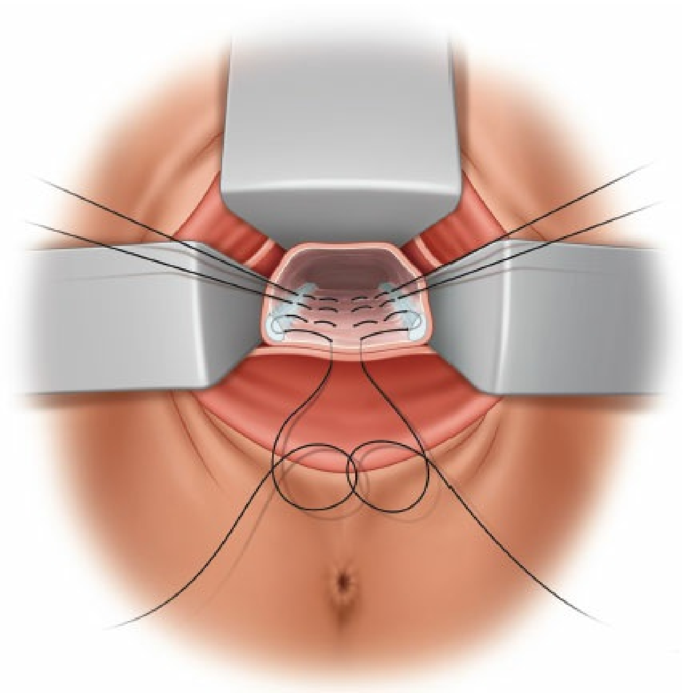

Figure 83.9 McCall procedure: this is one of several different methods of suture placement.

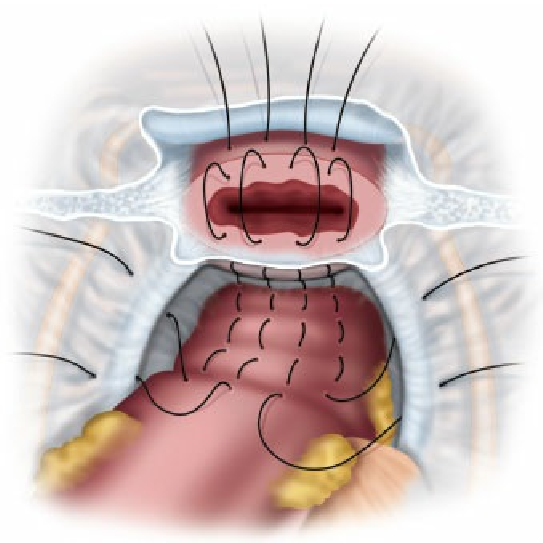

Figure 83.10 **A** combination of a Halban-type pouch of Douglas obliteration with sagittal sutures and a McCall-part with incorporation of the uterosacral ligaments after concomitant abdominal hysterectomy. Note that the anterior and posterior endopelvic fascia are joined over the vaginal vault and incorporated in the pouch of Douglas obliteration.

Vaginal enterocele repair comprises identification, preparation, and opening of the enterocele sac, high closure of the peritoneum with a purse-string suture, and excision of the sac if preferred. The failure rate with this repair was reported at 33% in one study although 72% of women also received a posterior repair and 22% had a Burch colposuspension [78]. A site-specific fascial defect repair with reattachment of the disruption might complete the vaginal repair. Although there are many studies employing grafts and mesh in the posterior vaginal compartment, only few analyze enteroceles separately. Graft reinforcement may reduce enterocele recurrence [79] but controlled studies are lacking.

Effect of Pelvic Organ Prolapse Operations on Enterocele Formation

A surgical technique to suspend the vaginal vault and reattach the endopelvic fascia to the uterosacral ligaments has been studied by Shull et al. [80]. During repair, the concept of prolapse as a hernia is meticulously followed. Using one suture, the anterior and posterior endopelvic connective tissue is connected to the uterosacral ligaments thereby completely covering the vault with this endopelvic connective tissue. Two or three permanent stitches along the ligament might be passed; the more proximal sutures correspond with, the more lateral placements in the anterior and posterior endopelvic connective tissue. The success rate for vault prolapse and enteroceles was reported to be 99% [80]. This method was originally described as a vaginal procedure but using these principal steps and some modification allows it to be performed (at least partly) laparoscopically as illustrated by Miklos et al. [81] and Paraiso et al. [75]. Laparoscopically, the sutures are placed through the uterosacral ligaments, which are later, during the vaginal part of the operation, passed through the anterior and posterior endopelvic connective tissue. Early success rates were 100%, with no recurrent enteroceles [81]. Similar vaginal procedures that include some form of uterosacral ligament plication and address an enterocele have been described by Karram et al. with a 7% enterocele recurrence rate [82].

There are two randomized controlled trials comparing the transvaginal and transanal rectocele repair [83,84]. The authors reported a higher incidence of enteroceles and rectoenteroceles in the transanal repair group. It was suggested that the transvaginal posterior repair with continuous plication of the endopelvic connective tissue from the perineal body to the vaginal apex offers protection against enterocele formation [85]. A posterior colporrhaphy augmented with Vicryl mesh is not superior to a simple posterior repair in terms of recurrent enterocele, according to one randomized controlled trial [86].

Combined Operations for Pelvic Organ Prolapse and Concomitant Enterocele

There are several vaginal, abdominal, and laparoscopic operations that address vaginal vault or uterine prolapse and concomitant enteroceles, but there is a paucity of studies that assess long-term objective and subjective outcomes. Open abdominal [87–89] and laparoscopic sacrocolpopexy [66,75,90,91] may include pouch of Douglas obliteration. Obliteration of the pouch of Douglas with Moschcowitz or Halban sutures or rectovaginal mesh interposition as advocated by Villet et al. [92] has been emphasized by several authors because posterior enteroceles behind the mesh have been observed [88,93]. However, on reviewing the available literature, there seems to be no higher incidence of enteroceles in women who did not undergo any form of pouch of Douglas obliteration [88]. There were 12 cases (2.2%) of recurrent vault prolapse or enterocele described out of 549 patients in whom the pouch of Douglas was obliterated. In 548 patients with no obliteration of the pouch of Douglas, the failure rate of vault prolapse was 4.0% (22 of 548 cases) [94].

In a meta-analysis of two randomized controlled trials, the abdominal sacrocolpopexy with mesh and vaginal sacrospinous colpopexy were equally effective with regard to occurrence of postoperative enterocele (OR 0.77; 95% CI 0.28–2.06) [95,96]. Nonrandomized comparisons of sacrospinous and iliococcygeus colpopexy did not reveal any difference with respect to postoperative enteroceles [97]. The same applies to fixation of the cervix/uterus or vaginal vault to the sacrospinous ligament [98]. Sacrospinous ligament fixation, sacrocolpopexy, and rectopexy appear to be effective in controlling enteroceles [66,87,95,99–101].

SYNOPSIS

An isolated enterocele is rare and usually occurs after pelvic surgery that displaces the vaginal axis, leads to disruption of the anterior and posterior endopelvic connective tissue, or exposes the pouch of Douglas. A deep pouch of Douglas might predispose to enterocele formation. Enteroceles are frequently associated with pelvic organ prolapse in other compartments. Symptoms vary widely and include prolapse sensation, disturbance of defecation and micturition, and dyspareunia. During careful clinical vaginal and rectal examination, enteroceles can usually be identified, but imaging techniques such as ultrasound, viscerography and MRI are helpful.

There are two procedures that close the peritoneum of the pouch of Douglas only: the Moschcowitz operation with horizontal sutures and the Halban method with vertical suture placement. Several other procedures and modifications utilize the uterosacral ligaments. These repairs can be performed vaginally, abdominally, or laparoscopically and are usually combined with other pelvic floor reconstructive surgeries. Operations that address vaginal vault prolapse might be necessary to accomplish a good anatomic and symptomatic result. To date, there are no data available to recommend one particular procedure.

84 Rectocele: Anatomic and Functional Repair

Audra J. Hill and Marie Fidela R. Paraiso

INTRODUCTION

Disorders of the posterior pelvic floor are associated with disturbances in the integrity of the pelvic floor musculature and disordered defecation. Since the early nineteenth century, surgeons have performed posterior colporrhaphy to manage tears of the perineum. The supports of the genital organs were largely a mystery, and there was little distinction between prolapse of the rectum, bladder, and uterus. As anatomic concepts developed, surgeons ascertained that the main support of the uterus was the vagina, which in turn is supported by the insertion of the levator ani muscles into the perineum. This concept was the basis for the incorporation of plication of the levator ani muscles into posterior colpoperineorrhaphy, with the surgical goals of restoring the anatomic support of the vagina and rectum without compromising functionality. Until recently, very little attention has been given to the functional derangements that are commonly associated with rectoceles.

In 2010, an estimated 166,000 women underwent surgery for pelvic organ prolapse with a rectocele procedure occurring in approximately half of the cases [1]. The prevalence of rectoceles ranges from 12.9% to 18.6% with an average annual incidence estimated to be 5.7 cases per 100 women years [2,3]. A rectocele is an outpocketing of the anterior rectal and the posterior vaginal wall into the lumen of the vagina and is fundamentally a defect of the rectovaginal septum, not of the rectum. Some rectoceles may be asymptomatic, whereas others may cause such symptoms as incomplete bowel emptying, sensation of a vaginal mass, pain, and pressure. The size of the defect does not necessarily correlate with the amount of functional derangement or severity of bowel symptomatology [4,5]. This chapter reviews the anatomy, pathophysiology, diagnosis, and management of rectoceles.

ANATOMY

In 1839, Denonvilliers first described a layer of fascia found in males, which he named the “rectovesical septum.” Nichols and Milley later recorded the existence of this septum in surgical dissections and autopsies of fresh female cadavers [6]. This layer of connective tissue is fused to the undersurface of the posterior vaginal wall. The rectovaginal “fascia” extends downward from the posterior aspect of the cervix and the cardinal–uterosacral ligaments to its attachment on the upper margin of the perineal body (PB) and laterally to the fascia over the levator ani muscle. Richardson [6] states that the rectovaginal septum and uterosacral ligaments provide suspensory support of the PB from the sacrum. Histologically, the rectovaginal septum shows that the distal portion contains dense connective tissue; the midportion contains fibrous tissue, fat, and neurovascular tissue; and the proximal portion is mostly fat cells [7]. Hence, it is recognized that this is not a true fascial layer. Posterior to the rectovaginal septum lies the rectovaginal space, which provides a plane for dissection. In between the rectovaginal septum and the rectum is the pararectal “fascia”; inside this fibromuscular layer lies blood vessels, nerves, and lymph nodes, which supply the rectum. The pararectal fascia, originating from the pelvic sidewalls, divides into fibrous anterior and posterior sheaths, which encompass the rectum. These layers provide additional support to the anterior rectal wall [7]. Histological study of the smooth muscle content of the posterior vaginal wall of women with prolapse revealed significantly reduced smooth muscle content compared to women without prolapse [8].

Further support is provided by the levator ani, which are composed of paired iliococcygeus, puborectalis, and pubococcygeus muscles. These muscles function to maintain a constant level of baseline tone and a closed urogenital hiatus. This constant basal tone prevents descent of the pelvic viscera on a daily basis. The puborectalis muscle act as a sling that angles the posterior wall about 45° from the vertical and closes the potential space of the vagina. These levator ani muscles also provide a contraction reflex to increased intra-abdominal pressures, preventing incontinence and prolapse. The PB fuses anteriorly in the distal posterior vaginal wall. The anterior portion of the external anal sphincter and its attachment to the internal anal sphincter makes up the posterior portion of the PB. The anterior sacral nerve roots S2–S4, which innervate these muscles, cross the pelvic floor, and are stretched and compressed during labor, increasing the risk of injury [7,9].

ETIOLOGY

Rectoceles were once thought to be a condition affecting only multiparous females and resulting from obstetric damage or increased tissue laxity with aging and menopausal atrophy. However, rectoceles and enteroceles have been noted to occur in approximately 40% of asymptomatic parous women [10]. Shorvon et al. performed defecography on healthy, young, nulliparous, asymptomatic volunteers, noting that 17/21 women had small or moderate-sized rectoceles. Rectoceles may be more prevalent than previously thought and may not be a result of parity [11].

The most common causes of rectoceles are obstetric events. Traumatic obstetric events, which usually occur when the presenting fetal part descends quickly in the second stage of labor, can predispose to rectocele formation. The forces of labor may separate, tear, or distend the pelvic floor, altering the functional and anatomic position of the muscles, nerves, and connective tissues. The rectal “fascia” may separate from the PB, causing a transverse defect and low rectocele. Low rectoceles are isolated defects in the suprasphincteric portion of the rectovaginal “fascia.” They are usually caused by obstetric trauma that disrupts the attachments of the levator ani fascia and bulbocavernosus muscles. A palpable defect at the level of the introitus will be noted on the physical examination.

If middle or high rectoceles form, they may alter the vaginal axis. Laxity of the levator ani secondary to the levator detaching from the PB along the vaginal axis allows the pelvic organs to slide downward, following the newly altered axis. High rectoceles often occur from pathological overstretching of the posterior vaginal wall as the rectovaginal “fascia” does not exist at this level. They may also coexist with congenital deepness of the pouch of Douglas [12].

Rectoceles may occur as a result of pathologic stretching of the pudendal nerves during descent of the fetal head, causing atrophy, and denervation of the pelvic floor muscles. Sultan reported that most damage to the pelvic support occurs in the first vaginal delivery [13,14]. Denervation will probably recover after the postpartum period; however, it has been demonstrated that injury may be cumulative with increasing parity [9]. Increased labor duration and weight of the baby directly influence the perineal damage and denervation of the pelvic floor. This neuropathy can lead to the weakening of pelvic floor muscles and development of a rectocele.

Defecation disorders may account for a subgroup of rectoceles. They may lead to the weakening of the rectovaginal septum by continuous straining against an obstruction. Some patients may suffer from paradoxical sphincter reaction (anismus), which is the unconscious contraction of the voluntary striated muscles when attempting to defecate. This constant straining with bowel movements has been shown to cause or worsen a preexisting rectocele and to increasingly weaken the rectovaginal septum by denervation injury [15]. Anismus eventually leads to the accumulation of stool in the rectum, which may complicate pelvic outlet obstruction and cause a progressive cycle, worsening the rectocele.

Congenital absence of the perineum may mimic a rectocele. This pseudorectocele has its posterior vaginal wall exposed because of the lack of inferior support; this may be corrected by surgical reconstruction of the perineum. Congenital absence allows for deepening of the cul-de-sac and weakening of the rectovaginal septum, leading to the development of a high rectocele and enterocele [10,12].

Clinical Presentation

The symptoms associated with a rectocele are summarized in Table 84.1. Clinical symptoms vary from being nonexistent to severe defecatory dysfunction. A common complaint is constipation, which can occur in 20%–58% of patients with rectoceles [16]. Patients may also complain of incomplete rectal emptying, a sense of rectal pressure, or a vaginal bulge. Patients may describe stool becoming trapped in the rectocele pocket itself. Vaginal digitation/splinting or perineal support is sometimes necessary to facilitate defecation [5,17–19]. It is also important to note that many women with rectoceles do not have to splint with defecation, and women without rectoceles may require splinting [4]. Constipation and straining may worsen the symptoms and lead to left lower quadrant abdominal pain if impaction occurs.

Many nonspecific symptoms, such as rectal pain, bleeding, fecal or gas incontinence, low back pain worsening throughout the day but relieved by lying down, and dyspareunia may occur, as well as many other defecatory disorders.

Table 84.1 Symptoms Associated with a Rectocele

Pelvic pressure
Lower abdominal and/or back pain
Sensation of a vaginal bulge
Dyspareunia
Constipation
Stool trapping in the rectum
Incomplete stool evacuation
Fecal incontinence
Asymptomatic

Physical Examination

A rectocele is detected by observing the bulge in the posterior vaginal wall during maximum Valsalva or cough. The patient may be in the dorsal lithotomy position (for the gynecologist) or in the left lateral decubitus position (for the colorectal surgeon). The use of the split blade of a Sims or Graves speculum will support the apex and the anterior compartment and can aid in visualization. A rectocele can be confirmed with a rectal examination during which anterior displacement of the vaginal wall adjacent to the rectum and the PB is noted. An exam should also be performed with the patient standing, as a vaginal exam in this position may identify a more prominent rectocele and rectovaginal examination will reveal small bowel herniating into this space when an enterocele is present. Of women with rectoceles, up to 80% are asymptomatic and can only be diagnosed on physical examination [9,20]. A rectal examination should be performed to evaluate anal sphincter tone and symmetry along with the integrity of the PB. Finally, it is important to evaluate for rectal prolapse or intussusception.

The current standardized system used for prolapse assessment is termed the pelvic organ prolapse quantification (POPQ) system and was described by Bump et al. [21]. The POPQ is a descriptive system that contains a series of site-specific measurements of a patient’s anterior, apical, and posterior pelvic organ support. This nomenclature has replaced the respective terms cystocele, enterocele, and rectocele as it is often uncertain which specific structures are contributing to prolapse at each segment. Prolapse is measured in centimeters relative to the hymenal ring in relation to the six defined points. Points proximal to the hymen are denoted as negative and points distal as positive. The other landmarks that complete the examination are the genital hiatus, PB, and total vaginal length.

In the POPQ system, the posterior segment includes analogous points ascribed to the anterior segment. Point Ba corresponds to a point 3 cm proximal to the hymen in the midline of the posterior segment. Possible values range from –3 to +3 cm from the hymenal ring. Point Bp represents the most distal portion of the posterior vaginal wall. The minimum value is –3 in the absence of any posterior wall prolapse. In the presence of complete vaginal eversion, the maximum value equals the value of C. The PB is measured from the posterior margin of the genital hiatus to the midanal opening. It is very important to note if the PB is truly a firm palpable muscular structure or just an exaggerated skin flap from previous surgical repair.

Richardson described site-specific defects in the rectovaginal septum that occur in various locations including the superior, inferior, right, left, and midline areas [6]. These defects are often noted at the time of surgical intervention [22]. One study has suggested that locating defects during clinical evaluation of the posterior vaginal wall is often inaccurate when compared to surgical assessment at the time of defect-specific repair [18].

DIAGNOSTIC STUDIES

Imaging Studies

Clinical examination has excellent sensitivity for the indication of a rectocele, making the routine use of imaging studies not indicated for the patient with an isolated rectocele. However, the use of imaging studies does become useful when combined with other ancillary data, especially history and symptomatology for the following patients: (1) symptomatology and physical findings do not correlate, (2) the pelvic anatomy is unusual or altered due to previous pelvic surgery or a congenital defect, and (3) the patient is unable to exert maximal straining during pelvic examination. Imaging results should not be used alone to make treatment decisions as studies have noted that radiographic findings of posterior compartment defects do not necessarily correlate with patient symptomatology [23,24].

Currently, universally accepted radiologic criteria for defining pelvic organ prolapse are lacking [25]. In order to identify a rectocele on imaging, a measurement is made from a reference line to a predefined point. Multiple reference lines have been described in the literature, i.e., midpelvic line, pubococcygeal line, or midperineal line [26,27], leading to the difficulty with interpreting and comparing radiographic results.

Dynamic Proctography or Defecography

The use of contrast media in pelvic fluoroscopy allows the various prolapsed organs to be opacified and seen in real time providing a two-dimensional view of rectal emptying. Traditionally, it has mainly been used in the study of anorectal dysfunction as evacuation proctography, which is also known as defecography. The addition of a cystogram (dynamic cystoproctography) to this modality allows further information to be gained during the assessment especially when the possibility of an enterocele or sigmoidocele exists [28].

The equipment required includes a thick barium paste, a radiolucent toilet, and video equipment. Images are taken at rest, during straining effort, and during and after evacuation.

A rectocele is seen radiographically as an anterior rectal bulge that is usually measured as the distance from the anterior border of the anal canal to the maximal point of the bulge of the anterior rectum into the posterior vagina wall. The cutoff value has not been universally agreed, but some authors consider a depth of >3 cm to be abnormal (many asymptomatic women will be found to have a small rectocele 2 cm or less in depth) [11,29]. Identification of posterior anatomic defects on defecography does not always indicate the need for evaluation. In a study of 52 symptomatic women over the age of 75, posterior compartment defects that were found on imaging did not correlate with reported bowel symptoms [23].

Proctography will also note the finding of postevacuation barium trapping, which may help to explain any evacuation dysfunction [30]. During testing, patients can be taught how to apply manual pressure in the vagina to obtain relief from the symptoms associated with incomplete emptying. Defecography may suggest the diagnosis of anismus, which may be the main contributor to a patient’s bowel dysfunction rather than a rectocele [31]. This has important implications because anismus is treated with biofeedback therapy rather than with surgery.

An enterocele is noted as a herniation of the small bowel into the vagina, rectovaginal space, or both. The vagina and small bowel in the pelvis need to be opacified to obtain this diagnosis. They are most evident after evacuation as a full rectum may obscure its visualization. Sigmoidoceles are noted in approximately 5% of proctograms [25]. However, there still may be false negatives with proctography due to insufficient filling of contrast media into the sigmoid. Identification of a sigmoidocele is important in that a patient may require a sigmoid resection or sigmoidopexy as treatment. Vaginal vault prolapse can also be assessed on postevacuation studies. Proctography will detect many enteroceles and sigmoidoceles not seen on pelvic examination [32]. Studies have shown that enteroceles are only identified approximately 50% of the time on physical examination, which is less than the rates of identifying rectoceles and cystoceles [20,33]. This has been attributed to the failure of the patient to strain maximally during pelvic examination, an impediment that is removed during the evacuation phase of cystoproctography. One study by Altringer et al. found that patient diagnosis was changed in 75% of cases after dynamic cystoproctography [33]. Another benefit is that fluoroscopy will identify the specific organs involved in the prolapse.

Magnetic Resonance Imaging

MRI was first introduced as a diagnostic modality for pelvic organ prolapse by Yang et al. [34]. It has many advantages over dynamic proctography:

- It is able to contrast soft tissue structures well.
- It provides images in numerous different planes; it can examine subtle pelvic floor changes such as superior rectovaginal, paravaginal, and uterine defects.
- It can assess pelvic floor musculature.
- Bony landmarks are easier to identify.
- No catheterization is necessary.
- The patient is not exposed to ionizing radiation.

The main limitation is the supine position usually employed by this modality.

It also shares some of the same advantages, including identifying prolapse not noted on physical examination. In addition, MRI defecography facilitates the diagnosis of anismus and intussusception. Another advantage is that the cervix and vaginal vault are often easier to see on MRI imaging than on fluoroscopy due to leakage of vaginal contrast during fluoroscopy. Fluoroscopy may not detect enteroceles in 20% of cases in which small portions of peritoneal fat enter the rectovaginal space [35]. However, due to greater soft tissue contrast with MRI, the various tissue components can be seen with relative clarity. A systematic review of the use of dynamic MRI in imaging of pelvic organ prolapse revealed that there is lack of any standardization of prolapse assessment and the posterior segment is the most promising segment where imaging can better aid in diagnosis [26].

Disadvantages of MRI include

- Limited access to a vertical configuration magnet
- Increased relative cost to fluoroscopy
- Less physiologic modality than fluoroscopy if performed supine and without evacuation studies
- Most importantly, lack of correlation with clinical staging [36,37]

Ultrasonography

Transperineal ultrasound has been described in the assessment of dynamic function of the pelvic floor [38]. Dynamic anorectal endosonography has also been described and may detect the presence of enteroceles [39]. Dietz and Lekskulchai performed translabial ultrasound to define cutoff points for prolapse on the basis of patient’s symptoms. They concluded that descent of the rectum >15 mm below the symphysis pubis was associated with symptoms [40]. Another study has compared the clinical evaluation using the POPQ system and compared it with the ultrasound assessment to discriminate between women with or without symptoms and found that the ultrasound assessment was not any better [41]. The use of endoanal ultrasound may be indicated on patients with decreased anal sphincter tone to evaluate the integrity of anal sphincter complex, which, if damaged, may lead to consideration of a sphincteroplasty. The role of these alternate modalities in regard to posterior compartment defects has not been fully elucidated and needs further study.

Anal Manometry

Anal manometry measures rectal pressures by a transducer or balloon. Its measurement of rectal sensation evaluates the first feeling, urge, and discomfort; this information is used to distinguish causes of constipation. When an individual is able to tolerate increased volumes without signs of increased discomfort or the urge to defecate, overflow incontinence may occur. Careful consideration must be given to this evaluation process because individuals able to tolerate only small volumes in the rectum may have an irritable rectum, causing incontinence or urgency. Overflow incontinence and irritable bowel syndrome may mimic rectocele symptoms such as incontinence or incomplete emptying. If misdiagnosis of a rectocele is made, rectocele repair may exacerbate these disorders by causing a worsening of symptoms [15,42].

Electromyography and Nerve Conduction Studies

EMG and nerve conduction studies also have been used to evaluate defecation disorders. Obstetrical trauma denervates and causes atrophy of the pelvic floor muscles and tissue, which may lead to subsequent pelvic floor weakness. This denervation may be detected by EMG studies, and pudendal nerve terminal motor latency can be used as a method to detect the causes of pelvic floor weakness.

However, the clinical utility of these evaluations is limited.

Colonic Transit Studies

In colonic transit studies, the patient ingests radiopaque markers, which are measured, and the patient undergoes serial abdominal imaging, typically over a period of 5 days, to follow the markers through the right colon, left colon, sigmoid colon, and rectum. A normal transit time is defined as 80% of the ingested markers being expelled by day 5 [43]. Clinically slow transit time is defined as less than two bowel movements per week over several years. The utility of this test in individuals with rectoceles is controversial; some have normal transit times whereas others have prolonged times [44]. Patients whose symptoms did not improve after repair were found to have longer transit times preoperatively [17].

Management

Treatment should only be undertaken if the patient is symptomatic. Once the clinical diagnosis has been made and (if necessary) confirmed by ancillary studies, the decision to operate or to treat conservatively must be made. Most nonsurgical treatments consist of proper bowel training, following an active lifestyle, and eating an appropriate amount of dietary fiber. These steps are the most important when the main complaint is constipation.

Nonsurgical therapies available for posterior prolapse symptoms include expectant management and/or the use of a vaginal pessary. In a study of 100 patients with symptomatic pelvic organ prolapse, patients successfully fitted with a pessary noted significant decreases in vaginal bulge, pelvic pressure, and the need to splint with defecation (14% down to 0%) [45]. For patients diagnosed with anismus, the use of pelvic physical therapy and/or biofeedback is the mainstay therapy [46,47].

Symptoms that respond well to surgery include pelvic pressure, vaginal bulge, vaginal digitation or splinting (which occurs in 20%–75% of symptomatic patients) and outlet obstruction constipation. Gustilo-Ashby et al. analyzed bowel function at 1 year after vaginal reconstruction in a randomized trial of three techniques of rectocele repair. They concluded that posterior vaginal wall repair was specifically associated with a reduction in symptoms of incomplete emptying and straining [48]. Janssen and van Dijke noted that repair increased rectal sensitivity, causing the urge to defecate earlier as a positive predictor of a good outcome [42]. In the colorectal literature, it has been noted that defecography showing a rectocele >2 cm with symptoms is also a good indicator for surgery; however, this finding has not been conclusive in all studies [16]. All patients who undergo a surgical repair should be appropriately counseled that some bowel dysfunction may persist following surgical repair, especially if a motility disorder is present.

Signs and symptoms that are predictive of a poor surgical outcome include a history of the use of potent laxatives, incidence of preoperative pain, and (possibly) large rectoceles in women who had previously undergone hysterectomy [17,42,49]. A few studies in the colorectal literature have noted that hysterectomy disrupts parasympathetic nerves, causing decreased rectal sensation as well as increased rectal compliance, which may not be improved after anatomic correction [42,49]. The persistence or development of dyspareunia after rectocele repair has been variable and is dependent on the surgical technique. Levator plication and overnarrowing of the introitus may lead to increased dyspareunia, whereas site-specific repair has been suggested to improve dyspareunia [22].

SURGICAL REPAIR

Traditionally, the vaginal and transrectal approaches have been used by gynecologists and colorectal surgeons, respectively, as a result of training and familiarity with each technique.

The transrectal approach is often used if perianal/rectal pathology such as hemorrhoids, anterior rectal wall prolapse, or rectal mucosal redundancy is surgically treated concurrently with the rectocele. A vaginal approach is advocated when

- Other genital prolapse (i.e., enterocele, perineocele, apical, or anterior vaginal wall prolapse) is to be repaired, thus avoiding a second incision
- Compromised anal function exists (a transanal retractor may further compromise function) [57,58]
- An anal sphincteroplasty is also performed

- A high rectocele exists (as the posterior fornix or vaginal apex is not reached through the transanal approach) [50]

When performing transvaginal repair of the posterior compartment, two main methods exist: site-specific repair and traditional posterior colporrhaphy.

Site-Specific Rectocele Repair

According to Richardson, rectoceles are caused by a variety of breaks in the rectovaginal fascia [6]. He described the most common break as being a transverse separation above the attachment to the PB, resulting in a low rectocele. Another common fascial break was considered to result from an obstetrical tear or episiotomy that was incorrectly repaired. This midline vertical defect may involve the lower vagina and extend to the vaginal apex. Less common separations involving a lateral separation down one side of the "fascia" were also found to exist. Richardson also stated that a U- or L-shaped tear in the "fascia" might occur. Since Richardson's observation, there has been an increased movement among gynecologists toward site-specific rectocele repair. Richardson recommended performing the repair with a finger in the rectum, so that defects can be easily identified and "fascia" can be appropriately approximated with interrupted sutures.

Before starting any rectocele repair, the surgeon should approximate the introitus by using Allis clamps bilaterally to help determine the amount of, if any, perineal and vaginal tissue that should be excised to correct a gaping introitus. The repaired opening should accommodate three fingerbreadths, taking into account that the levator ani and perineal muscles are relaxed from general anesthesia and may further constrict postoperatively and with postmenopausal atrophy. This is of great importance in a sexually active patient as overcorrection of the gaping introitus can cause narrowing of the vagina and dyspareunia. Initially, an injection of lidocaine with dilute epinephrine or vasopressin below the vaginal epithelium aids with hydrodissection and hemostasis. Next, Allis clamps are placed on the posterior perineum and a diamond-shaped perineal incision is made with the overlying skin excised. However, if the introitus is already narrow, a vertical perineal incision is performed to maintain adequate vaginal caliber. The length and width of the perineal incision are dependent on the epithelium needed for restoration of the PB. Sharp dissection is usually required over the PB because of previous scarring, and caution should be taken during the dissection of the PB, as entry into the rectum usually occurs within 3 cm of the PB (see Figure 84.1). Mayo scissors are used to dissect a plane in the rectovaginal space bilaterally. The posterior vaginal epithelium is dissected away from the underlying fibromuscularis (see Figure 84.2). This is continued laterally to the tendinous arch of the levator ani and extends inferiorly to the PB as seen in Figure 84.3. The surgeon performs blunt and sharp dissection to a level proximal to the bulge, which may correspond with the vaginal apex as seen in Figure 84.4.

Hemostasis is ensured and irrigation may be used to attain a clean operative field to allow inspection for defects. The rectovaginal "fascia" is inspected by the surgeon inserting a finger of the nondominant hand into the rectum. The rectal wall is brought forward, distinguishing the uncovered muscularis (fascial defect) from the muscularis covered by the smooth semitransparent rectovaginal septum. According to the plane of dissection and the location of the defect, frequently the rectovaginal "fascia" must be mobilized off the lateral vaginal epithelium. Defects are individually isolated and repaired with an absorbable No. 0 or No. 2-0 suture. Figure 84.5 is highlighting a transverse defect followed by Figure 84.6 with surgical reapproximation. The surgeon must continuously examine the vaginal caliber to ensure a smooth contour and a diameter of three fingerbreadths. A perineorrhaphy is performed, if indicated, followed by closure of the vaginal epithelium with a running No. 2-0 absorbable suture.

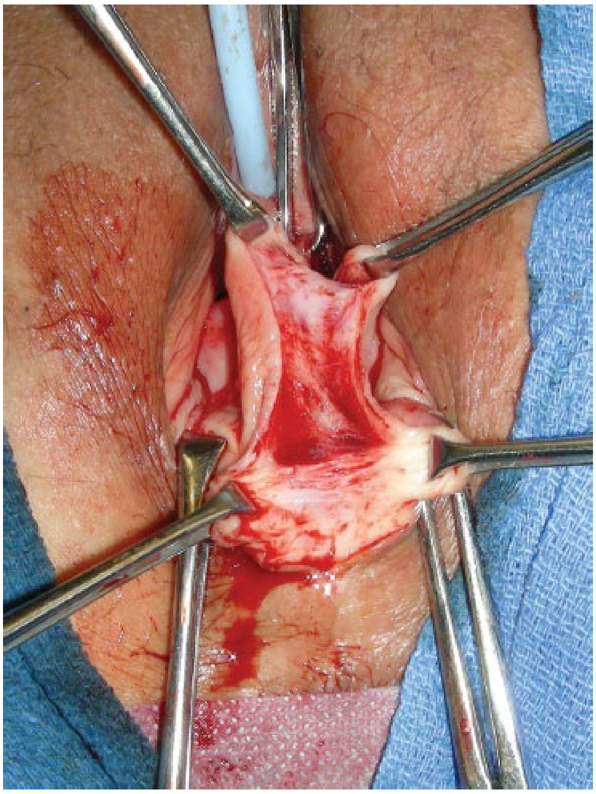

Figure 84.1 Initial view following incision of posterior vaginal epithelium.

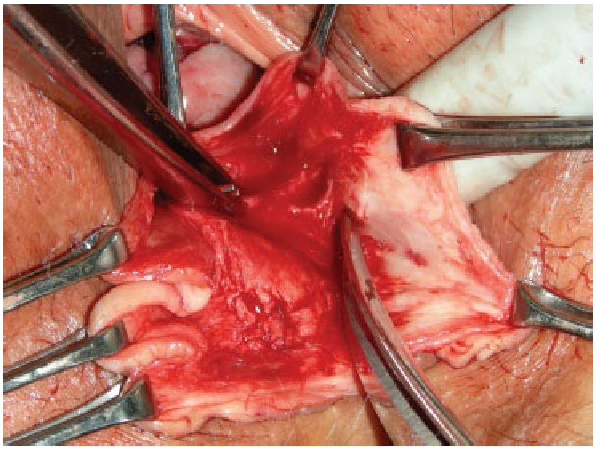

Figure 84.2 Dissection of the fibromuscularis from the lateral posterior vaginal epithelium.

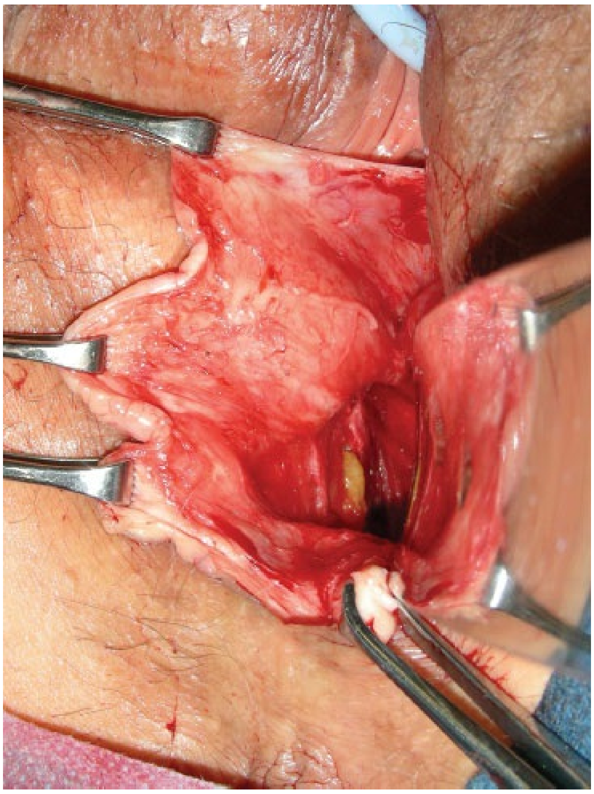

Figure 84.3 Lateral dissection to the level of the levator ani tendon.

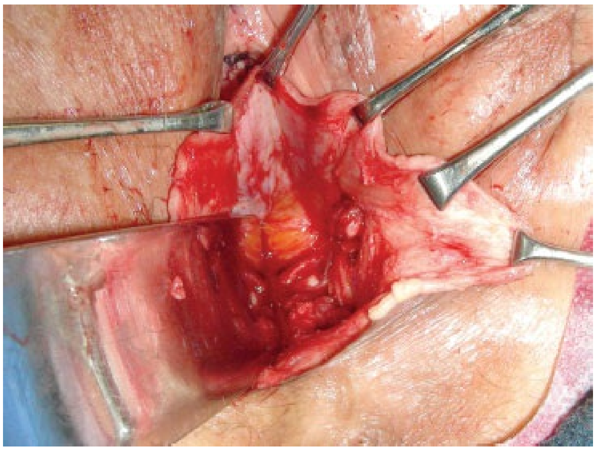

Figure 84.4 Apical dissection to a level beyond the identified defect.

Perineorrhaphy is routinely performed along with a rectocele repair. The goal of a perineorrhaphy is to reconstruct the PB and restore anatomic support. The PB consists of the anal sphincter, the superficial and deep transverse perineal muscles, the bulbocavernosus muscles, and the junction of the rectovaginal fascia with the anal sphincter. A triangular incision is made at the level of the posterior hymen extending to the midline of the perineal skin, and the vaginal epithelium is dissected off the underlying musculofascial complex. The bulbocavernosus muscles are then plicated in the midline using No. 0 absorbable suture in an interrupted fashion followed by the plication of the transverse perinei muscles. Care should be taken to prevent ridging and narrowing of the introitus in a sexually active woman. If dyspareunia is a concern, a triangular incision at the perineum and/or plication of the bulbocavernosus muscles should be avoided.

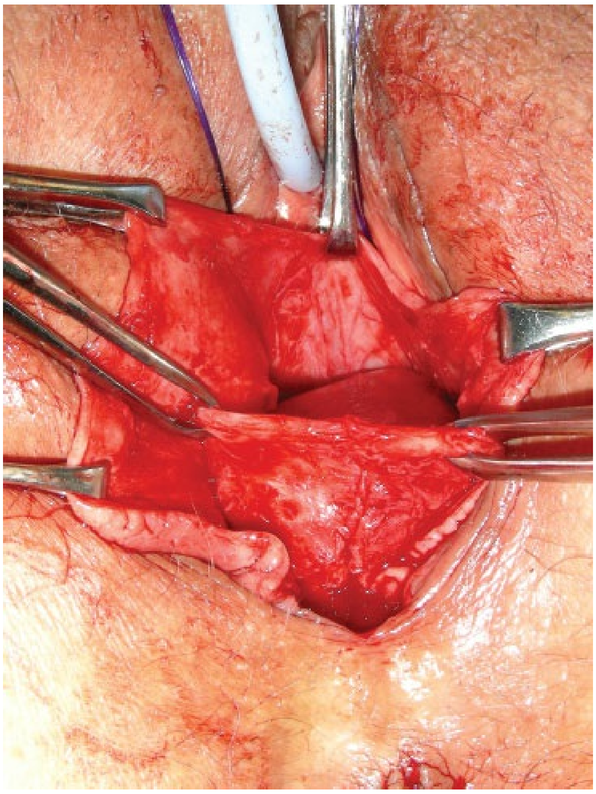

Figure 84.5 Transverse rectocele defect grasped between the Allis clamps.

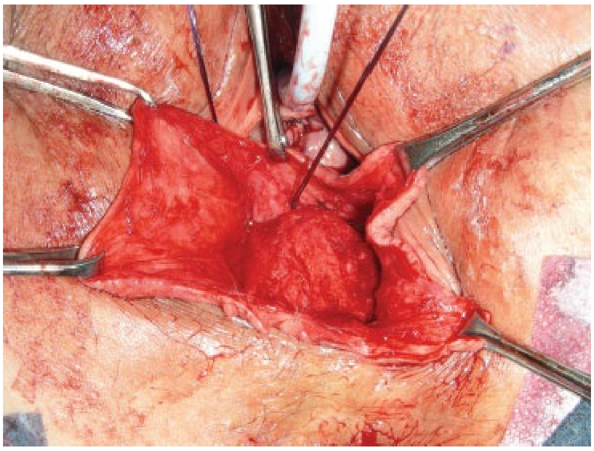

Figure 84.6 Site-specific surgical correction of defect.

Whereas rectocele repair is accomplished for identification of the fascial defect and reapproximation of the connective tissue, evaluation of the levator hiatus is an entirely different issue. In women who have an enlarged levator hiatus, it may be appropriate to place another set of interrupted sutures horizontally to provide a muscular posterior shelf and narrowing of the levator hiatus. This may be a source of postoperative pain and/or dyspareunia. This portion of the operation is not necessary in all patients and is independent of rectocele repair.

Traditional Posterior Colporrhaphy

The traditional rectocele approach has been described and illustrated by Nichols, Wheeless, and others. The opening of the vagina is previously described, via a midline incision or by removal of a triangular wedge of vaginal wall. Some surgeons will place an initial row of No. 2-0 interrupted sutures reapproximating the rectovaginal fascia. The rectocele is then depressed in the midline with the surgeon's finger to reveal the margin of the puborectalis portion of the levator ani muscle. With the rectocele still depressed, a No. 2-0 absorbable suture is used to plicate the fibromuscularis in an interrupted fashion as seen in Figure 84.7. These sutures should be placed in close proximity to each other to repair any noticeable defects. The surgeon should intermittently evaluate the repair both vaginally and rectally to ensure minimal ridging or narrowing of the vagina. The posterior vaginal wall epithelium is trimmed if necessary and closed with continuous 2-0 absorbable suture. The PB is repaired as previously described.

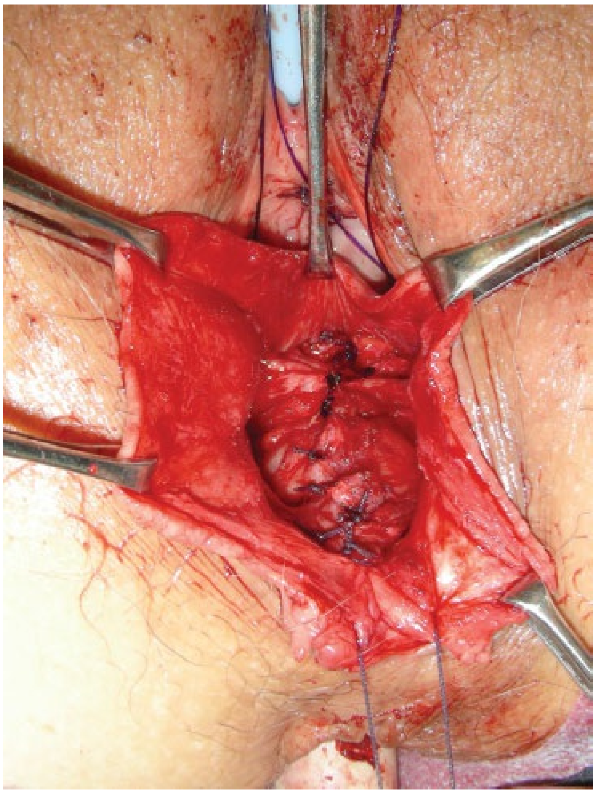

Figure 84.7 Traditional colporrhaphy with tissue plication in the midline.

Transrectal Approach

The transrectal approach was described by Sarles et al. [51] and is routinely utilized by colorectal surgeons in repairing distal rectoceles. Patients are placed in a prone or jackknife position. An anal retractor is used expose the anterior rectal surface. An incision of the anterior rectal mucosa is made 1 cm above the dentate line. The submucosal plane is sharply dissected 8–10 cm from the anal verge. Bleeding is controlled by electrosurgical coagulation. Dissection is performed anteriorly and laterally; the resulting bare areas are plicated using interrupted absorbable suture; the suture includes the rectal muscle and the rectovaginal septum. If the vaginal mucosa is perforated, the stitch is removed. The rectal mucosal flap is excised and a second layer of 3-0 absorbable sutures closes the mucosal defect. The advantage of this approach is that it allows for correction of rectal prolapse and hemorrhoids simultaneously. The disadvantage is that a perineorrhaphy or sphincteroplasty cannot be performed simultaneously. Also, a high rectocele repair is difficult to perform with the same incision.

The stapled transanal rectal resection procedure is another form of endorectal repair that is utilized for the treatment of outlet dysfunction constipation associated with rectocele. A circular stapler and a purse-string suture anoscope are introduced. A portion of the rectocele and the internal rectal prolapse, including the mucosa and muscularis, are resected and stapled off. Varying success rates have been reported following the procedure; however, complications such as fecal urgency, fistula formation, or postsurgical stenosis may occur [52,53].

Graft Augmentation

Graft materials have been employed in both the traditional posterior colporrhaphy and the site-specific technique in an attempt to strengthen the repair and prevent recurrences. Graft materials that have been used are xenografts, allografts, and permanent synthetic material. Some authors advocate the use of mesh or graft in recurrent rectoceles in patients with deficient rectovaginal fascia and weak tissue, in the presence of advanced prolapse, or with the coexistence of risk factors such as obesity and/or chronic constipation [54]. Following repair of the rectocele, either via a traditional colporrhaphy or via a site-specific repair, the graft is then attached to the rectovaginal and pubocervical fascia proximally, levator ani muscles laterally, and PB distally with a series of interrupted sutures [54]. The repair of a high rectocele can be challenging as there is commonly a deficiency of rectovaginal and pubocervical fascia proximally. However, this repair can be facilitated by entry into an associated enterocele with attachment of the graft to the distal uterosacral ligaments.

Abdominal Sacral Colpopexy (Colpoperineopexy)

An abdominal approach may be utilized for the correction of a rectocele when accompanied by apical prolapse. This may be performed through an open incision or laparoscopically with or without robotic assistance. Identification of the right ureter is confirmed prior to opening the pelvic peritoneum. The peritoneum is opened in a vertical fashion from the sacral promontory to the pelvic cul-de-sac along the lateral border of the right colon and medial to the right ureter. Next, sharp and blunt dissection is used to expose the anterior longitudinal ligament of the sacrum over S1–S2 being mindful of the surrounding vasculature. With the aid of an end-to-end anastomosis sizer placed in the vagina and the rectum, the rectovaginal space is identified and entered sharply. This is an avascular space and if one is in the correct plane, limited bleeding should occur. This plane is then dissected down to the level of the PB and bilateral pubococcygeus muscles for correction of a distal rectocele and perineal descent (colpoperineopexy) if indicated. Following this, dissection of the bladder off the anterior vaginal wall is performed to the level of the bladder neck. The mesh is then attached to the PB and levator musculature (if indicated) and posterior and anterior vaginal wall with a series of interrupted No. 2-0 absorbable sutures. Finally, the mesh is affixed to the anterior longitudinal ligament with two separate sutures of No. 0 permanent suture taking care not to place the mesh on excess tension and avoiding the middle sacral vessels. The mesh is then trimmed and the peritoneum is closed over the mesh using a No. 2-0 absorbable suture. Of note, this procedure may also be combined with a vaginal approach to further correct a distal rectocele.

RESULTS AND COMPLICATIONS

Posterior Colporrhaphy without or with Levatorplasty

Anatomic cure rates after posterior colporrhaphy with or without levator plication range from 76% to 96% after a mean follow-up period of 12–42 months [44,55–59]. Results are shown in Table 84.2. One study revealed an improvement from 100% to 88% cure rate for constipation in 24 patients that were prospectively followed and evaluated pre- and postoperatively with standardized questionnaires, defecography, colon transit studies, anorectal manometry, and electrophysiology. This study also showed improvement in symptoms of vaginal bulge from 21% preoperatively to 4% postoperatively. The rate of de novo dyspareunia was 8% [55].

In comparison, two studies showed a modest improvement (<50%) [56] or an increase [60] in the constipation rate (from 22% to 33% after a mean follow-up of 52 months). Reasons suggested for these observations include (1) unselective approach used in offering surgical treatment for persistent constipation [69], (2) retrospective analysis of the data [1], and (3) the possibility that patients with a pathologic transit study might have a less favorable outcome with respect to constipation [55,59]. In addition, the study by Kahn and Stanton showed an increase in rates of incomplete bowel emptying and fecal incontinence (4% preoperatively vs. 11% postoperatively) after posterior colpoperineorrhaphy [60]. In contrast, Maher et al. reported an anatomic cure rate of 87% and 79% at 12 and 24 months, respectively. All bowel function parameters showed improvement with overall patient satisfaction of 97% [61]. Additionally, a prospective study of 60 women who underwent posterior colporrhaphy with or without perineorrhaphy reported significant improvement of subjective bowel symptoms within 3–6 months postoperatively. Bowel evacuation scores improved by 42% and continence by 37% based on a validated questionnaire given pre- and postoperatively [62]. Both subjective and objective outcomes following repair of the posterior compartment vary due to the various surgical procedures that routinely accompany rectocele repair, making the ability to compare and contrast the current studies difficult.

[b] One of the patients had a levator plication.

Dyspareunia appears to be associated with posterior colporrhaphy. Komesu et al. compared women who underwent posterior repair to those who did not in a cohort study. Preoperatively, there was no difference in dyspareunia in both groups, but postoperatively, the prevalence of dyspareunia was significantly lower in the group without posterior repair [63]. De novo dyspareunia rates after levatorplasty have been reported to range from 12.5% to 16%. An additional study showed an increased rate of sexual dysfunction (18%–27%) after levatorplasty [60]. A study by Weber et al. reported an even higher dyspareunia rate of 26% after posterior repair only (except for one patient who had a levator plication) and 38% after a posterior repair with Burch colposuspension [57]. The postoperative introital calibers in patients with or without dyspareunia were not different. The reasons for the unexpectedly high rate of dyspareunia in that study are unclear.

Site-Specific Rectocele Repair

The surgical outcomes after a defect-specific rectocele repair are summarized in Table 84.3 [22,63–67]. Anatomic cure rates range from 56% to 100% after a mean follow-up period of 3–18 months. Improvements in constipation were seen in 43%–84% of patients [22,64,67] with de novo constipation rate of 3%–4%; however, Kenton et al. found that the rate of constipation was not statistically significantly different after 1 year of follow-up and attributed this to the predominantly medical etiology for the disorder. In addition, the lack of a standardized definition of constipation contributes to the difference in constipation rates seen in the literature after rectocele repair. Improvements in the symptoms of manual evacuation was noted in 36%–63% [22,64,67] with a de novo rate of 7% in one study [22].

Most studies report some improvement in dyspareunia after site-specific repair (35%–92%) [22,64–67] (Table 84.3). The only study where site-specific rectocele repair was not combined with other prolapse or incontinence surgery followed 42 women for a period of 18 months. Improvement in sexual function was reported in 35% and there were no patients who developed de novo dyspareunia [66]. Other studies report a de novo dyspareunia rate of 0%–8% [22,64–67]. Abramov et al. compared outcomes of site-specific repair to posterior colporrhaphy. This study showed higher anatomic recurrence rate in the site-specific repair group with similar rates of dyspareunia and bowel symptoms [68].

One prospective randomized trial by Paraiso et al. compared three surgical techniques of rectocele repair: traditional colporrhaphy, site-specific repair, and site-specific rectocele repair augmented with a porcine-derived graft on 106 patients. The results included both anatomic results and subjective condition-specific validated quality of life questionnaires. Anatomic cure of prolapse ≤ Stage II at 1 year was comparable between the traditional colporrhaphy and the site-specific groups (86% vs. 78%). When compared to the site-specific graft-augmented group, both the traditional colporrhaphy and site-specific rectocele repair were improved (54%) and statistically significant. Also, recurrence of the prolapse to or beyond the level of the hymen developed in 20% of those who underwent a graft-augmented approach, compared to 7.1% in the traditional colporrhaphy group and 7.4% in the site-specific repair group. There was no significant difference between the groups in regard to preoperative or postoperative dyspareunia, but improvement in sexual function was noted after rectocele repair, regardless of the technique used [69].

Graft-Augmented Approach

The ideal mesh or graft material used to augment repairs of pelvic fascial defects remains elusive. It should be inexpensive and improve recurrence rates, should not be rejected, and should cause no detriment to sexual and bowel function. The results of graft augmentation are summarized in Table 84.4 [54,59,61,70–73]. Anatomic cure rates range from 92% to 100% (12–30-month follow-up) with the transvaginal approach and 89% to 95% (12–29-month follow-up) with the transperineal approach. De novo dyspareunia rates range from 3% to 20%.

In a prospective, controlled trial, Sand et al. randomly assigned 160 patients to undergo anterior and posterior colporrhaphy with (80 patients) or without (80 patients) polyglactin 910 mesh reinforcement.

Preoperatively, 91 women had a rectocele to the midvaginal plane, 31 to the hymenal ring, and 22 beyond the introitus. In the treatment group, a strip of mesh was incorporated into the imbricating endopelvic “fascia” during the midline plication. Thirteen recurrent rectoceles were noted at 1 year follow-up, with no differences observed between the two groups (10% vs. 8%) [59].

Another randomized trial by Sung et al. evaluated the use of porcine subintestinal submucosal graft as an augmentation for rectocele repair compared to native tissue repair alone. A total of 80 patients were allocated to each group with results reported at 12 months. In the nongraft group, 8.6% (6/70) compared to the graft group 12% (8/67) experienced anatomic failure that was defined as points Ap or Bp −1 or greater with a p value of 0.5. Subjectively, there were no statistically significant differences between the groups for vaginal bulge symptoms or defecatory dysfunction. The authors concluded that augmentation with porcine submucosal graft was not superior to native tissue repair at 12 months [74].

[a] Prospective, all other studies retrospective.

The use of nonsynthetic grafts may have a lower erosion rate, although this has yet to be confirmed in randomized controlled trials. In a retrospective review by Dwyer and O'Reilly, polypropylene mesh was used as an overlay for repair of large or recurrent anterior and posterior compartment prolapse. Forty-seven women had mesh placed in the anterior compartment, 33 in the posterior compartment, and 17 had mesh placed in the both compartments. Of the erosions that occurred in nine women (9%), six lesions were in the posterior segment. One woman required surgical repair of a rectovaginal fistula [75]. Milani et al., in a series of 31 women, undergoing posterior colporrhaphy with polypropylene mesh, showed anatomic cure rate of 100%. The rate of dyspareunia increased from 6% preoperatively to 69% postoperatively. The rate of mesh erosion was 6.5% [73]. In contrast, at 12 months of follow-up, Kohli and Miklos reported no complications (including erosion or fistula) in 43 women after placement of a cadaveric dermal graft [54]. At 1-year follow-up of 35 women, Dell and O'Kelley noted no erosions after the use of a porcine collagen mesh that contained fenestrations in the graft material. They also described 6/41 patients that experienced wound separation and delayed vaginal healing when they previously employed the nonfenestrated form of the same material. The authors suggested that the fenestrations allowed immediate contact between the vaginal mucosa and underlying host tissues, thus facilitating appropriate tissue ingrowth [72].

The use of synthetic mesh for vaginal reconstruction has become a highly discussed topic in the past few years. In 2008, the Food and Drug Administration (FDA) released a public health notification that was followed by an update in 2011 regarding the use of transvaginal mesh. The results of a systematic review from 1996 to 2011 stated the routine use of vaginal mesh compared to native tissue repairs, particularly in the posterior compartment, was shown to be of no additional benefit [76]. Previously, the majority of studies comparing vaginal mesh kits to native tissue repair were retrospective in nature [73,77,78]. Since the FDA announcement, the prospective research for vaginal mesh kits has drastically increased. Many randomized controlled trials have been performed comparing native tissue repair to vaginal mesh kits in multiple compartments, with a few reporting results specifically for the posterior compartment [79–81]. In 2010, Iglesia et al. conducted a randomized controlled trial of 65 women comparing transvaginal mesh to native tissue repair that was halted due to a mesh extrusion rate of 15.7% at a median follow-up of 9.8 months [82]. Results after 1 year reported a rectocele recurrence rate of 21.9% in patients with mesh compared to 18.2% recurrence without mesh in the posterior compartment; however, the findings were not statistically significant. There were no significant differences identified with new onset dyspareunia between the two groups (9.1% [mesh] versus 21.4% [no mesh]) [79]. At 3 years, both subjective and objective data were evaluated between the two groups showing no statistically significant differences in cure rates. No differences were observed at 3 years in regard to prolapse stage or individual POPQ points in patients with or without vaginal mesh [83]. It is important to note that the subjects in this study underwent a wide range of vaginal reconstructive procedures and the results may not be generalizable to patients with rectoceles alone. Currently, there is insufficient evidence for the use of mesh or graft material in the repair of the posterior compartment [84,85], and based on the current data, native tissue repair appears to have similar objective and subjective cure rates without the risk of mesh extrusion.

Transanal Approach

The majority of studies are based on the experience of colorectal surgeons whose primary focus is defecatory dysfunction and anal incontinence. Anatomic cure rates range from 70% to 98% after a 12–74-month follow-up [17,42,86–92]. Reported rates of symptomatic improvement are 58%–100% after the transrectal approach. De novo anal incontinence may be a concern, especially in those with occult sphincter lacerations, as a transanal retractor may further compromise function. One study reported a 38% rate of new-onset fecal incontinence after this approach [56].

In a combined transvaginal/transanal approach, van Dam et al. found an anatomic cure rate of 72% in 89 women after a mean follow-up period of 52 months. Rates of constipation were 63% preoperatively and 33% postoperatively, while difficulty in evacuation decreased from 92% to 27%. However, rates of dyspareunia were found to be 28% preoperatively and 44% postoperatively, in which the authors attributed to the transvaginal portion of the operation [93].

Studies comparing the transvaginal and transanal approaches have been mainly retrospective [56,94] or prospective and nonrandomized [93]. Previously, retrospective reviews suggested equivalence between transanal and transvaginal rectocele repairs [56,94]; however, current evidence appears to suggest transvaginal repair is superior to the transanal approach. A retrospective study in 2005 by Roman et al. identified 71 females who underwent transanal rectocele repair from 1992 to 2000. All procedures were performed by a single surgeon. In a survival analysis, a 50% rectocele recurrence rate was noted over a mean 6-year time frame [92].

Also, in 2004, in a randomized controlled trial of 30 patients by Nieminen et al. [95], 15 patients underwent transanal rectocele repair, while the other 15 underwent vaginal posterior colporrhaphy. They excluded patients with other symptomatic prolapse or compromised anal sphincter function as evidenced by colon transit study. At 12 months follow-up, 14 (93%) patients in the vaginal group and 11 (73%) in the transanal group reported improvement in symptoms ($p = 0.08$). The need to digitally assist rectal emptying decreased significantly in both groups, from 11 to 1 (73%–7%) for the vaginal group and from 10 to 4 (66%–27%) for the transanal group ($p = 0.17$ between groups). Rectocele recurrence rates were 7% and 40%, respectively ($p = 0.04$), and enterocele rates were 0% and 27%, respectively ($p = 0.05$). A 27% improvement rate in dyspareunia was noted; none of the patients developed de novo dyspareunia.

The Cochrane review on surgery for pelvic organ prolapse identified three studies comparing transvaginal and transanal rectocele repairs. After review, patients who underwent transvaginal repair were found to have fewer subjective and objective findings of recurrent prolapse. Therefore, with the current evidence available, transvaginal correction of the posterior compartment appears to be superior over a transanal approach in the prevention of recurrent rectocele [58].

CONCLUSIONS

Posterior compartment defects are often identified on physical exam and may or may not be symptomatic. Rectocele repair is a common surgical procedure and occurs in approximately half of the patients undergoing prolapse repair. A thorough history and physical examination is paramount before considering surgical or nonsurgical interventions. The use of pelvic floor imaging may complement the clinical assessment of the pelvic floor, but its use needs to be further studied and defined prior to advocating its routine use. Numerous surgical techniques and materials exist for repairing the posterior compartment. These surgical decisions should be made based on the current evidence and the surgeon's experience.

85 Vaginal Approach to Fixation of Vaginal Apex

May Alarab, Salomon Zebede, and Harold P. Drutz

INTRODUCTION

Caring for women with pelvic floor disorders has become an increasingly important component of women's health care. Pelvic organ prolapse (POP) is a major health issue for women; it affects almost half of all women over 50 years of age, with a lifetime prevalence of 30%–50% [1]. It is estimated that the lifetime risk of surgery for either stress urinary incontinence (SUI) or POP is 20.0% by the age of 80 years [2]. With the current generation of women maintaining a more active lifestyle into an older age, it is likely that an increasing number of women will seek treatment for prolapse, conditions requiring increasing expertise on the part of the urogynecologist and pelvic reconstructive surgeons in the management of these conditions. It has been projected that the demand for care for pelvic floor disorders will increase by 35% between 2010 and 2030 [3].

Conservative management of POP using vaginal pessaries is a known and effective method in treating this problem; however, patients are more inclined toward more permanent solutions to correct their symptoms, while maintaining body image and coital function. Numerous surgical operations have been described for the support of the vaginal apex at the time of hysterectomy or for the posthysterectomy vault prolapse and are performed either abdominally or vaginally. In this chapter, we will describe the different vaginal approaches for fixation of the vaginal apex.

HISTORY

Genital prolapse in antiquity finds its roots in the Ebers Papyrus (1500 BC) [4].

Soranus of Ephesus (AD 98–138) is commonly considered the foremost gynecologic authority of antiquity. He proposed vaginal hysterectomy for uterine prolapse in AD 120 [5]. The vaginal reconstructive approach was first described by Zweifel in 1892 [6] and involved suspension of the prolapsed vagina to the sacrotuberous ligament. In 1909, White suspended vaginal vault to the tendinous arch of the obturator fascia via a transvaginal approach [7]. A transvaginal technique suspending the vaginal vault to the sacrouterine ligaments just below the sacral promontory was reported by Miller in 1927 and then popularized by Shull in the late 1990s [8,9]. In 1951, Amreich described a transgluteal and later a transvaginal approach to attach an everted vagina to the sacrotuberous ligament [10]. Sederl first tried the use of sacrospinous ligament for this purpose in 1958 [11]. Richter, in 1967, introduced the sacrotuberous fixation in Europe [12] and 1 year later described the use of the sacrospinous ligament as an improvement technique for the suspension of the vaginal vault; the procedure that was made popular in the United States by Randall and Nichols in 1971 [13]. Since then, it has been increasingly popular. Cruikshank and Cox have described the use of sacrospinous ligament fixation as an adjuvant to vaginal hysterectomy and colporrhaphy for marked uterovaginal prolapse in the presence of poor integrity of the endopelvic fascia [14]. In 2001, the FDA approved the first "mesh kit" for the correction of POP in the United States (Posterior IVS Tunneller, Tyco Healthcare LP, Norwalk, CT). While initial publications regarding this device looked promising, the IVS Tunneller is now rarely used, presumably due to reports of high failure and complication rates [15–17]. However, the IVS Tunneller remains important in the history of transvaginal "mesh kits" because it served as the "predicate" device for subsequent kits. In the year 2004, the first transvaginal mesh trocar-based kits that use a transobturator or transgluteal approach to suspend the vagina were introduced. In 2006–2007, the nontrocar or single-incision kits were introduced to the market.

ANATOMICAL CONSIDERATION

The normal support of the pelvic floor is based on three mechanical principles: (1) the uterus and vagina are attached to the walls of the pelvis by the endopelvic *fascia* that suspends the organs from the pelvic side walls, (2) the levator ani muscles constrict the lumens of these organs until they are closed forming an occlusive layer on which the pelvic organs may rest [18], and (3) the flap valve, where the vagina suspended in such a way that it rests against the supporting wall adjacent to it, increases in pressure forces the vagina against the wall pinning it in place [19]. The part of the pelvic *fascia* that attaches the uterus to the pelvic walls (i.e., the broad, cardinal, and uterosacral ligaments) is called the parametrium; a similar tissue that attaches the vagina to the pelvic walls is called the paracolpium. Unlike other ligaments in the body that are made of dense connective tissue, these ligaments contain blood vessels, nerves, and fibrous connective tissue (smooth muscle, collagen, and elastin), a composition that reflects their function as neurovascular and supportive structures. The paracolpium is attached to the upper two-thirds of the vagina and consists of two portions: apical supporting tissues consist of a relatively long sheet of tissue that converges from their broad origin on the lateral pelvic walls and sacrum to their attachment to the lateral walls of the vagina. Defective suspension at this level presents clinically as uterine or vaginal vault prolapse. The midportion of the vagina is attached laterally and more directly to the pelvic sidewalls. This connective tissue stretches across the vagina transversely between the bladder and the rectum and includes the pubocervical anteriorly and the rectovaginal *fascia* posteriorly. At this level, the vagina becomes closer to the pelvic sidewall, and failure of midvaginal support presents as a cystocele, rectocele, or both. In the distal vagina, the vaginal wall fuses from 2 to 3 cm above the hymenal ring laterally to the levator ani muscle, posteriorly to the perineal body, and anteriorly it blends with the urethra and is embedded in the connective tissue of the perineal membrane, with no intervening paracolpium. The attachment at this level is so dense that it leaves the vagina with no mobility, and displacement of the levator muscle, the perineal body, or the urethra will carry the vagina along with it [20].

SURGICAL ANATOMY

Pelvic endopelvic connective tissue (often called *fascia*) and the pelvic ligaments have been used to suspend the prolapsed vagina. The nerves and vessels surrounding these anchoring structures may be susceptible to injury during surgical repair. In order to reduce the hemorrhage and postoperative pain secondary to colpopexy operations, it is essential to understand the anatomical relationships of the pelvic organs and their adjacent neurovascular structures. The pararectal space is filled with fat and loose areolar tissue through which the middle rectal artery and the nerve of the levator ani muscle course [21]. The sacrospinous ligament, located within the substance of the coccygeal muscle [22], extends from the lateral sacrum to the ischial spine (Figure 85.1a). The average length of the sacrospinous ligament was measured to be 43.04 ± 6.58 mm [23], and it divides the sciatic notch into the greater and lesser sciatic foramina. The inferior gluteal artery, after originating from the internal iliac artery, descends inferolaterally passing through the greater sciatic foramen leaving the pelvis and crossing the upper border of the sacrospinous ligament 8.54 mm from the ischial spine, accompanied by the inferior gluteal vein. After emerging from the sacral plexus, the inferior gluteal nerve passes close to the vessels and leaves the infrapiriform foramen crossing the upper border of the sacrospinous ligament 13.82 mm from the ischial spine. Leaving the pelvis, the inferior gluteal complex crosses the sciatic nerve posteriorly and branches inside the gluteus maximus muscle. The internal pudendal artery, after originating from the anterior branch of the internal iliac artery and accompanied by the internal pudendal vein, reaches the upper border of the ligament and leaves the infrapiriform foramen accompanied by the pudendal nerve. The pudendal complex lies a maximum of 5.5 mm medial to the ischial spine. The sciatic nerve is situated the most laterally among the structures emerging from the infrapiriform foramen; on average, it is measured to be 25.14 ± 3.94 mm lateral to the ischial spine [23] (Figure 85.1b). The coccygeal branch of the inferior gluteal artery passes immediately behind the midportion of the sacrospinous ligament and pierces the sacrotuberous ligament in multiple sites. During the procedure of sacrospinous vault suspension, placing the sutures immediately medial and inferior to the ischial spine may have a potential of injury to the pudendal vessels. However, placing the sutures superior to the midportion of the ligament may cause injury to the inferior gluteal artery. The coccygeal branches of the inferior gluteal artery might be injured by any deep suture that traverses the full thickness of the ligament. Thompson has shown, by dissecting 23 female cadavers, that placing the sutures through the sacrospinous ligament 2.5 cm or more medial to the ischial spine along the superior border of the ligament and not through the full thickness reduces the risk of complications [24].

ETIOLOGY AND PATHOPHYSIOLOGY

The opening in the levator ani muscle, through which the vagina and urethra pass, is called the urogenital hiatus of the levator ani (through which prolapse occurs); the rectum, although passes through the opening, is not included in the hiatus because the levator ani muscle attaches directly to the anus and the external anal sphincter. The hiatus is surrounded by the pubic bones anteriorly, the levator ani muscle laterally, and the perineal body and the external anal sphincter posteriorly. The levator ani muscle is always tonically contracting, keeping the urogenital hiatus closed. It closes the vagina, urethra, and rectum by compressing them against the pubic bone. The continuous contraction of the levator ani muscle keeps the hiatus closed and prevents any opening in the pelvic floor through which prolapse may occur. As long as the levator ani muscle functions normally, the pelvic floor is closed; the ligaments and fascia are under no tension. When the muscles relax or are damaged, the pelvic floor opens and the pelvic organs lie between the high abdominal pressure and the low atmospheric pressure of the introitus. Then, the organs must be held in place by the ligaments, which can sustain the load for short periods of time but eventually become damaged and fail to hold the vagina in place. This failure is due not only to acute damage of the ligaments and connective tissue but also from inability of these structures to repair themselves. The injury to the connective tissue in the pelvis is due to rupture rather than stretching [25]. Neuromuscular injuries to the pelvic floor are associated with the development of POP [26]. The health and function of the pelvic floor muscles provide significant protection to the ligaments to avoid POP. The neuromuscular damage of the pelvic floor that occurs during parturition plays a major role in the etiology of prolapse; however, the repetitive loads on the pelvic floor resulting from increases in abdominal pressure also play a significant role in the development of this disorder. This results from continuous heavy lifting, chronic obstructive pulmonary disease, obesity, chronic constipation, and large fibroids or tumors; direct damage to the muscle that may result from previous pelvic surgery, spinal cord conditions and injury, and thinning of the muscle and fascia that happens with postmenopausal atrophy and attenuation; and finally the collagen status of these patients. It has been shown that women with Marfan or Ehlers–Danlos syndrome have high rates of urinary incontinence and POP. This finding supports the hypothesized etiologic role of connective tissue disorders as a factor in the pathogenesis of these conditions [27]. These facts have been confirmed by recent studies showing decreased collagen and smooth muscle content in women with POP with or without SUI regardless of age, parity, BMI, or smoking [28] and increased collagen breakdown in SUI and POP groups compared to controls [29].

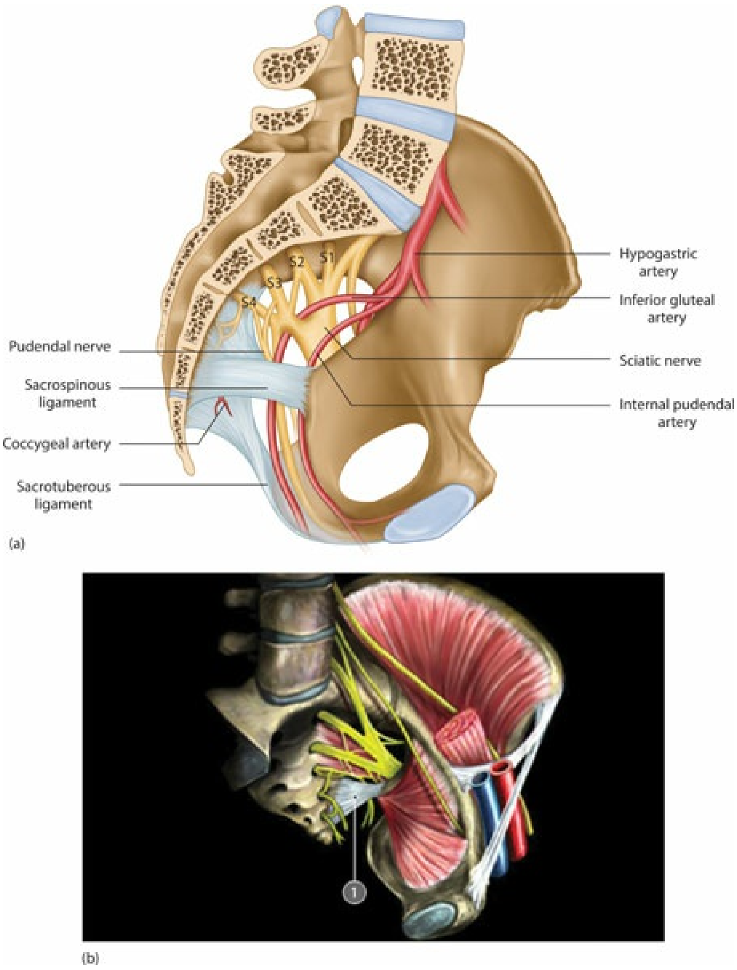

Figure 85.1 (a) Left hemipelvis. The sacrospinous ligament covered by the coccygeus muscle extends from the ischial spine to the sacrum. The pudendal neurovascular structures pass beneath the sacrospinous ligament at the ischial spine. The inferior gluteal artery passes between the sciatic nerve and the sacrospinous ligament. (b) The roots of the sciatic plexus converge obliquely toward the subpyramidal canal that is limited superiorly by the pyramidal muscle and inferiorly by the sacrospinous ligament itself (1 = sacrospinous ligament). SYMPTOMS, PRESENTATION, AND EVALUATION

Patients' symptoms of vaginal apical prolapse can vary from being asymptomatic to various complaints of vaginal pressure, feeling a bulge or something coming down, coital difficulties, and urinary symptoms (urgency, frequency, incontinence, or voiding dysfunction) or bowel emptying difficulties due to concomitant anterior and posterior vaginal wall defect. Burrows et al. looked at the correlation of symptoms with the severity of POP and concluded that the more advanced the pelvic prolapse, the less likely the women will have SUI and the more likely to manually reduce prolapse to void; however, prolapse severity was not associated with sexual or bowel symptoms [30]. A study correlating symptoms in women with or without enterocele showed that women with enterocele were likely to be older and postmenopausal, have had hysterectomy or vaginal prolapse surgery, had more advanced apical and posterior vaginal prolapse, but showed no significant difference in bowel function symptoms [31].

Patients may present to a gynecologist, urologist, or colorectal surgeon depending on their major complaint. A detailed history is undertaken, including the chief complaint, urinary and bowl symptoms, obstetrical history, medical history, and current medication. A traditional clinical history taken in women presenting with prolapse should ideally be supplemented by a tool to assess the symptoms and impact of the POP on the patient's life. This lends some degree of objectivity to the preliminary assessment and can be compared with a postintervention questionnaire to evaluate the efficacy of the intervention. The Pelvic Floor Distress Inventory (PFDI) and the Pelvic Floor Impact Questionnaire (PFIQ) and their shortened versions PFDI-20 and PFIQ-7, are popular, reliable, and validated quality of life questionnaires for women with pelvic floor disorders [32].

A careful speculum and digital examination at rest and with straining is performed to quantify POP. By placing the Sims speculum along the posterior vaginal wall and asking the patient to bear down, we look for anterior compartment prolapse, and the opposite is done to examine the posterior vaginal wall. A digital rectal–vaginal examination while the patient is straining is performed to differentiate between a high rectocele and an enterocele. There are numerous grading systems for prolapse [29–31,33–36], the Pelvic Organ Prolapse Quantification (POPQ) system [36] produced by the International Continence Society has gained popularity among urogynecologists to describe, measure, and stage prolapse. The careful vaginal examination is vital to clearly identify the site specific vaginal wall prolapse. Other variables should be taken into consideration at the time of assessment of the prolapse. The time of the day the examination is done should be recorded. Prolapse can change throughout the day, with it being more pronounced at the end of the day, especially after prolonged standing. Position of the patient during examination, straining, and traction on the prolapse and fullness of the bladder are other variables that can influence the assessment [37].

SUI has been strongly associated with POP [38,39], and it has been shown that mild to moderate POP is often associated with SUI; however, women with severe POP rarely complain of urine leakage because of urethral kinking and increased urethral resistance with the urogenital prolapse in an unreduced state [40–42]. After correction of the prolapse, the leakage problem will be manifested in what is called occult or latent SUI—which is one of the common problems seen with complex vault prolapse [43]. The incidence of occult SUI can vary from 22% to 80% and can be quite distressing [44,45]. As a result, it is recommended to perform a prolapse reduction stress test to identify patients at risk of developing SUI after their reconstructive surgery. Although a negative preoperative prolapse reduction stress test alone may reduce the risk of de novo SUI, some recent studies suggest that this test alone may not be sufficient to determine the need for anti-incontinence surgery at the time of reconstructive pelvic surgery [46,47]. A recent study has demonstrated that prophylactic incontinence surgery using a midurethral sling during vaginal prolapse surgery will result in a lower rate of urinary incontinence at 12 months; however, this benefit should be weighed against higher rates of adverse events [47]. In order to balance the risks and benefits and to help us better counsel patients, a model for predicting the risk of de novo SUI in women undergoing POP surgery has been developed and published by the Pelvic Floor Disorders Network [48]. This model has shown that it outperforms preoperative stress testing, prediction by experts, and preoperative reduction cough stress testing [48].

The investigations, which may be required prior to any prolapse repair, are accurate preoperative urodynamic studies, with prolapse reduced to examine the expected outcome after repair, cystourethroscopy, and abdominal–pelvic ultrasound. In addition, transanal studies may be required if there is a history of fecal incontinence. Other tests include defecography, anorectal motility studies, pudendal motor nerve latency studies, and magnetic resonance imaging of the pelvic floor.

VAGINAL SURGICAL TECHNIQUES IN SUPPORTING THE VAGINAL APEX

The vaginal approach to prolapse surgery carries significant low postoperative morbidity. It does not require additional skill or the cost of laparoscopy; however, it requires a well-trained pelvic surgeon, who is well versed in different techniques and has the ability to repair other pelvic defects simultaneously. In addition, it provides the option to perform the operation under regional or general anesthesia. Various techniques have been described for the treatment of vault prolapse, these include sacrospinous vault suspension, iliococcygeus muscle fixation, uterosacral ligament fixation, McCall culdoplasty, posterior intravaginal slingplasty (IVS), and more recently total vaginal mesh (TVM) kits. We will outline the different techniques of restoration of the vaginal apical defect.

Sacrospinous Vault Suspension

Indications

The main indication for sacrospinous ligament suspension is to correct total procidentia, posthysterectomy vaginal vault prolapse with an associated weak cardinal uterosacral ligament complex, and posthysterectomy enterocele [49,50]. This procedure suspends the vaginal apex to the sacrospinous ligament, either unilaterally or bilaterally, typically using an extraperitoneal approach [51]. Bilateral sacrospinous ligament fixation has been described and recommended in patients with recurrent vault prolapse [52,53] or a desire to maintain a wide vaginal vault [54]. The procedure has also been described as a prophylactic step at the time of vaginal hysterectomy against subsequent vaginal vault prolapse [13,55], as well as in young and elderly patients with marked prolapse, who wish to retain their uterus [56–60].

Contraindications

A short vagina, usually attributed to prior repairs is considered to be a contraindication to performing sacrospinous colpopexy; the surgeon needs to ensure that there is an adequate vaginal depth to allow the attachment of the vault to the ligament without any tension. Surgical inexperience is another contraindication, and the procedure should only be performed by experienced reconstructive pelvic surgeons.

Surgical Techniques

Postmenopausal patients with vaginal atrophy usually benefit from preoperative local hormone treatment to improve the quality of the tissues and help to improve the vascularity of the operative site. Rahn et al. have shown that using vaginal estrogen application for 6 weeks preoperatively increased the synthesis of mature collagen, decreased the degradative enzyme activity, and increased the thickness of the vaginal wall, suggesting that this intervention improves both the substrate for suture placement at the time of surgical repair and the maintenance of the connective tissue integrity of the pelvic floor [61]. Preoperative intravenous prophylactic antibiotics and prophylaxis against venous thromboembolism (with intermittent pneumatic compression devices and/or pharmacological thromboprophylaxis with unfractionated heparin or low-molecular-weight heparin depending on the surgical risk following the guidelines set forth by the American College of Chest Physicians and supported by the American College of Obstetrics and Gynecology) [62,63]. After the patient receives the appropriate anesthesia, having in mind the feasibility of regional anesthesia with the vaginal approach, the surgery is performed with the patient in dorsolithotomy position. An intraoperative assessment allows the surgeon to identify the extent of the prolapse and to confirm that the vault can reach the ligament without tension. In a marked uterovaginal prolapse, a vaginal hysterectomy is performed first in the usual fashion, if a cystocele is present; it will be dealt with next. Some authors have suggested that the addition of polyglactin mesh may provide extra support to the anterior vaginal wall; however, a randomized trial by Weber et al. used the absorbable mesh as an overlay, which did not improve the cure rate compared to the standard anterior colporrhaphy [64]. Sand et al., in a larger prospective randomized controlled trial, found the addition of mesh of polyglactin 910 mesh placed in the plication to be useful in the prevention of recurrent cystocele at 1-year follow-up [65]. Altman et al., in a randomized controlled trial, compared the use of a trocar-guided, transvaginal polypropylene mesh repair kit with traditional colporrhaphy in women with anterior vaginal wall prolapse and found that the trocar-guided mesh kit for cystocele repair resulted in higher short-term rates of successful treatment at a price of higher rates of surgical complications and postoperative adverse events including mesh extrusion, de novo SUI, and surgical reintervention to correct mesh exposure [66]. When an enterocele is identified, usually noted as a distinct loss of the rectovaginal fascia with a sudden protrusion of the enterocele sac, it’s demarcated by the pubocervical *fascia* anteriorly and the rectovaginal septum posteriorly. The sac is dissected free, opened, and a high ligation is performed with a 2-0 delayed absorbable purse-string suture [67]. The sacrospinous ligament suspension is usually performed via the posterior approach and is started with a longitudinal incision in the posterior vaginal wall, after infiltration with a dilute solution of epinephrine (1:200,000). The incision extends from the introitus to the vaginal apex. The epithelium is dissected laterally on both sides, penetrating the right rectal pillar into the pararectal space near the ischial spine (Figure 85.2a). The right ischial spine is palpated and using a combination of sharp and blunt dissection, a window is created between the ligament and the rectovaginal space (Figure 85.2b). It is important to split the *fascia* in front of the ligament that is palpated as a cord-like structure or visualized, to ensure that the suture placement will involve the body of the ligament (Figure 85.2c). The rectum is mobilized medially with the fingers and with a Heaney or Breisky vaginal retractor protecting the rectum medially. Two delayed absorbable sutures (PDS I, Ethicon, San Angelo, TX) are placed into the ligament at two fingerbreadths medial to the spine and just inferior to the superior border of the ligament, hence avoiding injury to the pudendal complex (Figure 85.2d). Care must be taken not to penetrate the full thickness of the ligament to avoid injury to the inferior gluteal vessels and nerve. The two sutures are paired, loaded separately onto a Mayo needle, and passed through the angles of the vaginal epithelium at the level of the vault, 1–2 cm apart, and held for later tying [68]. If bilateral suspension to be performed, one suture will be placed per site [69].

The anterior rectocele and the rectovaginal septum are repaired by interrupted absorbable sutures (Vicryl 2-0), the levator muscles are approximated separately with (Vicryl No. I) suture, but left untied at this stage, and the ends are held. The bulbocavernosus muscle is approximated and held, and the vaginal skin is closed with continuous locking suture until the level of the introitus. The sacrospinous sutures are tied, pulling the vault onto the ligament. It is important to ensure a close approximation, avoiding a suture bridge between the vault and the ligament. Finally, the levator and bulbocavernosus muscle sutures are tied, and the vaginal skin is closed. A slight deviation of the vaginal apex to the right would be noted at the end of the procedure, this may be of benefit as the vault will be no longer subject to the intra-abdominal pressure after the operation [50]. At the end of the surgery, the bladder is drained transurethrally; a vaginal pack is inserted in the reconstructed vagina, all to be removed after 24 hours.

The earlier description of the procedure involves exposure of the ligament and placement of the sutures under direct vision [50,70], the ligament is grasped with an Allis forceps, and Deschamps ligature carrier is used to place the suture onto the ligament. This technique requires more dissection in the pararectal space [70]. Another option is to use the Miya hook ligature carrier (Figure 85.3a). Also, the Sharp technique has been described using the Shutt suture punch system [71]; with its automatic suture retrieval, this method proved to be a quick and easy way especially in obese patients. The downside is that the sutures have to be of rigid material such as nylon or polypropylene. Watson has described using the Endo Stitch (a laparoscopic suturing instrument) to pass the suture through the sacrospinous ligament. With this tool, the depth of the penetration is predictable, without the need for a retrieval hook [72]. The same advantages have been described with the Raz Anchoring System [73]. More recently, some authors have described using the Capio suture-capturing device demonstrating a low risk of complications and a reduction in operative time and blood loss when compared to the traditional technique [74–76] (Figure 85.3b). On the other hand, Morley and DeLancey [50] found that with the help of traditional retractors, a straight or curved needle holder could position the suture without much difficulty. Their other modifications include creating a neovaginal apex via a circumscribing incision at the apex [50]. They have recently published on the long-term patient satisfaction using this technique and a supplemental video in the article that better describe their technique [77,78].

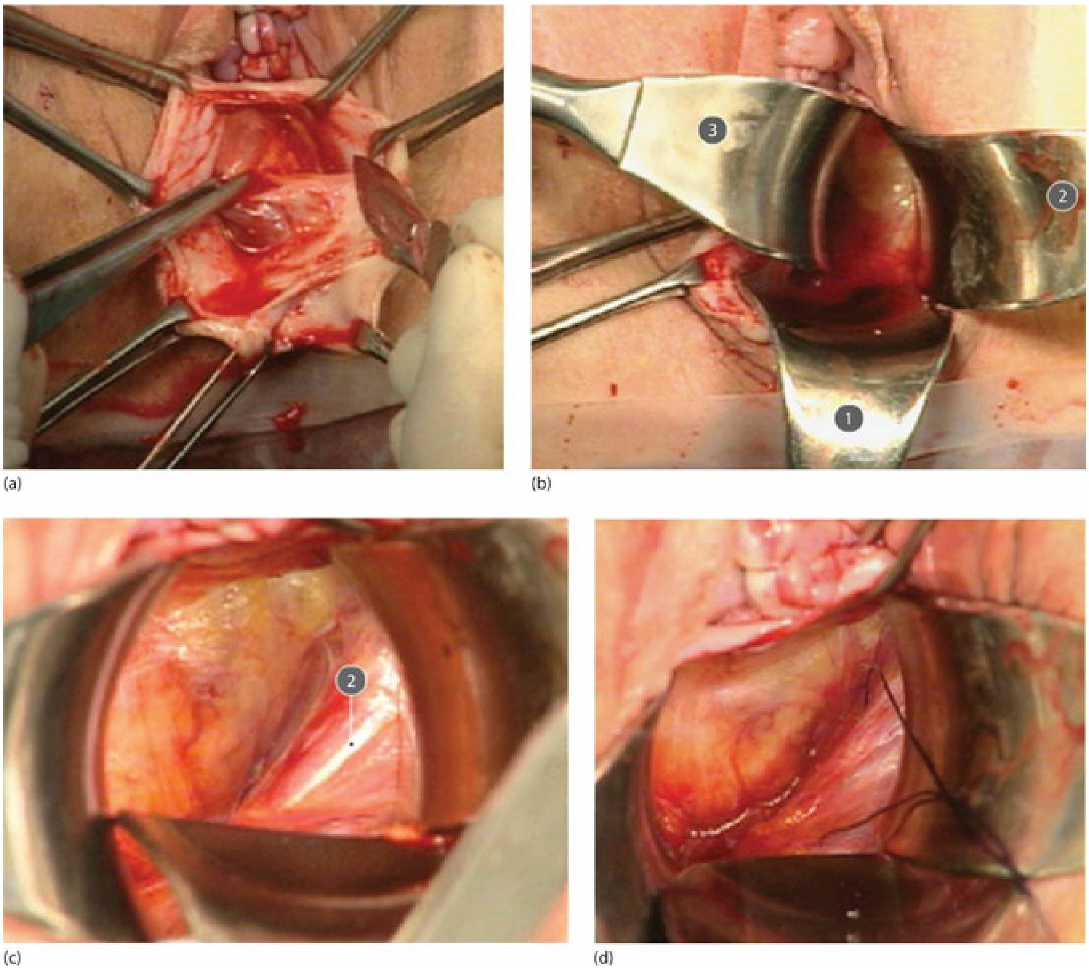

Figure 85.2 (a) Rectovaginal dissection. (b) Opening the fossa (1–3 = proper positioning of the Briesky retractors). (c) Ligament location and visualization (2 = left sacrospinous ligament). (d) Suture placement. (Redrawn from www.websurg.com with courtesy of M. Cosson and IUGA.)

The anterior sacrospinous vault suspension has been described, where the ligament is approached through an anterior vaginal incision; Goldberg et al. had shown that with this technique, there was a slight increase of the vaginal length, with a decrease in the recurrence of the anterior vaginal wall prolapse [79].

The choice of the suture used remains controversial; some advocate the use of absorbable sutures [11,12,21,50,80], and others use delayed absorbable or permanent sutures [13,49,50,52,68,81,82] to allow adequate time for fibrosis and scarring between the sacrospinous ligament and the vaginal apex. When absorbable sutures are used, they are passed through the full thickness of the vagina and tied over the vaginal epithelium. This is unlike permanent sutures where they should be passed submucosally in a double helix and tied beneath the vaginal epithelium [68,69].

Results

Numerous studies on sacrospinous colpopexy have been published, including multiple retrospective studies, three prospective studies, three randomized controlled trials including sacrospinous vault suspension compared with abdominal sacrocolpopexy, and one randomized control trial comparing it to uterosacral vault suspension [50,52,69,77,78,82–97]. Most of these data were recently summarized by Barber and Maher in a review article [51]. The lack of objective outcome measures and the variety of definitions of success made the data difficult to collate.

Morgan et al. had published a systematic review on anatomical outcomes of sacrospinous ligament fixation for prolapse [98]. In this review, they included 17 studies. They reported an overall failure rate at any site of 28.8% (95% CI 18.4%–36.3%), with failure of the anterior segment seen in 21.3% (17.3%–25.3%), the apical segment in 7.2% (95% CI 4.0%–10.4%), and the posterior segment in 6.3% (95% CI 4.2%–8.4%) with follow-up varying widely from 12 to 83 months [98]. When subjective outcomes were assessed using the definition of failure to provide relief of prolapse symptoms, an analysis of the pooled data showed a 10.3% subjective failure rate (95% CI 4.4%–16.2%) [98].

Goldberg et al. have shown, in a retrospective analysis, that anterior sacrospinous vault suspension showed a subtle but statistically significant decrease in the anterior wall relaxation compared to the traditional posterior approach [79]. Lovatsis and Drutz [69], in a 5-year case series, with a total of 293 cases, had a cure rate of 97% for those with at least 1 year of follow-up. The incidence of de novo SUI was 3.1% and anal incontinence was 6%. However, 38 out of 43 patients, who had preoperative anal incontinence, denied any symptoms after surgery, giving a cure rate of 88.4%. The incidence of postoperative cystocele was 8.5%, and rectocele was 3.5%. Nieminen and Heinonen looked at sacrospinous ligament fixation in women over 80 years old with massive genital prolapse [92]. They showed comparable results with younger women and concluded that in the absence of major vascular diseases, this operation is as safe as the obliterative procedures, and in high-risk patients, intraoperative bleeding control is important.

Complications

- *Hemorrhage*: This is the most commonly reported complication with an average blood loss ranging from 75 to 839 mL [94]; Sze and Karram reviewed 1229 cases of sacrospinous ligament suspension and found that only 27 (2%) cases required transfusion [89]. Barksdale et al. dissected 10 female cadaveric pelvises and concluded that the inferior gluteal artery is the vessel most likely to be injured. This is because of its perpendicular course relative to the sacrospinous ligament, approximately midway between the ischial spine and the sacrum, lying in a position immediately posterior to the most common location of suture placement. Injury of the pudendal vessels is uncommon because the pudendal neurovascular bundle was found to be relatively protected by the ischial spine and would respond to ligation of the internal iliac artery. Massive intraoperative bleeding should be dealt with by packing and vascular clips or packing and arterial embolization [105]. Other causes of bleeding are injury to the perirectal veins [13], sacral veins [49], and severe adhesions [83] from previous surgery.

- *Nerve injury*: Neural tissue was found in all parts of the sacrospinous ligament with the highest concentration at the center of the ligament [106]. Postoperative sciatic neuralgia, induced by traction of the suture in the ligament, may cause tension transmitted to the sciatic nerve. Usually, the pain resolves in 2–3 weeks but may be helped by transvaginal infiltration of xylocaine [106]. Gluteal pain has been reported after sacrospinous fixation with an incidence of 3% [89] to 6.1% [69] and usually resolves spontaneously within 6 months. Immediate postoperative gluteal pain radiating to the posterior surface of the leg, accompanied by paresthesia, usually indicates posterior cutaneous, pudendal, or sciatic nerve injury [70]. The recommended treatment is immediate reoperation to remove the offending suture and to reposition the new suture in a more medial position on the same or the opposite sacrospinous ligament [70].
- *Injury to pelvic organs*: such as the bladder and the rectum has been reported [21,50,70,100,107] because of their close proximity to the sacrospinous ligament. These injuries should be immediately repaired using conventional techniques. The surgeon must be vigilant about these complications and intraoperative cystoscopy and careful rectal examination after insertion of the suture to the ligament is mandatory.
- *Dyspareunia*: Sexual function following sacrospinous ligament suspension has been evaluated in numerous studies [21,99–103]. The vaginal length is maintained after sacrospinous suspension procedure. Richter and Albright [21] reported that eight of their patients were afraid to attempt coitus because of narrowed vagina, while Given et al. [104] found that the procedure did not interfere with coital function. Holley et al. [101] compared preoperative and postoperative sexual activity of 35 patients and found a higher frequency of sexual intercourse postoperatively, with no association with dyspareunia.
- *Postoperative* SUI: This complication may result from vesicourethral junction straightening that results from restoration of vaginal length and depth and/or a significant reduction of urethral closure pressure when the vaginal vault is replaced intra-abdominally [70,108]. It is recommended that all patients with large prolapse be evaluated preoperatively to rule out the presence of occult urinary stress incontinence.
- *Voiding dysfunction*: Temporary voiding dysfunction has been described especially when the sacrospinous ligament fixation has been performed in conjunction with an anti-incontinence procedure. This can be attributed to the dislocation of the vesicourethral region to the right and ventral fixation when done in combination with the colposuspension [106].
- Other reported rare complications are death from postoperative coronary thrombosis (two patients) [70,109], and one patient died of pulmonary embolism [92]. Evisceration through the vaginal incision has also been reported [110].

Failures

Failure to maintain the support of the vault after sacrospinous suspension procedure may be attributed to a variety of reasons. Poor approximation of the vault to ligament may play a major role; the presence of a suture bridge will prevent fibrosis between the ligament and the vault, leaving the support mainly dependent on the suture material. This is the main reason why this procedure is contraindicated in patients with short vaginas. There is no supportive evidence in the literature that permanent sutures reduce the incidence of recurrence. Although bilateral attachment offers excellent anatomical results with more surface area of attachment, it does not seem to reduce the failure rate of the procedure [53].

Nieminen et al. have shown that postoperative infection is an independent and important individual risk factor for recurrence of prolapsed. The lack of intravenous antibiotic prophylaxis, preoperative vaginal ulcerations, and low age at operation were significantly associated with infectious complications [92], and for that reason, prophylactic antibiotics are highly recommended and should be a routine. Vaginal ulcerations should be treated preoperatively.

When the sacrospinous procedure fails, it can be repeated on the opposite side or bilateral sacrospinous fixation can also be done. Fibrosis and scarring may make repeating the procedure on the same side extremely difficult.

Vault Prolapse Repair: Vaginal or Abdominal Repair, Which Route to Choose and Why?

Both sacrospinous ligament vault suspension and abdominal sacrocolpopexy (laparoscopy, robotics, or laparotomy) have their own indications with their pros and cons. Reconstructive pelvic surgeons need to have the surgical expertise to do both and choose for the individual patient taking into consideration the patient's age, weight, medical condition, coital activity, multiple previous laparotomies, and history of previous failed surgery.

The sacrospinous ligament vault suspension has the following advantages: (1) It significantly reduces postoperative morbidity and does not require the additional skills or cost of laparoscopy or robotics. (2) It offers the option to perform the procedure under local or regional anesthesia. (3) It allows the repair of other pelvic defects simultaneously. (4) It has shorter operating time. However, orthopedic deformities, coexisting intra-abdominal pathology, and compromised vaginal length may favor the abdominal route. Furthermore, the abdominal route whether open or laparoscopic has its own complications of lumbosacral osteomyelitis [111] and mesh erosion into the vagina [112], the bladder [113], and the rectum or colon [114].

Hardiman and Drutz, in a retrospective review comparing the vaginal sacrospinous colpopexy and the abdominal sacral colpopexy, found each of the two procedures to be equally effective [68]. Benson et al., in a prospective randomized study, found abdominal sacral colpopexy to be superior to bilateral sacrospinous suspension in the treatment of POP [82]. However, in both studies, 50% of women had uterovaginal prolapsed and the results may be not be generalized to women with posthysterectomy vault prolapse.

A prospective randomized study by Maher et al. found that both the abdominal and the vaginal procedures were highly effective in the treatment of vaginal vault prolapse. However, the abdominal route was associated with a longer operating time, slower return to activities, and more cost. Both procedures significantly improved patients' quality of life [93].

Maher et al., in a systematic review, found three trials that were considered to be similar enough to address the comparison of abdominal sacral colpopexy and vaginal sacrospinous colpopexy [115].

There were no statistically significant differences between the abdominal and vaginal approach in the number of women reporting prolapse symptoms. They found that abdominal sacral colpopexy had a lower rate of recurrent vault prolapsed, dyspareunia, and de novo SUI; however, abdominal sacrocolpopexy had a longer operating time, longer time to return to activities of daily living, and increased cost [115].

There aren't any randomized trials comparing laparoscopic or robotic sacral colpopexy to sacrospinous ligament suspension.

Different Vaginal Approaches for Fixation of the Vaginal Apex

Iliococcygeal Fixation

The suspension of the vaginal cuff to the iliococcygeal fascia was described by Inmon in 1963 [116] and was popularized by Shull et al. [117], with the proposed advantages of decreasing the risk of neurovascular injury or recurrent cystocele [117,118]. During this procedure, the vaginal vault is fixed to the iliococcygeus fascia on both sides just anterior to the ischial spine. The muscle can be approached by either an anterior or posterior vaginal incision. Usually, no vaginal epithelium needs to excised, as the upper vagina is attached bilaterally resulting in good vaginal length and circumference. Meeks et al., in a case series of 110 patients undergoing iliococcygeal vault suspension, reported a 96% objective cure rate following patients for up to 13 years [118]. Maher et al., in a case-controlled study, compared sacrospinous vault suspension to iliococcygeal fixation of the vaginal vault and found the two procedures to be equally effective in treating vaginal vault prolapse, with similar rates of postoperative cystocele, buttock pain, and hemorrhage requiring transfusion [119]. It was believed that fixation of the vault to this more distal location could potentially foreshorten the vagina; however, Medina et al., in a retrospective cohort study of vaginal length after iliococcygeus fixation and sacrospinous ligament fixation, found that iliococcygeus fixation did not significantly shorten the vaginal length whereas the sacrospinous ligament fixation procedure shortened the vaginal length [120].

Milani et al. retrospectively compared iliococcygeus fixation to abdominal sacral colpopexy and found that both procedures were effective in restoring normal anatomy in patients with vaginal vault prolapse and in relieving associated symptoms. They did not find any difference in subjective or objective outcomes [121].

Uterosacral Ligament Suspension

This procedure restores the vagina to its normal axis, avoiding the retroflexion that may be associated with sacrospinous vault suspension [51]. This apical suspension is ideal at the time of a vaginal hysterectomy and may also be used in patients with posthysterectomy vault prolapse.

Surgical Technique

The technique described later is the original technique described by Shull et al. [122].

The procedure starts by identifying the uterosacral ligaments. In cases where the suspension has been done at the time of a vaginal hysterectomy, the uterosacral ligaments are identified by marking the pedicles and using this to facilitate the location during the suspension. For patients that present with a posthysterectomy vault prolapse, the operation is performed through a vertical midline incision in the vaginal epithelium. The incision should be extended from the base of the urethra to the perineal body. After completion of the epithelial dissection, the enterocele sac is located and the hernia sac is opened and the bowel packed out of the operative field.

The uterosacral ligaments are identified posterior and medial to the ischial spines at the 4 o'clock and 8 o'clock positions. An Allis clamp is used to apply traction to the tissue, and the contralateral index finger is used to trace the strong suspensory tissue of the uterosacral ligament toward the sacrum. A retractor is used to retract the rectum medially, and a retractor is used to hold the bowel and surgical pack cephalad. With a long needle driver, the suture is placed through the ligament on the sacral side of the ischial spine. In an effort to minimize the risk of injury to the ureter, each needle is passed lateral to medial because the surgeon has better control over the entry point of the needle than over its exit point. In addition, the points of needle entry should be medial and posterior to the ischial spines. Two additional sutures are placed distal (on the sacral side) to the initial suture. The same procedure is carried out on the opposite side, with the goal of placing three suspensory sutures on each side (Figure 85.4a). Once all the suspensory sutures are placed, any midline (central) defects in the pubocervical and rectovaginal fascia are repaired by side-to-side plication. The suspensory sutures closest to the surgeon are placed most laterally in the *fascia* (Figure 85.4b). The more proximal sutures are placed more medially in the *fascia*. Before the suspensory sutures are tied, the patient is given 5 mL of indigo carmine dye intravenously and cystoscopy is performed to rule out ureteric injury. The sutures are tied in the sequence in which they are placed, bringing the transverse portions of pubocervical and rectovaginal *fascia* together at the apex (Figure 85.4c).

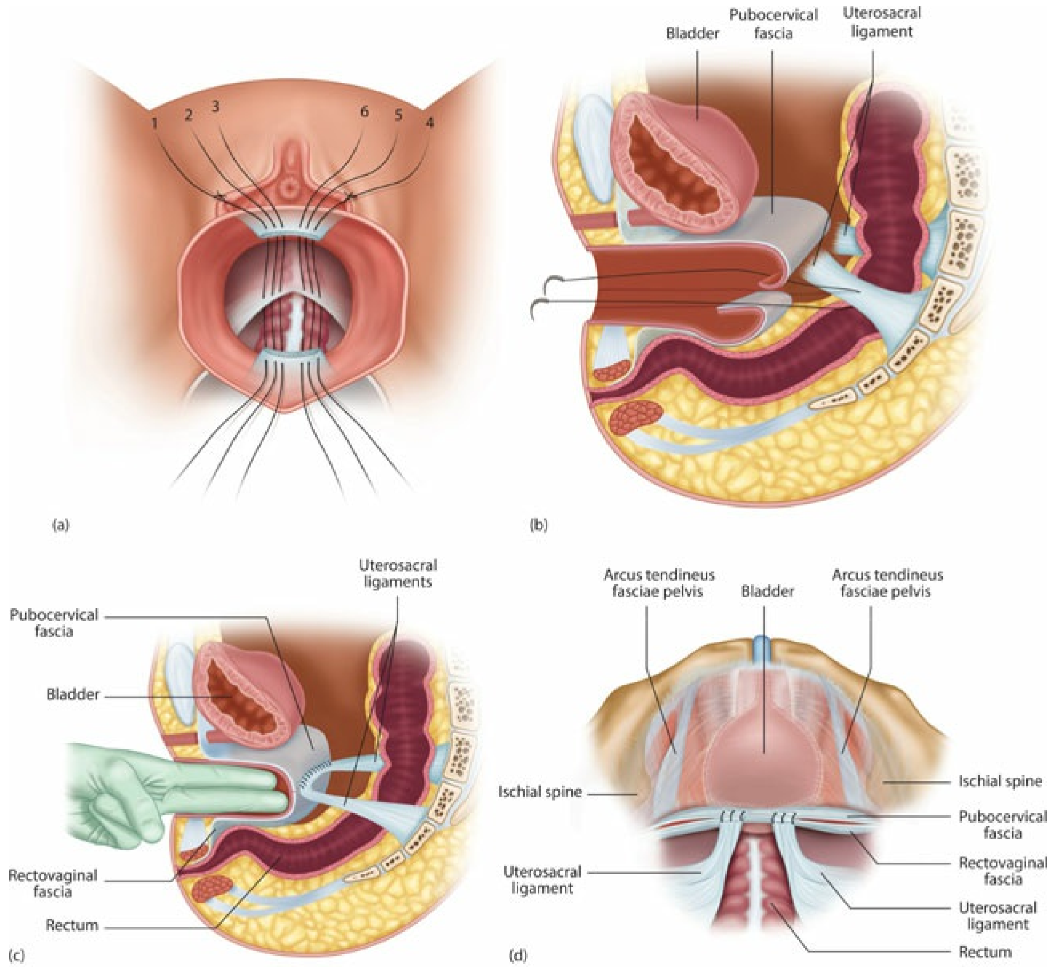

Figure 85.4 (a) Three sutures are placed in uterosacral ligament pedicles on each side. One arm of each suture is placed in transverse portion of pubocervical and rectovaginal fascia. (b) Sagittal view of suspensory suture in left uterosacral ligament (USL) with one arm through pubocervical fascia (PCF) and one arm through rectovaginal fascia (RVF). PS, pubic symphysis; B, bladder. (c) Sagittal view of PCF and RVF suspended to USLs. PS, pubic symphysis; B, bladder; R, rectum. (d) Abdominal view of completed repair. ATFP, arcus tendineus fasciae pelvis; B, bladder; IS, ischial spine; PCF, pubocervical fascia; RVF, rectovaginal fascia; USL, uterosacral ligament; R, rectum. (a–c: Courtesy of B. Shull.)

Dwyer and Fatton have described a different approach where the ischial spines are palpated extraperitoneally, and a delayed absorbable suture is placed through the ligaments bilaterally and suspended to the full thickness of the vaginal apex [123].

Results

A meta-analysis performed by Margulies et al. found pooled rates of anatomical success (POPQ stage 0–1) of 81.2% (95% CI 67.5%–94.5%) for the anterior segment, 98.3% (95% CI 95.7%–100%) for the apical segment, and 87.4% (95% CI 67.5%–94.5%) for the posterior segment. Subjective outcomes were reassuring; however, it was not possible to pool data because of methodological differences between studies [124].

There is only one randomized controlled trial comparing sacrospinous vault suspension with uterosacral ligament suspension (ULS), the OPTIMAL trial [125]. In this trial, they followed patients for 2 years, and they did not find any statistically significant difference in surgical success with the ULS 59.2% (93/154) vs. sacrospinous vaginal vault suspension 60.5% (92/152), OR 0.9 (95% CI 0.6%, 1.5%), or serious adverse event rates (ULS 16.5% [31/188] vs. SSLF 16.7% [31/186], OR 0.9 [95% CI 0.5%, 1.6%]). Prolapse symptoms were resolved in both groups [125].

Complications

The main concern with this procedure is the risk of ureteral kinking/injury. The rates have been reported to vary widely between 1% and 11% [124]. Gustilo-Ashby et al. reported a ureteral injury rate of 5.9% directly attributable to ULS [126]. They found that 87% were identified at cystoscopy. Only 3 of the 355 ULS (0.9%) performed in this series required additional procedures to relieve or correct ureteral obstruction or injury [126]. Other complications reported with this procedure are blood transfusions in 1.3%, bowel injury in 0.2%, and cystotomy in 0.1% [124].

McCall Culdoplasty

In 1957, McCall described suspension of the vaginal vault from the origins of the uterosacral ligament along with obliteration of the pouch of Douglas [127]. The difference between the uterosacral vault suspension and the McCall culdoplasty rests on the obliteration of the cul-de-sac. Elkins et al. described a high McCall culdoplasty technique to repair the prolapsed vault at hysterectomy, where the uterosacral ligaments (ULS) are plicated close to the pelvic sidewall [103]. Cruikshank and Kovac, in a randomized comparison of the three surgical methods used at the time of vaginal hysterectomy, concluded that McCall culdoplasty was superior to a vaginal Moschcowitz-type procedure and to simple peritoneal closure in preventing recurrence of enterocele [128]. Colombo and Milani, in a retrospective case-controlled study comparing the functional and anatomic outcomes of sacrospinous vault suspension and McCall culdoplasty, found no statistical difference in the recurrence of vault prolapse between the two procedures [87]. Webb et al. followed patients up to 8.8 years and reported 71% did not require any further prolapse operation. They also found that 82% were very satisfied [129].

Posterior Intravaginal Slingplasty

Papa Petros (2001) had first described the IVS in 75 patients aged 40–70 years with vault prolapse [130]. There were 71 patients who were followed up between 1 and 4.5 years. Vault prolapse recurred in 6%, and the main complication was tape erosion (5.3%). However, due to a high reported rate of adverse effects, the posterior intravaginal sling kit has now been withdrawn from the market and recruitment in this clinical trial stopped prematurely. Complications reported in other studies included tape erosion into the vagina, rectal perforation, pararectal hematoma, abscess, and rectovaginal fistula [17,131]. Gluteovaginal fistula and a rate up to 18% of mesh erosions have also been reported [132].

Total Vaginal Mesh

Placing graft material in the vagina, as an alternative to traditional surgical repairs, has been widely used by gynecologists over the last decade. This can be attributed to the proposition that the use of mesh will improve the outcome of the repair and reduce the recurrence risk. Based on the principles of synthetic mesh in abdominal surgery and after the successful introduction of synthetic vaginal tapes for SUI, in 2002 a group of French urogynecologists started a prospective multicenter study on transvaginal POP repair using a tension-free polypropylene mesh in patients with ≥stage III vaginal prolapse (Prolift^{TM}). The preliminary published reports were encouraging, and within a relatively short period of time, many gynecologists decided to introduce this technique or modifications of this technique into their practice [133].

Although these techniques were meant to replace or reinforce damaged pelvic tissue, a growing concern regarding the lack of long-term results and safety issues have been surfacing in relation to these kits.

On October 20, 2008, the FDA issued a Public Health Notification and Additional Patient Information on serious complications associated with surgical mesh placed through the vagina (transvaginal placement) to treat POP. Based on an updated analysis of adverse events reported to the FDA and complications described in the scientific literature, the FDA identified surgical mesh for transvaginal repair of POP as an area of continuing serious concern. They issued an update on July 13, 2011, to inform that serious complications associated with surgical mesh for transvaginal repair of POP are not rare. They state that it is not clear that transvaginal POP repairs with mesh is more effective than traditional nonmesh repairs in all patients with POP, and it may expose patients to greater risk [134].

Many of these products have been withdrawn from the market. Currently, American Congress of Obstetricians and Gynecologists (ACOG) and The American Urogynecologic Society (AUGS) recommend the use of vaginal mesh repair only in high-risk women for whom the benefit may justify the risk [135].

Results

There is only one prospective randomized trial comparing native-tissue repair (ULS or sacrospinous fixation) to a vaginal mesh kit (Prolift) for patients with vault prolapse [136]. At 12 months, both groups had improvement of POPQ test points with similar recurrence rates. The quality of life improved and did not differ between groups: 96.2% mesh vs. 90.9% nonmesh subjects reported a cure of bulge symptoms, 15.6% had mesh exposures, and reoperation rates were higher with mesh. Unfortunately, owing to the ethics committee imposing a stopping criterion of a 15.6% mesh exposure rate, the study was terminated and did not recruit the appropriate sample size and is underpowered to detect a significant difference between the groups—if it exists [136]. The 3-year follow-up from the same study was published, and there were no differences in cure rates between both groups [137].

There was one study comparing a vaginal mesh kit to laparoscopic sacrocolpopexy [138]. Maher et al. found that laparoscopic sacral colpopexy group had a longer operating time, reduced inpatient days, and quicker return to activities of daily living as compared with the TVM group. At the 2-year review, the total objective success rate at all vaginal sites was (77%) for laparoscopic sacral colpopexy as compared with (43%) in TVM group ($p < 0.001$). The reoperation rate was significantly higher after vaginal mesh surgery (22%) as compared with laparoscopic sacral colpopexy (5%) ($p = 0.006$). This study concluded that at 2 years, the laparoscopic sacral colpopexy group had a higher satisfaction rate and objective success rate than the TVM group with lower perioperative morbidity and reoperation rate [138].

A systematic review [139] on trocar-guided vaginal mesh kits for apical suspension reviewed the Posterior Prolift, Apogee, intravaginal slingplasty, and infracoccygeal sacropexy. They examined the success rate and complications of these minimally invasive “mesh kits” placed through small perianal skin incisions posteriorly through the ischioanal fossa designed to repair the vaginal apex.

Outcomes included both objective and subjective outcomes relating to prolapse; urinary, bowel, and sexual function; pain; mesh erosion/extrusion; and perioperative surgical complications.

Totaling in 2653 participants, 30 studies were reviewed for the analysis. For apical and posterior vaginal prolapse, eight studies on Apogee had a mesh extrusion rate of 11% and dyspareunia rate of 3%. Perineal, pelvic, or buttock pain was reported in 1%. The only severe intraoperative complication was proctotomy, documented in two women (0.4%).

Eight studies used the Prolift system with a varying proportion of women undergoing anterior, posterior, or total Prolift procedures. Only data relating to posterior and total Prolift were quoted with no randomized controlled trials available. Overall, posterior or total Prolift procedures were performed in 1295 women with mean follow-up time of 30 weeks (range 12–52 weeks). The mean objective success rate was 87% (range 75–94) and the mean complication rate was 16% (range 2–61). Some inconsistency in measuring success and failure following prolapse surgery among authors was noted partly due to the use of nonstandardized grading systems for prolapse quantification.

The most common complications using Prolift were mesh extrusion (7%) and dyspareunia (2%). Vaginal or buttock pain was reported in 2% and mesh contraction in 1.5%. While there was only a single woman with rectal injury, cystotomy occurred in 1% with 3 women developing fistula and 10 participants who received blood transfusions. There was a single woman with necrotizing fasciitis, which was treated by complete removal of the mesh, extensive perineal debridement, laparotomy, and colostomy followed by prolonged stay in the intensive care unit.

This review suggests that there is an overall high, short-term objective success rate (ranging from 87% to 95%) of the commonly used mesh kits in the treatment of apical vaginal prolapse. A significant limitation included management of mesh erosions. Management ranged from local estrogen, through operative excision and oversewing of the eroded mesh, to complete excision of the mesh. Additionally, repeated excisions may have occurred in the same subject and in different settings. Dyspareunia was reported between 1.5% and 3%. It is possible that the lower prevalence of dyspareunia following mesh kit procedures is attributed to the fact that fascial or levator placation is not performed with the mesh kits.

Complications associated with these trocar kits include cystotomies, proctotomies, and vascular injuries. Unlike mesh-related complications that can evolve at any stage during the postoperative course, trocar-related complications occur intraoperatively and can lead to extremely unfavorable consequences if not identified and treated meticulously at the time of occurrence.

Complication rates reported in more recent systematic reviews found rates of organ perforation (2.6%), bleeding (hematoma) (3.8%), and mesh exposure (5%–19%) (mean 10.3%) with 56% of the mesh exposure requiring surgical reintervention, vaginal scarring (8%–11%), dyspareunia (4.4%–7.7%), infection (1.6%–7.3%), pain (1.0%–9.8%), reoperation (5.5%–8.5%), and urinary problems (4.7%–10.2%) [133].

Few prospective cohort trials assessing the new single-incision transvaginal kits had been published with initial results showing promising efficacy and fewer complications when compared to trocar kits [140–142]. With these new kits, complications related to trocar passage are virtually eliminated, and initial reports show lower rates of mesh extrusion; however, these are still seen in 4.5%–6.5% of the cases [141–143]. Only short-term follow-up data are available. It is important to recognize that this rate may increase with time. Also with these kits, there is an evidence of an increased rate of de novo SUI after surgery [142]. Further research comparing single-incision kits with native-tissue repair are needed examining both objective and subjective outcomes.

In conclusion, based on limited peer-reviewed data, transvaginal mesh kits appear to be effective in restoring apical vaginal support, but data on functional outcomes and long-term follow-up are unclear. In the current literature, there is no level 1 evidence that vaginal mesh should be used in primary cases to correct vault prolapse. Surgeons should counsel women that device-related complications with these procedures are not rare; most are related to the use of mesh and their management might necessitate surgical intervention under an anesthetic. Future research should be directed toward well-conducted and adequately powered randomized controlled trials with longer follow-up, comparing vaginal mesh procedures with traditional native-tissue surgeries for apical prolapse and on how surgeons should manage device- and mesh-related complications. Functional outcomes following these procedures and their impact on prolapse symptoms and quality of life should also be thoroughly studied.

CONCLUSION

Optimal management of vault prolapse remains an enigma, and with an increasing aging and active population, there will be an increased need to manage women with complex vaginal prolapse utilizing procedures that restore anatomy and maintain bladder, bowel, and sexual function.

With the availability of different routes and procedures, it is important to individualize caretaking into consideration the patient’s age, medical status, sexual activity, reproductive history, previous surgery, and bowel and bladder function. Well-designed prospective randomized trials need to be done to determine whether or not any of these procedures can truly be considered the “gold standard.”

86 Open Abdominal Approach to Supporting the Vaginal Apex

Kristina Cvach and Peter Dwyer

INTRODUCTION

Prolapse of the vaginal apex may occur with the uterus in situ or following a previous hysterectomy. The vaginal apex is normally supported by the uterosacral–cardinal ligament complex and the levator ani musculature, nominated by DeLancey [1] as Level 1 support. This defect in most cases occurs secondary to weakness in the muscular levator ani complex, which can occur as a result of obstetric injury with muscular tearing or denervation, aging, or even congenital defects such as spina bifida or bladder extrophy. Apical loss of support secondary to muscular injury may be unilateral or bilateral resulting in apical prolapse. This often occurs in the presence of anterior and/or posterior compartment prolapse. Identifying the extent of apical prolapse during the clinical examination and then addressing the apex during prolapse surgery is crucial to providing a durable repair.

The route by which prolapse surgery takes place is a decision based on patient characteristics as well as surgeon preference and experience. Both abdominal (open, laparoscopic, and robotic) and vaginal routes are utilized with varying surgical techniques performed in order to recreate Level 1 support. This chapter will focus on the open abdominal techniques used to repair apical prolapse, both in the posthysterectomy patient and in the patient with uterine descent wishing to preserve her uterus.

SACROCOLPOPEXY

Technique

Abdominal sacrocolpopexy (ASC) was first described by Frederick Lane in 1962 [2]. It is performed in the posthysterectomy patient and involves resupporting the vaginal apex to the sacrum with the use of an intervening graft, most commonly made of synthetic polypropylene mesh. In brief, the patient is placed in low lithotomy, and once the abdomen has been opened and with a probe in the vagina to aide dissection, the peritoneum, bladder, and rectum are dissected off the vagina. The graft material (either self-made strips, self-made “Y,” or precut “Y”) is then attached to the vagina using either delayed-absorbable or permanent sutures. The anterior longitudinal ligament overlying the sacral promontory is exposed by incising the overlying peritoneum. Care must be taken to identify the right ureter and right and left iliac vessels as these structures are all within 3 cm of the promontory [3]. The dissection is then continued caudally down the right paracolic gutter to the posterior vagina.

The tail of the graft is attached to the anterior longitudinal ligament just below the most prominent point of the sacral promontory (Figure 86.1). In an MRI study, Abernethy showed that the L5–S1 disc was situated at the prominence in 73% of cases [4]. Therefore, attaching the graft with permanent suture or surgical tacks just below the prominence may avoid the complication of discitis. Care must be taken not to over suspend the vagina—the graft material needs to be an adequate length (15–20 cm) in order to achieve tension-free attachment to the sacrum. Oversuspension in our opinion can lead to an increased incidence of de novo stress urinary incontinence and anterior compartment prolapse. The peritoneum is closed over the graft in order to avoid entrapment of the sigmoid colon and development of bowel adhesions to the graft. Vaginal assessment is performed to ascertain if any concomitant anterior or posterior compartment repairs are required. Anti-incontinence procedures may be performed concurrently, if indicated. Cystoscopy is performed to ensure bladder integrity and ureteric patency.

Patients with uterine prolapse may undergo a concomitant total hysterectomy at the time of sacrocolpopexy. However, any opening of the vagina, intentional or not, will increase the risk of subsequent vault mesh exposure (ME), with one study reporting an odds ratio of 4.9 when a concomitant total hysterectomy was performed [5]. In an effort to mitigate this risk, a number of authors advocate that supracervical hysterectomy be performed.

Efficacy

ASC has been shown to be an effective procedure for apical prolapse [6]. Nygaard published a comprehensive review of all studies reporting outcomes on ASC [7]. Efficacy was reported on 64 studies; with mean follow-up between 6 months and 3 years, the success rate for apical prolapse was reported as 78%–100%, and that for all compartment cure was 58%–100%. The median reoperation rate for prolapse was 4.4%. Many of these studies were retrospective case series or cohort studies with relatively short follow-up.

The Colpopexy and Urinary Reduction Efforts (CARE) trial assessing the utility of retropubic urethropexy performed at the time of ASC in stress-continent women recently reported outcomes at 7 years [8]. This is a very valuable study as it provides longer-term data on efficacy of ASC in the framework of a randomized controlled trial (RCT). When using a composite definition of treatment failure for prolapse incorporating both anatomical and symptom definitions, this study reported prolapse failure rates considerably higher than previously published. The estimated probability of failure at 7 years for the urethropexy group was 34% and that of the no urethropexy group was 48%. Despite this high failure rate, only 5% of women underwent surgical correction of the recurrent prolapse. This study highlights the need for long-term reporting of efficacy of prolapse repair procedures, as failure rates appear to increase over time.

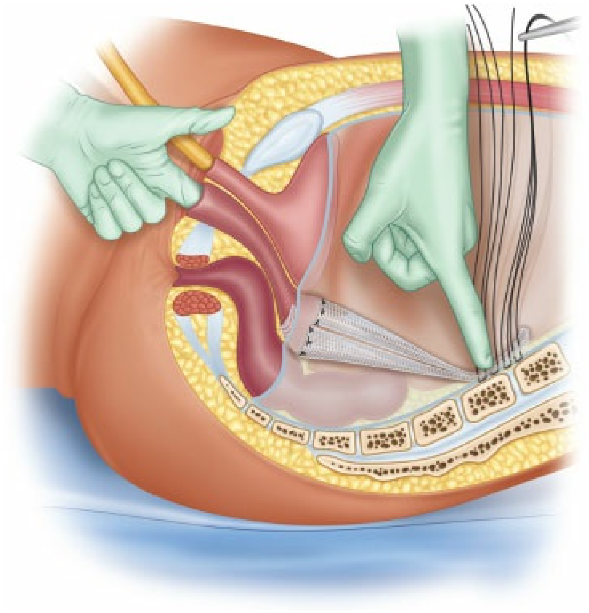

Figure 86.1 Abdominal sacrocolpopexy technique. (Reprinted from Cvach K et al., *Female Pelvic Med Reconstr Surg*, 18, 286, 2012. With permission from Wolters Kluwer Health.)

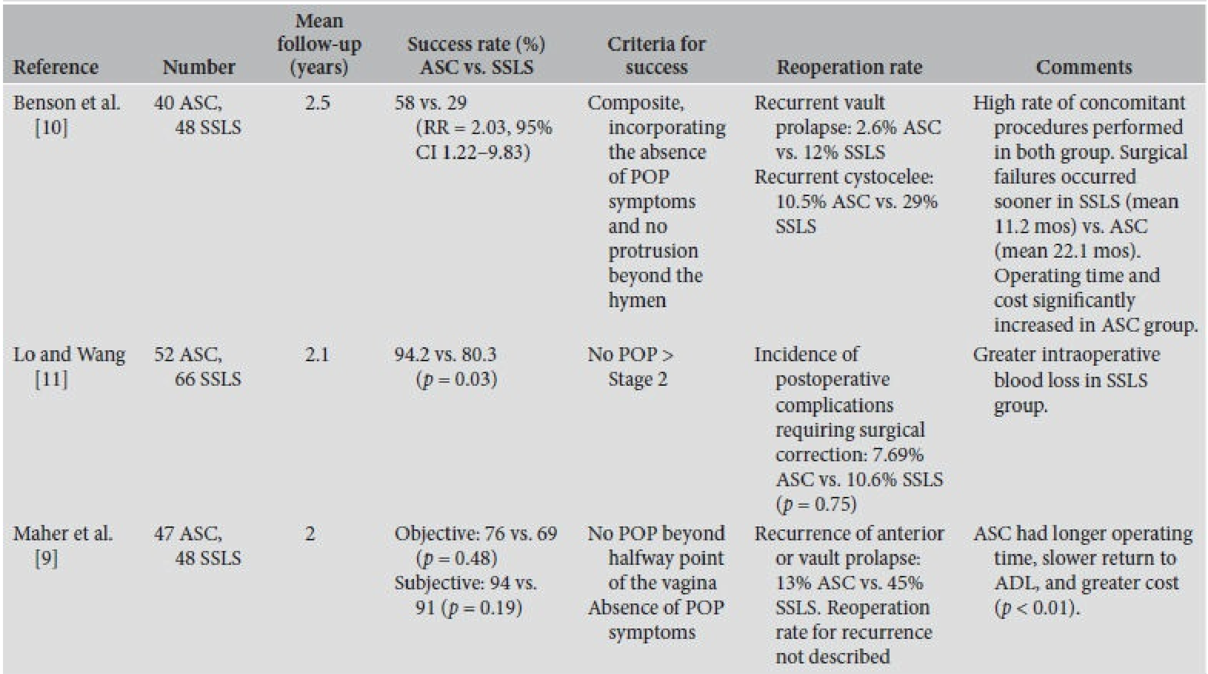
ASC compares favorably to other apical suspension procedures. Maher et al. reported on 2-year follow-up of an RCT in 95 women comparing ASC to sacrospinous ligament suspension (SSLS) [9]. The subjective success rate in ASC and SSLS was 94% and 91% (p = 0.19), respectively. Anatomic successes in ASC and SSLS were 76% and 69% (p = 0.48), respectively. Both groups showed significant improvement in the quality of life (Table 86.1). Despite these equivalent findings, the most recent Cochrane review on surgical management of prolapse has shown the superiority of ASC when compared to SSLS [6]. Analyzing the Maher et al. study with similar studies by Benson et al. [10] and Lo and Wang [11] showed ASC had a lower all compartment failure rate (RR 0.29, 95% CI 0.09–0.97), a lower rate of recurrent vault prolapse (RR 0.23, 95% CI 0.07–0.77), and a lower rate of postoperative dyspareunia (RR 0.39, 95% CI 0.18–0.86).

Comparisons to other vaginal apical suspension procedures in the literature are lacking. Braun et al. [12] published a small study comparing total abdominal hysterectomy (TAH) and ASC to vaginal hysterectomy (VH) and Mayo McCall culdoplasty with a mean follow-up of 33 months, which showed anatomical failure rates of 0% for TAH/ASC compared to 17% for VH/McCall. Rondini et al. [13] randomly allocated women to ASC or high uterosacral vault suspension (HUSLS) with follow-up to 1 year and showed anatomical success (point C less than −1 cm) in 100% of ASC compared to 83% HUSLS. Recurrent anterior or posterior compartment prolapse was 5.5% in ASC compared to 33.9% in HUSLS with corresponding lower rates of reoperation in ASC (5%) compared to HUSLS (17.8%). Lim et al. reported on an RCT comparing ASC to extraperitoneal vaginal uterosacral ligament suspension (VEULS) with anterior mesh reinforcement [14]. Objective success was 76.5% for ASC and 70% for VEULS ($p = 0.38$). There were no between-group differences for subjective outcomes based on changes in symptoms (Pelvic Floor Distress Inventory [PFDI-20]), prolapse quality of life (Pelvic Floor Impact Questionnaire [PFIQ-7]), and sexual health (Pelvic Organ Prolapse/Urinary Incontinence Sexual Questionnaire [PISQ-12]). ME occurred in three women in the ASC group and in two women in the VEULS group. A further retrospective study by Sanses et al. [15] compared vaginal mesh procedures (VMP) to uterosacral ligament suspensions (USLS) and ASC. This study was based on short-term follow-up (3–6 months) and showed equivalent apical success rates for all procedures of >98%; however, VMP showed a significant reduction in total vaginal length.

Table 86.1 Randomized Controlled Trial Results Comparing Abdominal Sacrocolpopexy to Sacrospinous Vaginal Vault Suspension



Reference	Number	Mean follow-up (years)	Success rate (%) ASC vs. SSLS	Criteria for success	Reoperation rate	Comments
Benson et al. [10]	40 ASC, 48 SSLS	2.5	58 vs. 29 (RR = 2.03, 95% CI 1.22–9.83)	Composite, incorporating the absence of POP symptoms and no protrusion beyond the hymen	Recurrent vault prolapse: 2.6% ASC vs. 12% SSLS Recurrent cystocelee: 10.5% ASC vs. 29% SSLS	High rate of concomitant procedures performed in both group. Surgical failures occurred sooner in SSLS (mean 11.2 mos) vs. ASC (mean 22.1 mos). Operating time and cost significantly increased in ASC group.
Lo and Wang [11]	52 ASC, 66 SSLS	2.1	94.2 vs. 80.3 ($p = 0.03$)	No POP > Stage 2	Incidence of postoperative complications requiring surgical correction: 7.69% ASC vs. 10.6% SSLS ($p = 0.75$)	Greater intraoperative blood loss in SSLS group.
Maher et al. [9]	47 ASC, 48 SSLS	2	Objective: 76 vs. 69 ($p = 0.48$) Subjective: 94 vs. 91 ($p = 0.19$)	No POP beyond halfway point of the vagina Absence of POP symptoms	Recurrence of anterior or vault prolapse: 13% ASC vs. 45% SSLS. Reoperation rate for recurrence not described	ASC had longer operating time, slower return to ADL, and greater cost ($p < 0.01$).

Abbreviations:RCT, randomized controlled trial; POP, pelvic organ prolapse; RR, relative risk; CI, confidence interval; mos, months.

The choice of graft material, synthetic versus biologic, has not been extensively studied. Tate et al. have reported on 5-year follow-up of an RCT of ASC with polypropylene mesh versus cadaveric fascia lata [16]. Objective results at 5 years reflected 1 year data, with superior results in the polypropylene group (93% vs. 62%, $p = 0.02$). Subjective results, however, did not reach statistical significance (97% vs. 90%, $p = 0.61$). Reoperation for recurrent prolapse occurred in two patients, one in each group. There were two MEs in the mesh group and one in the fascia lata group.

All studies, comparing ASC to vaginal procedures, show that ASC does have higher intraoperative morbidity with longer operating time, higher blood loss, longer hospital stay, and slower return to activities of daily living. These results have driven the development of new procedures using laparoscopy and robotics to potentially mitigate the negative aspects of what is an anatomically superior approach to apical prolapse repair. Freeman et al. published an RCT assessing the clinical equivalence of ASC and laparoscopic sacrocolpopexy (LSC) in 53 women with follow-up at 1 year [17]. Anatomical outcomes for point C showed equivalence (−6.63 ASC vs. −6.65 LSC), as did subjective assessment of improvement (90% ASC vs. 80% LSC), and change in quality of life outcomes. Reoperation occurred in 2 ASC and 3 LSC. LSC had less blood loss, less narcotic use, and shorter length of stay (4.1 days ASC vs. 3.2 days LSC). Paraiso et al. published an RCT of LSC and robotic sacrocolpopexy (RSC) with follow-up at 1 year [18]. The primary outcome was total operating time, with RSC taking significantly longer (+67 minute difference, 95% CI 43–89; $p < 0.001$). Women in the RSC group also had significantly higher pain and longer use of nonsteroidal anti-inflammatory drugs. Not surprisingly, RSC incurred a higher cost than LSC (+$1936, 95% CI $417–$3454; $p = 0.008$). There were no differences in anatomical or subjective outcomes between groups, with significant improvements from baseline in both LSC and RSC. While the laparoscopic approaches to sacrocolpopexy appear to have some advantages over the open approach, they do require a different skill set. There is a definite learning curve for both techniques, and the surgeon embarking on these must undergo the appropriate training.

SACROHYSTEROPEXY

Technique

Abdominal sacrohysteropexy (ASH) is a uterine-conserving procedure for women with uterovaginal prolapse. Current cervical or uterine pathology is excluded prior to this procedure, and women at high risk of developing endometrial carcinoma should not undergo uterine conservation. Women need to continue to have their cervical screening following the procedure and are counseled about the potential difficulties of future pelvic surgery in the presence of pericervical mesh. While preservation of fertility is one of the reasons women may wish to avoid hysterectomy, there are few published cases of pregnancy and prolapse outcomes following ASH [19–21], and, in general, it is preferable that women have completed their childbearing prior to prolapse surgery. In those contemplating future pregnancy, there is little evidence to guide the discussion regarding mode of delivery, and it is conceivable that pregnancy per se, as well as vaginal delivery, increases the risk of recurrent uterine prolapse following ASH.

After entry into the abdomen, the sacral, paracolic, and posterior vaginal dissections are carried out as per ASC. Synthetic mesh may be attached over the upper posterior vagina and cervix and suspended to the anterior sacrum. If there is significant anterior compartment prolapse, synthetic mesh can also be attached over the anterior vaginal wall. An incision is made in the anterior leaf of the broad ligament bilaterally, inferior to the fallopian tubes, and extended down to the uterovesical fold. The bladder is mobilized off the cervix to expose 3–4 cm of the underlying anterior vaginal wall. Windows are made in the broad ligament bilaterally at the level of the cervicouterine junction, lateral to the uterine artery. Two mesh strips are then fashioned; one is bisected to produce a Y-configuration for the anterior mesh. The anterior mesh arms are passed through the broad ligament windows. Both the anterior and posterior mesh strips are attached to the vagina using permanent or delayed absorbable sutures (Figure 86.2). Other authors attach the broad end of the anterior Y mesh to the vagina and pass the arms of the Y through the broad ligament, attaching these to the posterior mesh [20,22,23], or have reported on the use of a single mesh strip attached only posteriorly [24]. Irrespective of the mesh strip configuration, the proximal end(s) is attached to the anterior longitudinal ligament and the peritoneum closed over the mesh as per the ASC.

Efficacy

Most studies assessing the efficacy of ASH are case series of 12–55 subjects with variable follow-up of up to 5 years (Table 86.2). Barranger et al. reported on a series of 30 women undergoing ASH with concomitant Burch colposuspension and posterior vaginal repair [20]. With a mean objective follow-up of 44 months and mean subjective follow-up of 94 months, failure rates were 6.6% (2/30) and 3.3% (1/30), respectively. Demirci et al. published a series of 20 cases of ASH with concomitant anti-incontinence surgery and posterior vaginal repair, with follow-up of 25 months [24]. One patient (5%) developed early recurrence with Stage 2 anterior and posterior prolapse within 1 month of surgery. Subjective improvement based on a prolapse-specific symptom inventory and quality of life questionnaire showed significant reduction in total scores, signifying improvement in prolapse symptoms postoperatively. Costantini et al. reported on their 5-year follow-up of 52/55 women undergoing sacrohysteropexy [23]. There were no cases of recurrent uterine prolapse. Stage 2 or more anterior recurrence occurred in 4/52 (7.7%) and posterior recurrence in 3/52 (5.7%); however, these recurrences were asymptomatic and did not require further surgical intervention. Both Urinary Distress Inventory (short form) and Incontinence Impact Questionnaire (short form) scores were significantly reduced postoperatively showing improvement in both urinary symptoms and quality of life. Satisfaction with prolapse surgery was measured on a 10-point visual analogue scale, with a mean score of 8.6, suggesting high satisfaction. No cervical or uterine abnormalities were detected with annual screening postoperatively.

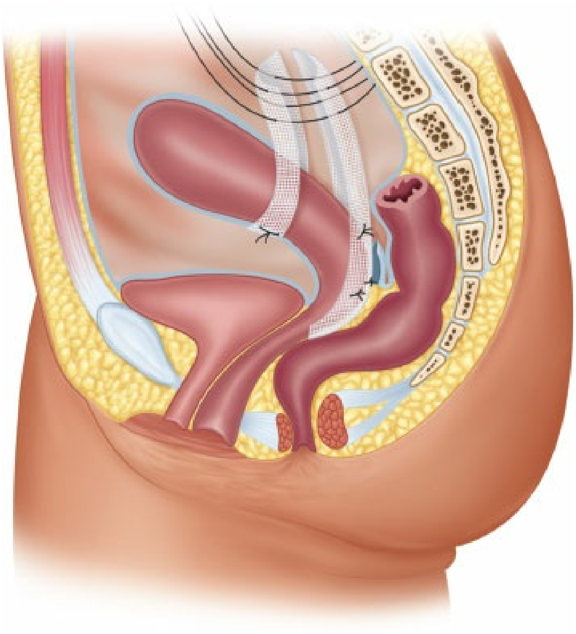

Figure 86.2 Abdominal sacrohysteropexy technique. (Reprinted from Cvach K et al., *Female Pelvic Med Reconstr Surg*, 18, 286, 2012. With permission from Wolters Kluwer Health.)

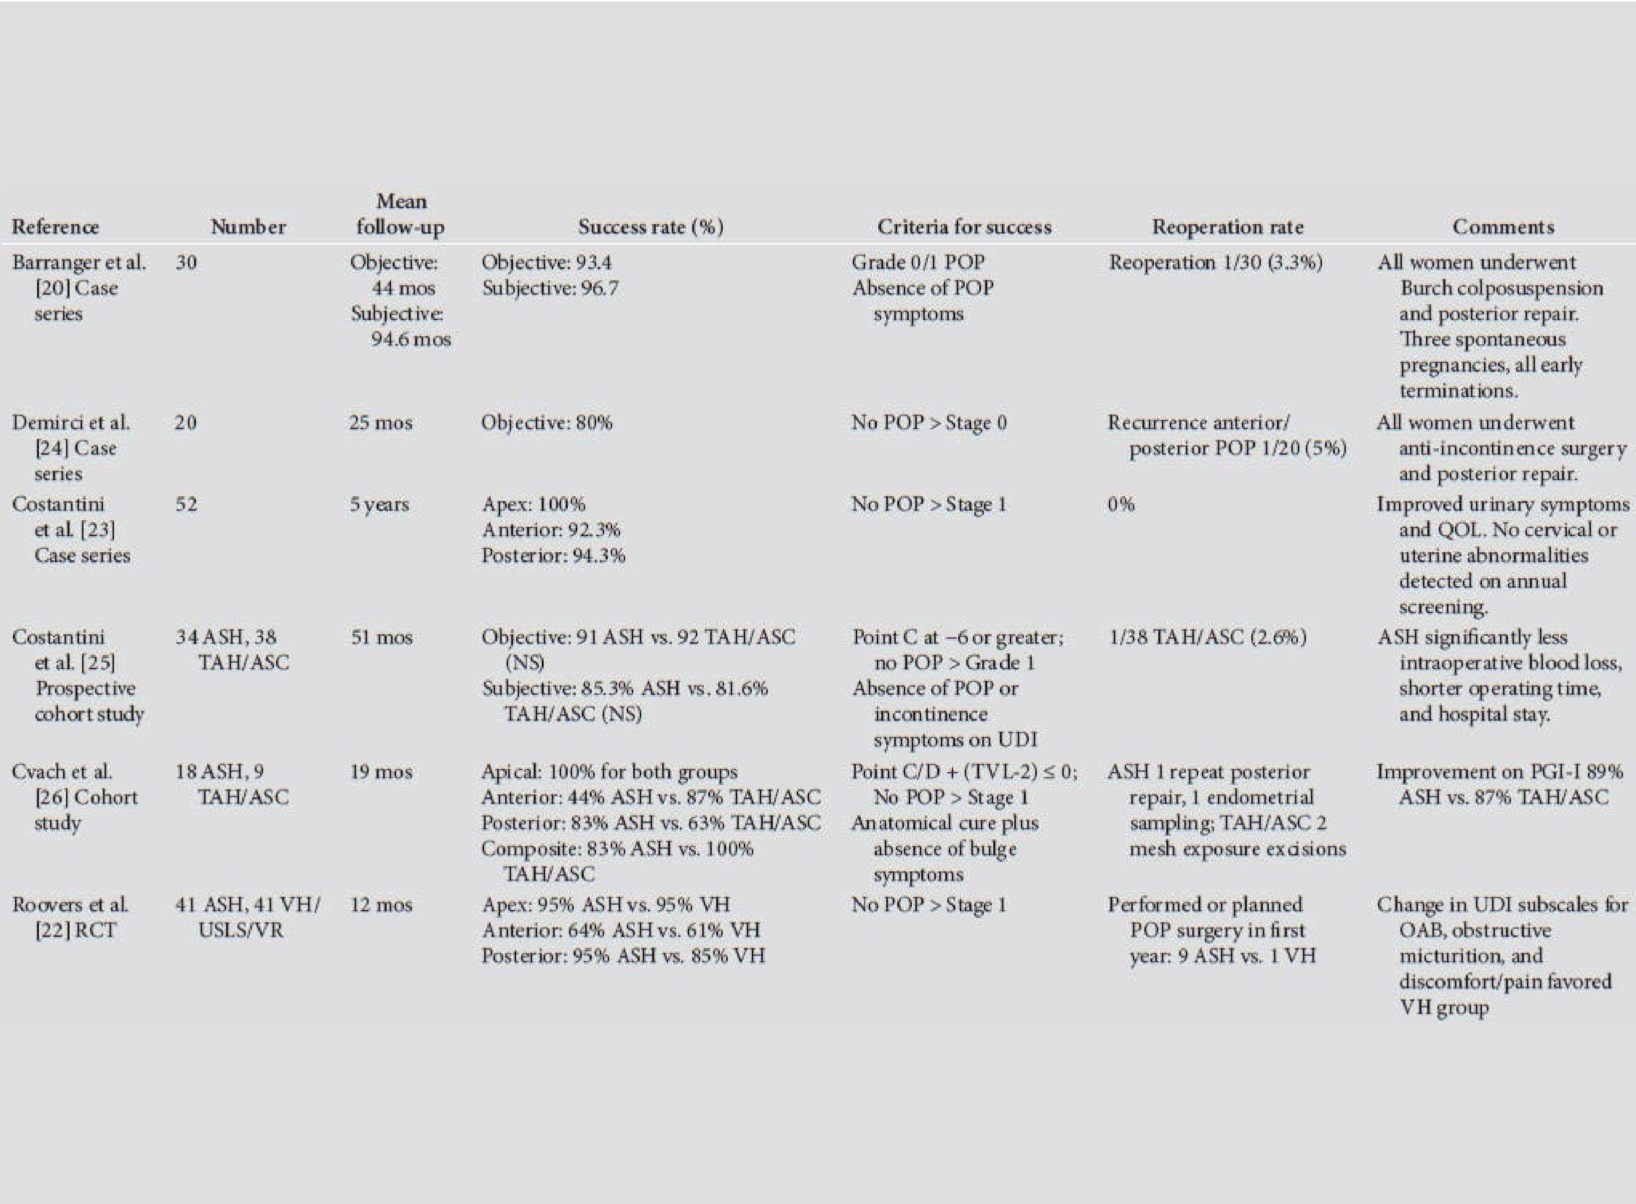
There are few comparative studies of ASH. Costantini et al. published a prospective cohort study comparing 34 women undergoing ASH to 38 undergoing TAH/ASC with mean follow-up of 51 months (range 12–115 months) [25]. Objective successes were 91% (31/34) in the ASH group (3 had recurrent anterior prolapse) and 92% (35/38) in the TAH/ASC group (3 had recurrent posterior prolapse, 1 required repeat prolapse surgery). Subjective successes based on the absence of prolapse or incontinence symptoms using the Urogenital Distress Inventory (UDI) were 85.3% in the ASH group and 81.6% in the TAH/ASC group (not significant). Satisfaction rates were also not statistically different between the groups (ASH 91%, TAH/ASC 86.8%). Cvach et al. have published a similar comparative study of 18 ASH and 9 TAH/ASC patients with a mean follow-up of 19 months [26]. There were no apical recurrences in either group. Objective success for the anterior compartment was 44% (8/18) in the ASH group and 87% (7/8) in the TAH/ASC group and, in the posterior compartment, 83% (15/18) in the ASH group and 63% (5/8) in the TAH/ASC group. One patient in the ASH group required repeat posterior vaginal prolapse surgery. Subjective success based on change in Pelvic Floor Distress Inventory and Pelvic Floor Impact Questionnaire scores was seen in both groups postoperatively with no statistical difference between surgical groups. Patient satisfaction was high; 89% in the ASH and 87% in the TAH/ASC group (NS). If a composite measure of success was used (based on anatomical cure plus absence of bulge symptoms), then 83% of ASH and 100% TAH/ASC were considered cured.

Roovers et al. published an RCT comparing ASH (with no concomitant vaginal surgery) to VH, USLS, and vaginal repair (VH) in 82 women with 12 months of follow-up [22]. Primary outcome was based on change in UDI scores. While both groups showed significant changes in all UDI subscales, there was a significant difference in the changes of the overactive bladder, obstructive micturition, and discomfort/pain subscales, favoring the VH group. Objective success in the apical compartment was 95% for both the ASH and VH groups, in the anterior compartment 64% for the ASH group and 61%

for the VH group, and in the posterior compartment 95% for the ASH group and 85% in the VH group. Performed or planned prolapse surgery within the first year of the original prolapse surgery occurred in 9 women in the ASH group (5 anterior, 4 uterine) and 1 women in the VH group (vault). There are currently no studies comparing abdominal to vaginal uterine preservation techniques.

Overall, studies assessing the efficacy of ASH have shown excellent results for the apical compartment. Anterior and posterior compartment results are variable and may reflect differences in configuration of the mesh (use of posterior mesh only), the anchoring of the anterior mesh (broad end or mesh arms), and whether concomitant anterior or posterior vaginal repairs are performed. There may be an advantage in intraoperative and short-term postoperative morbidity in avoiding hysterectomy at time of uterine prolapse surgery. In Costantini's study of ASH versus TAH/ASC discussed earlier, uterine conservation was associated with a shorter operating time (89 vs. 115 minutes; $p < 0.001$), less intraoperative blood loss less (325 vs. 200 mL; $p < 0.001$), and shorter hospital stay ($p < 0.05$).

Table 86.2 Abdominal Sacrohysteropexy Studies



Reference	Number	Mean follow-up	Success rate (%)	Criteria for success	Reoperation rate	Comments
Barranger et al. [20] Case series	30	Objective: 44 mos Subjective: 94.6 mos	Objective: 93.4 Subjective: 96.7	Grade 0/1 POP Absence of POP symptoms	Reoperation 1/30 (3.3%)	All women underwent Burch colposuspension and posterior repair. Three spontaneous pregnancies, all early terminations.
Demirci et al. [24] Case series	20	25 mos	Objective: 80%	No POP > Stage 0	Recurrence anterior/ posterior POP 1/20 (5%)	All women underwent anti-incontinence surgery and posterior repair.
Costantini et al. [23] Case series	52	5 years	Apex: 100% Anterior: 92.3% Posterior: 94.3%	No POP > Stage 1	0%	Improved urinary symptoms and QOL. No cervical or uterine abnormalities detected on annual screening.
Costantini et al. [25] Prospective cohort study	34 ASH, 38 TAH/ASC	51 mos	Objective: 91 ASH vs. 92 TAH/ASC (NS) Subjective: 85.3% ASH vs. 81.6% TAH/ASC (NS)	Point C at −6 or greater; no POP > Grade 1 Absence of POP or incontinence symptoms on UDI	1/38 TAH/ASC (2.6%)	ASH significantly less intraoperative blood loss, shorter operating time, and hospital stay.
Cvach et al. [26] Cohort study	18 ASH, 9 TAH/ASC	19 mos	Apical: 100% for both groups Anterior: 44% ASH vs. 87% TAH/ASC Posterior: 83% ASH vs. 63% TAH/ASC Composite: 83% ASH vs. 100% TAH/ASC	Point C/D + (TVL-2) ≤ 0; No POP > Stage 1 Anatomical cure plus absence of bulge symptoms	ASH 1 repeat posterior repair, 1 endometrial sampling; TAH/ASC 2 mesh exposure excisions	Improvement on PGI-I 89% ASH vs. 87% TAH/ASC
Roovers et al. [22] RCT	41 ASH, 41 VH/ USLS/VR	12 mos	Apex: 95% ASH vs. 95% VH Anterior: 64% ASH vs. 61% VH Posterior: 95% ASH vs. 85% VH	No POP > Stage 1	Performed or planned POP surgery in first year: 9 ASH vs. 1 VH	Change in UDI subscales for OAB, obstructive micturition, and discomfort/pain favored VH group

COMPLICATIONS

Complications following ASC/ASH can be divided into those occurring intraoperatively or postoperatively.

Intraoperative Complications

These are similar to those of any open abdominal procedure. In Nygaard's review of ASC [7], median rates of complications were cystotomy 3.1%, ureteric injury 1%, enterotomy/proctotomy 1.6%, and hemorrhage requiring transfusion at a rate of 2.6%–4.4% [7,10]. Specific to ASC/ASH is hemorrhage occurring during the presacral dissection due to injury to the presacral vascular plexus. Bleeding from these vessels can be difficult to control as they retract into the bony surface of the sacrum and often require the use of bone wax or sterile thumb tacks to achieve hemostasis.

Postoperative Complications

Urinary tract infection is the commonest postoperative complication (10.9%), followed by wound problems (4.6%), ileus (3.6%), deep vein thrombosis or pulmonary embolism (3.3%), operation for small bowel obstruction (1.1%), and incisional hernia repair (5%) [7].

Mesh Complications

ME is a recognized complication of ASC/ASH and can occur at any time point following surgery. ME rates vary according to the synthetic material used with the overall ME rate reported by Nygaard et al. at 3.4% [7]. It is thought that the Amid classification of the material with regard to pore size and weave has a bearing on the risk of ME, with macroporous, monofilament meshes having lower ME rates compared with those having a microporous, multifilament design (Table 86.3). Currently, polypropylene mesh is the most commonly used mesh in prolapse surgery. For published ME rates to be meaningful, long-term follow-up of women with reporting of these data is crucial. The 7-year follow-up of the CARE trial reported a 10% probability of ME, much higher than previously reported [8]. It is important to note that 48% of women in this trial had Mersilene or Gortex mesh, both of which are recognized to have higher rates of ME than polypropylene.

ME may be affected by other factors. Concomitant hysterectomy may increase the risk of ME, with an ancillary study of the CARE trial reporting an OR of 4.9 [5]. The same study showed current smoking increased ME with an odds ratio (OR) of 5.2.

Management of ME requires thorough counseling of the patient. Rarely does conservative management with application of topical estrogen rectify the problem. Most women will require surgical revision of the mesh with an initial vaginal approach to excise the exposed mesh. Complete excision of the mesh may be required if the initial partial excision fails. Quiroz et al. reported on a series of women undergoing mesh revision surgery, with only 48% success with initial vaginal surgery. Most women required more than one mesh revision, often through an abdominal approach [27].

Multiple case reports of small bowel obstruction related to abdominal mesh or scar tissue occurring up to 14 years following ASC have been published, highlighting the need for ongoing follow-up of any women undergoing these procedures [20,28–30].

A small number of case reports of discitis and osteomyelitis occurring 2 months to 8 years after ASC have been published [31–34]. All required open exploration and removal of the mesh, with debridement of the L5–S1 disc.

CONCLUSION

The abdominal sacrocolpopexy or sacrohysteropexy is an effective procedure for the treatment of apical vaginal prolapse. However, the significant morbidity associated with the abdominal approach must be carefully weighed against potential benefits when considering this option. There are advantages and disadvantages of all techniques, and the decision should be based on the patient's needs and wishes once sensible discussion has occurred. Relevant clinical factors in making this decision are the patient's age and general health, whether further pregnancies are desired, sexual activity, presence of dyspareunia, and vaginal size. The abdominal approach will be preferable in the presence of other abdominal pathology requiring treatment such as an ovarian cyst or when vaginal capacity is already reduced from previous surgery in a sexually active woman. In most cases, further vaginal surgery is more likely to decrease vaginal capacity and cause coital difficulty than the abdominal approach.

However, the vaginal approach may be preferable in the presence of severe adhesions increasing the difficulty and risk of an abdominal approach. Older women with medical comorbidity will be better served by shorter operations with a lower risk profile performed vaginally. The risk of recurrence may influence the decision in favor of the abdominal approach and the use of synthetic mesh. However, poor publicity and outcomes with vaginal mesh have also impacted on patient's perceptions with the ASC and rectopexy procedures. Surgical training and experience will and should have an influence on surgical choice so that the procedure can be completed safely. Finally, pelvic floor dysfunction is frequently caused by multiple defect sites. Apical prolapse may be associated with rectoceles, perineal defects, and stress or fecal incontinence that may require concomitant correction and surgical repair. In many cases, these are best performed vaginally, so a combined abdominovaginal approach may be required.

Table 86.3 Comparison of Mesh Type and Mean Exposure Rate

Mesh type	**Manufacturer**	**Mean exposure rates**
Autologous or cadaveric fascia		0% (0/88)
Polypropylene	Prolene, Ethicon[a]	0.5% (1/211)
Polyethylene terephthalate	Mersilene, Ethicon[b]	3% (25/811)
Polytetrafluoroethylene	GORE-TEX, W.L. Gore[c]	3.4% (12/350)
Polyethylene	Marlex, Phillips Sumika[d]	5% (20/402)
Polytetrafluoroethylene	Teflon, EI Dupont[e]	5.5% (6/119)

87 Laparoscopic and Robotic Approaches to Apical and Vaginal Vault Suspension

Vaneesha Vallabh-Patel and Patrick J. Culligan

INTRODUCTION

Pelvic organ prolapse (POP) is often described as a herniation of the pelvic organs toward the vaginal walls. It is further divided into different categories based on the anatomical location of the herniation to include anterior, apical, and posterior prolapse. Apical prolapse is further described as the descent of the uterus and cervix or vaginal vault in posthysterectomy cases toward the hymen. This chapter will focus on the treatment of apical prolapse using laparoscopic techniques with or without robotic assistance. The two techniques specifically discussed are high uterosacral ligament suspension (HUSLS) and sacrocolpopexy.

ETIOLOGY

Although there are little data about the epidemiology of POP, there is no dispute that it is a growing problem in the United States as the population of elderly Americans rises. A recent study performed by Wu et al. extrapolating data from the U.S. Claims and encounters database estimated the lifetime risk for females 18 years and older to develop pelvic floor dysfunction and need for surgical management to be as high as 20% in the United States [1].

Presently, there are at least 300,000 operations performed annually in the United States for symptoms of POP [2]. Several studies have shown that of these patients, up to 30% will require an additional surgery for recurrence of prolapse [3,4].

The most notable risk factors associated with POP include vaginal delivery, advancing age, obesity, history of prior hysterectomy, chronic constipation, and other repetitive increases in abdominal pressure. Caucasian and Latina females have a fourfold to fivefold increase when compared to African-American females [4].

Clinical manifestations associated with POP include vaginal bulging, pelvic heaviness, constipation, incomplete bladder and bowel emptying, the need to perform evacuation techniques, or simply having discomfort with intercourse [5].

HIGH UTEROSACRAL LIGAMENT SUSPENSION

In 1927, Miller first described “lifting sutures” when suspending the uterosacral ligaments to the apex of the vaginal vault [6]. A similar technique was again described by Milton L. McCall in 1957 using the culdoplasty technique that revealed the importance of this suspension at the time of a vaginal hysterectomy to prevent an enterocele and posthysterectomy vaginal vault prolapse [7]. Richardson later modified this approach in 1976, introducing the HUSLS [8,9].

Now nearly 60 years after McCall described his technique, the same attachment points and surgical principles are used via laparoscopic approaches.

Laparoscopic Approach for High Uterosacral Ligament Suspension

Laparoscopic Port Placement

Traditionally, three laparoscopic ports are placed in the abdomen. The first is the camera port placed in the umbilicus or up to 2 cm caudal to the umbilicus depending on the patient’s habitus. The second and third ports are 5 mm ports placed suprapubically and at the right paramedian [10] (Figures 87.1 and 87.2).

Technique

A 0° laparoscope is placed through the epigastric/umbilical port. The patient is transitioned into steep Trendelenburg to assist with bowel retraction and to better visualize the pelvic sidewalls. To further assist with visualization of the uterosacral ligaments, a probe is placed in the vagina to hold the ligaments on tension. This will assist the surgeon in tracing the ligaments back to their proximal origin [10]. Next, the ureters should be identified lateral to the uterosacral ligaments. The bladder peritoneum anteriorly and posteriorly should be dissected free. This is performed so that the pubocervical fascia and the rectovaginal fascia can be visualized. Next, a figure-eight suture is then placed approximately two-thirds cephalad to the proximal origin of the ligament and 1 cm caudal to the most anterior palpable margin of the sacrum [11]. The suture is then connected to the ipsilateral portion of the vaginal apex. We recommend using a delayed absorbable or permanent suture cut to a length of 36–48 in. Additionally, when first performing this technique, it is recommended to use the extracorporeal approach with a closed knot pusher to secure knot placement, as this is the easiest method to both learn and teach. After knots are secured in place, the ureters should be inspected on each side, and an intraoperative cystoscopy should be performed. It is important that cystoscopy is performed prior to the removal of the laparoscopic ports, so that any ureteral compromise can be addressed prior to the completion of the case.

Robotic-Assisted Laparoscopic Approach for High Uterosacral Ligament Suspension

Robotic Port Placement

At our institution, robotic-assisted laparoscopic HUSLSs are performed in selected patients who are not candidates for a sacrocolpopexy or have an objection to mesh utilization.

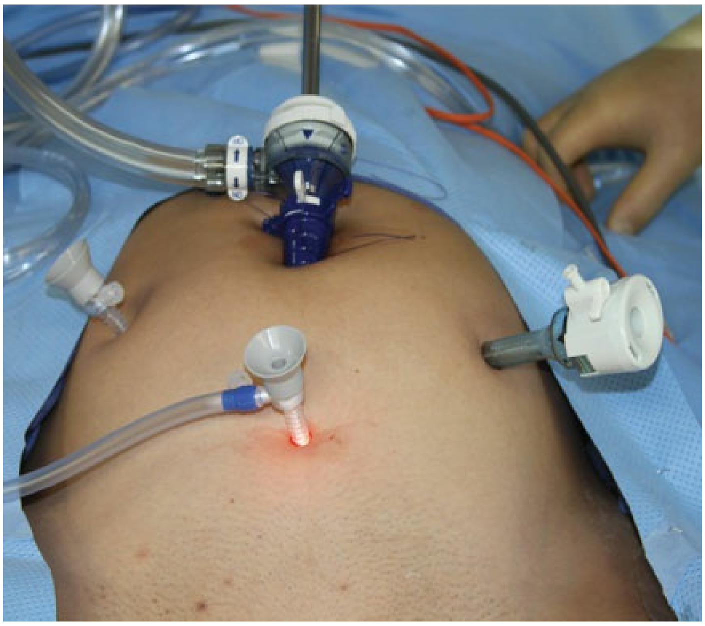

Figure 87.2 Laparoscopic trocar placement. (Courtesy of Drs. Miklos and Moore, 2015.)

The camera port is 12 mm in diameter and is placed in the umbilicus. For the main operative ports, a line is marked 16 cm cephalad to the inferior margin of the symphysis pubis. A left and right port are then placed 9 cm lateral to this mark once the abdomen has been insufflated. This is to prevent the robot arms from colliding with each other during the procedure. The third arm port is then placed on the left side, 4 cm superior and 3 cm lateral to the camera port. An assistant 5 mm diameter port is placed 5 cm lateral to the camera port [12] (Figure 87.3).

Technique

Once the patient is placed in steep Trendelenburg, the robot patient side cart is positioned either between the patient's legs to align the center of the cart with the patient's midline (central docking) or aligned alongside the patient for parallel docking. Docking position is based on surgeon preference. A 0° laparoscope is then placed through the camera port. The remainder of the robotic arms is then connected to the already placed ports.

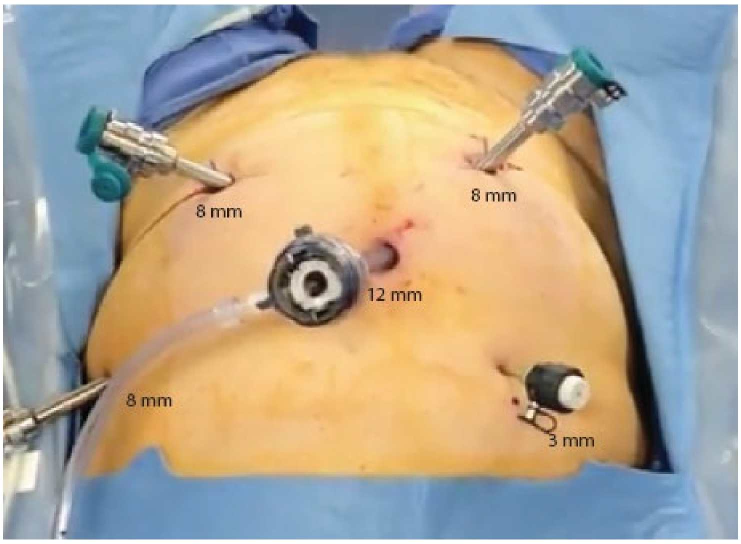

Figure 87.3 Trocar placements for robotic-assisted laparoscopic techniques.

Identification of the uterosacral ligaments can be achieved by placing traction on the vaginal apex with a probe in the vagina when the uterus is not present or by using a uterine manipulator when the uterus is present. If the later method is indicated, after the uterus has been completely devitalized and prior to colpotomy, upward pressure is placed on the uterine manipulator to help with the identification of the uterosacral ligaments. The complete pelvic course of the ureter is then identified prior to placing sutures. 2 CV-2 polytetrafluoroethylene sutures are passed on each side in the upper portion of the uterosacral ligament (Figure 87.4a, b), lateral to the rectosigmoid. At this level, the uterosacral ligaments are the furthest from the ureters as they are heading toward S3 and the ureters are clearing the pelvic brim. The distal end of the sutures are then passed through the pubocervical and rectovaginal fascia and then incorporated into the vaginal cuff. The vaginal cuff is then tied down after the completion of the cuff closure with polyglactin sutures. A third row of sutures can be used in the instance of elongated uterosacral ligaments. It is important to note that the vaginal cuff closure is completed prior to the HUSL sutures being tied down (Figure 87.5). Again as stated in the laparoscopic section, an intraoperative cystoscopy should be performed prior to removal of the ports.

The goal of both procedures is to restore normal anatomical support by suspending the apex of the vagina above the level of the ischial spines toward the level of the sacrum without causing any significant distortion to the vaginal axis [13].

Complications

The most common complication associated with the HUSLS is obstruction or kinking of the ureters, which occurs at a rate up to 11% making the performance of intraoperative cystoscopy to determine ureteral patency an important step. In most cases, removing the offending suture(s) will alleviate any obstruction without consequence as long as the surgeon finds the problem intraoperatively [14,15]. Other potential complications include bowel injury, pelvic abscess, dyspareunia, hemorrhage and in rare cases bladder injury, and exposure of permanent sutures into the vaginal lumen [16].

Outcomes

Although multiple studies and meta-analyses have been performed evaluating the long-term success of uterosacral ligament suspension when approached vaginally, there are few studies describing the long-term outcomes associated with the laparoscopic and robotic-assisted approach. In 2005, Diwan and colleagues reported that when comparing postoperative pelvic organ prolapse quantification (POP-Q) scores in 50 patients between the vaginal and laparoscopic approaches, point C was better improved with the laparoscopic approach. However, in this study, the uterus was conserved in the laparoscopic approach [17].

A study performed by Carter et al. in 2001 presented a series of eight patients who underwent laparoscopic vaginal vault suspension. In this series, at 6 months follow-up, there was a 100% objective success rate [18,19]. Another study performed by Seman et al. followed 73 females after laparoscopic apical pelvic floor repair demonstrating a 100% objective success rate at 12 months and a 90% objective success rate at 24 months follow-up [20].

Finally, a cadaveric study performed in 2003 by Culligan et al. comparing the tensile strength of uterosacral ligament sutures between the vaginal and laparoscopic approach revealed that the average peak tension required to break a laparoscopic suture was 26.2 psi compared to 22.5 psi with vaginally placed sutures [21]. Contrary to many previous studies, this further suggests that the laparoscopic approach is as effective as the traditional vaginal approach.

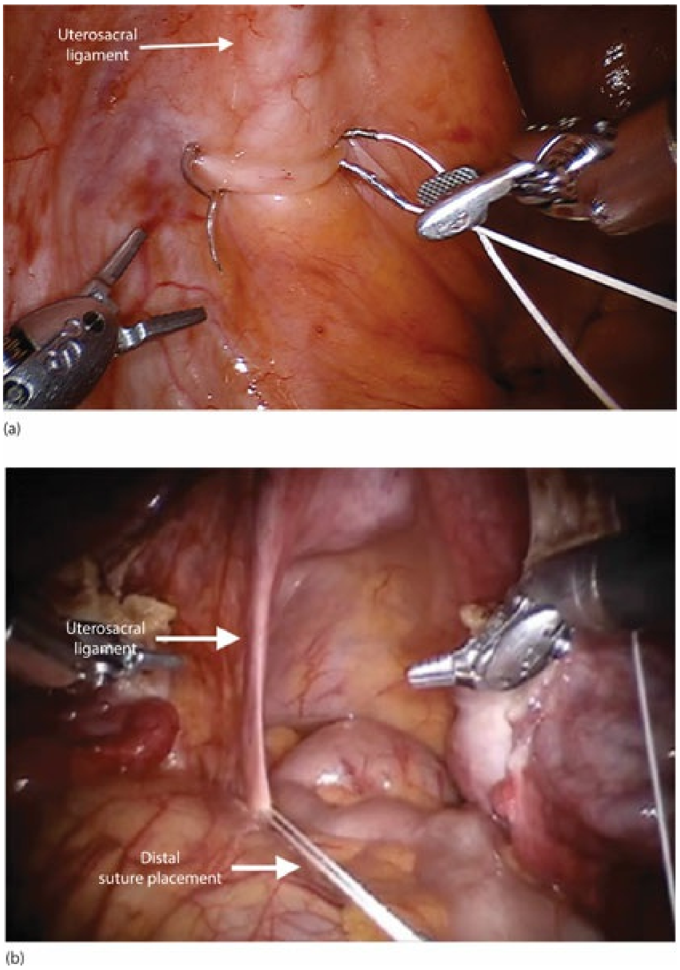

Figure 87.4 (a) Initial step of identification and suture placement for high uterosacral ligament suspension. (b) Final suture placement for high uterosacral ligament suspension.

The laparoscopic and robotic approach to performing uterosacral ligament suspension allows the surgeon to have a more global view to inspect the pelvic cavity. Other advantages include the ability to use pneumoperitoneum to access better surgical planes and the also the accuracy of suture placement to achieve an optimal result [18]. The postoperative advantages of this approach are less blood loss, shorter hospital stays, decreased postoperative pain, and the ability to perform adhesiolysis when necessary to obtain a better anatomical result [20].

SACROCOLPOPEXY

In 1962, Lane was the first to describe sacrocolpopexy using an abdominal approach utilizing grafts to anchor the vaginal apex to the sacral promontory. Although the procedure has been modified through the years, the same principles of using multiple interrupted permanent sutures to attach mesh to the vagina and elevating this up to the anterior longitudinal ligament at the level of the sacrum are still important today. Lane also describes the importance of reapproximating the peritoneum over the synthetic material to avoid interaction of the graft with other pelvic structures. He further emphasized the importance of using mesh to replace the inadequately supported structures that contribute to prolapse as a disorder [22].

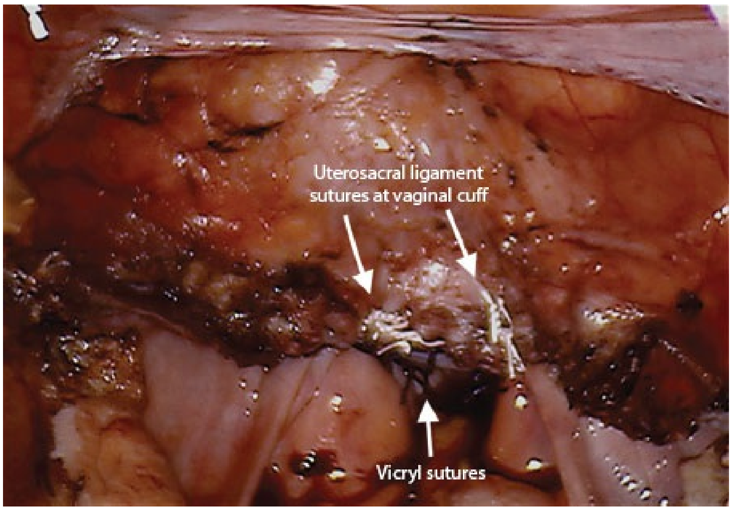

Figure 87.5 Post supracervical hysterectomy with completion of high uterosacral ligament sutures anchored to the vaginal cuff.

Although the gold standard for treatment of apical prolapse is the abdominal sacrocolpopexy due to its effectiveness and availability around the world, many institutions have adopted the more minimally invasive approaches of laparoscopy and robotic-assisted techniques [17,23,24].

Nezhat in 1994 first introduced the laparoscopic sacrocolpopexy, showing its decrease in operative blood loss and, most importantly, patient recovery time while still producing high success rates [23]. In 2006, Elliot et al. and multiple others described the introduction of the robotic-assisted laparoscopic sacrocolpopexy and its importance in negating the technical difficulties associated with straight stick laparoscopy, improvement in visualizing anatomical planes, and decreasing recovery time, while still maintaining a high success rate [25–28].

Although there is no strict definition of success for this procedure, we and many other authors define a successful procedure based on both the "clinical cure" and "objective anatomic cure" rates [12,29]. Clinical cure rate is defined as the patient meeting all of the following criteria: (1) no symptoms of vaginal bulge as measured by the Pelvic Floor Distress Inventory-20 (PFDI-20), (2) no reoperation for POP since the initial surgery, (3) POP-Q point C less than or equal to −5, (4) no POP-Q points greater than 0, and (5) an answer of "satisfied" or "very satisfied" on the Surgical Satisfaction Questionnaire-8. Objective anatomic cure rate is defined as (1) POP-Q point C less than or equal to −5, (2) overall POP-Q stage of 0 or 1, and (3) no reoperation for POP [30].

Laparoscopic Approach for Sacrocolpopexy

Port Placement

Traditionally, four laparoscopic ports are placed in the abdomen. The first is a 5 mm camera port placed intra-umbilically. A 10 mm suturing port is placed in the left paramedian region, and two additional 5 mm ports are placed. The first accessory port is placed suprapubically, and the second is placed in the right paramedian region [24] (Figures 87.1 and 87.2).

Technique

To assist with clearly visualizing the vaginal apex, a probe is placed in the vagina. Next, the peritoneum is dissected away from the vaginal apex anteriorly, exposing the full thickness of the vaginal wall. The dissection is continued one-third down the anterior wall and the space between the rectovaginal fascias. The dissection is continued down to the level of the rectal reflection or further down to the level of the perineal body [31]. If an enterocele is encountered, it should be repaired in a site-specific fashion to avoid suture placement near the area of the graft.

The peritoneum overlying the sacral promontory is then incised in a longitudinal fashion and extended down to the right paracolic gutter between the ureter and the colon. The presacral adipose tissue can then be carefully dissected away to reveal the anterior longitudinal ligament. The peritoneum on the sidewalls should be freed enough so that the mesh can be easily retroperitonealized at the end of the procedure [32].

Mesh is introduced through the 10 mm port. The Y-shaped mesh can usually be cut 5–7 cm anteriorly and 8–10 cm posteriorly. The anterior leaf of the mesh is sutured using approximately six to ten 2-0 permanent, evenly placed sutures beginning distally toward the vaginal apex. The posterior leaf is sutured in a similar fashion through the rectovaginal fascia. Knots can be tied using the extracorporeal method. As previously discussed in the high uterosacral section, the choice of suture should be a monofilament suture such as ePTFE, polypropylene, or polydioxanone. Braided sutures have an increased risk of bacterial colonization, biological tissue response with cellular ingrowth, high tissue reactivity, and suture and mesh erosion [33].

A vaginal probe or Breisky® vaginal retractor (Novosurgical, Oak Brook, IL) is used to place tension on the vaginal apex to delineate its natural position in the pelvic cavity. Our institution uses the manual tension approach, where a probe is placed in the vagina to assist with the tensioning of the sacral arm of the mesh. The probe is then removed half way out of the vaginal canal for the placement of the sacral promontory sutures. The surgeon can then tie the free end of the mesh to the anterior longitudinal ligament using two #0 permanent sutures. An assistant then palpates the anterior and posterior wall of the vagina to insure that appropriate tension is used prior to the final sutures being placed. It is important to note that the mesh is not placed on increased tension to prevent postoperative pelvic pain and dyspareunia [29]. The peritoneum is then reapproximated to cover the mesh to prevent adhesion or entrapment of the bowel to the mesh. At this time, an intraoperative cystoscopy should be performed to ensure no bladder or ureteral injury [32].

Robotic-Assisted Laparoscopic Approach for Sacrocolpopexy

In 2005, our institution transitioned from performing laparoscopic sacrocolpopexy to utilizing the robotic-assisted approach [29]. We felt that the robotic-assisted approach offered better visualization of the anatomical planes, decreased operative time, and allowed us to further dissect the pubocervical and rectovaginal fascial planes to offer more optimal anatomical results [29,31]. If a concomitant hysterectomy procedure is performed, we have found that performing a supracervical hysterectomy decreases the patient’s predisposition to graft erosion at the level of the vaginal cuff [12].

Port Placement

Port placements are the same as previously described in the robotic-assisted HUSLS section.

Technique When Uterus Is Present

After a supracervical hysterectomy is performed, the anterior cervix may be grasped with a robotic single tooth tenaculum on the third robotic arm. The cervix is then tensioned anterior and cephalad toward the sacral promontory. This technique with the tenaculum eliminates the need to place any instrumentation in the vagina for the first part of the procedure (Figure 87.6). The peritoneum is then dissected from the anterior portion of the vaginal apex. A manual grasper is introduced through the assistant port to grasp the bladder peritoneum to assist with countertraction while dissecting the anterior portion to further expose the vesicovaginal plane. The boundaries of this dissection includes the bladder neck distally and the vaginal sulcus laterally [12,29] (Figure 87.7).

For the posterior dissection, the rectal reflection is identified along with the insertion of the uterosacral ligaments to the cervix. The posterior portion of the cervix is grasped with the tenaculum and pulled anterior toward the symphysis pubis. The dissection is started at the level of the cervical stump to avoid bleeding. The peritoneum is then incised in a horizontal fashion between the uterosacral ligaments. Using a combination of sharp and blunt dissection with the monopolar scissors, the posterior vaginal wall is exposed. The distal boundary of the dissection is the rectal reflection or perineal body and the posterior boundary in the rectum. Once the space is exposed, a robotic double fenestrated grasper can be used to assist with traction and countertraction to further dissect the space [12,29].

At the level of the sacral promontory, the peritoneum is lifted and hot CO_2 from the cautery is allowed to infiltrate the space in order to better expose the areolar tissue, which assists in identifying an avascular plane to dissect. At this stage of the procedure, the location of the common iliac vein, middle sacral, and hypogastric vessels should be visualized. Any small vessels that are identified should be cauterized as hemostasis is of the upmost importance to fully visualize the correct planes (Figure 87.8).

Approximately 2 cm of the anterior longitudinal ligament is then exposed with blunt dissection, and the peritoneum is extended down to the right paracolic gutter between the ureter and the colon [12,29].

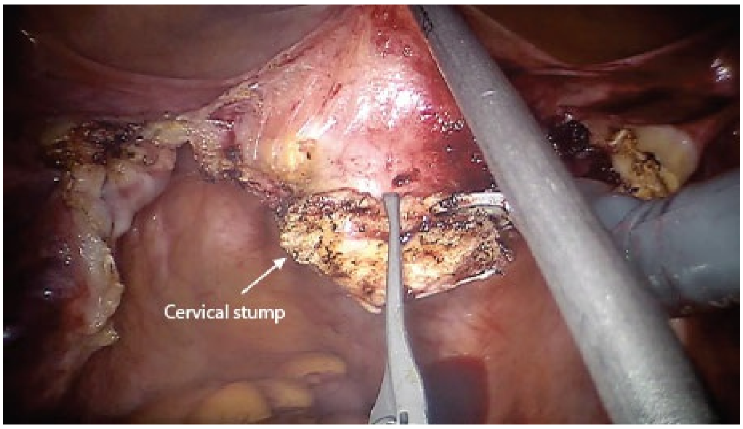

Figure 87.6 Demonstrating tensioning of the cervical stump anterior and cephalad toward the sacral promontory to assist in anterior vaginal wall dissection.

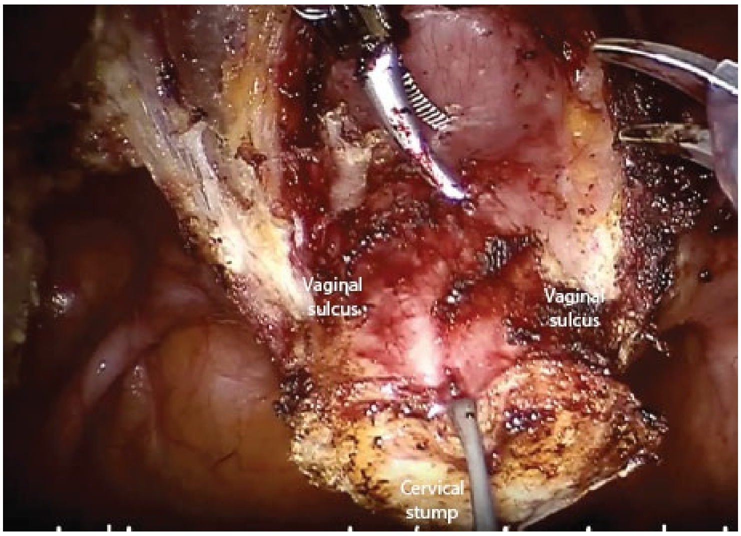

Figure 87.7 Completion of anterior vaginal wall dissection in robotic-assisted laparoscopic sacrocolpopexy.

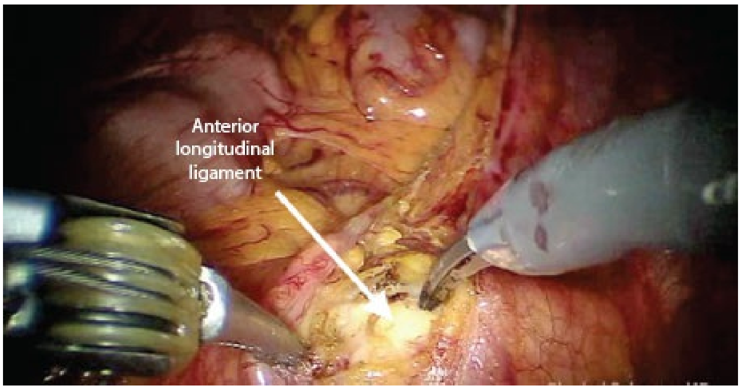

Figure 87.8 Dissection of the anterior longitudinal ligament.

A lightweight Y mesh is used with the anterior arm of the mesh cut between 6 and 8 cm and the posterior arm between 8 and 11 cm. The arms are cut longer than reported in most literature to accommodate for the 2 cm cervical stump (Figure 87.9). The anterior mesh is then loosely tied to the sacral arm and passed through the camera port, along with six 8 in. CV-4 GORE-TEX sutures on a TH-26 needle, and one 10 in. 0 monocryl (Ethicon^{TM}) suture on an SH needle [12,29].

The posterior arm of the mesh is placed on the posterior vaginal wall with traction applied on the cervix from the tenaculum attached to the third robotic arm. The sutures are then placed so the knots lie flat between the vagina and the mesh. Three sutures are placed at the distal end of the posterior dissection, being careful to avoid placing sutures at the junction of the vagina and the rectum. Next, two sutures are placed in the midline 2 cm proximal to the most distal sutures, and two additional sutures are placed 2 cm proximal to the midline sutures at the lateral boundary of the dissection. This is continued until the level of the cervix or uterosacral ligaments. The knot previously attaching the anterior arm to the sacral arm is released and removed by the assistant. The tenaculum is adjusted to the anterior portion of the cervical stump providing tension superiorly and cephalad toward the sacrum. The bladder peritoneum is tractioned in a similar manner by the assistant grasper. The anterior arm of the mesh is then placed into the already dissected space with the first three sutures placed at the distal end of the dissection at the level of the bladder neck. The knots will now lie anterior to the mesh and lateral sutures are then placed every 2 cm cephalad until the level of the cervix [12,29].

The peritoneum overlying the vaginal portion of the mesh is covered by approximating the peritoneum using 0 monocryl (Ethicon). This technique can be accomplished with the first stitch being placed in the middle of the bladder peritoneum and continuing out to the left round ligament and then toward the rectovaginal peritoneal edge. The suture is then taken over the mesh and the middle portion of the bladder peritoneum is reapproached. The suture is continued toward the right round ligament and down to the cut edge of the pelvis peritoneum to include the right uterosacral ligament. The posterior rectal peritoneum is attached to the anterior peritoneum through a previously made loop at the end of the suture (Figure 87.10). The suture is temporarily placed on the anterior abdominal wall while the assistant performs manual vaginal tensioning [12,29].

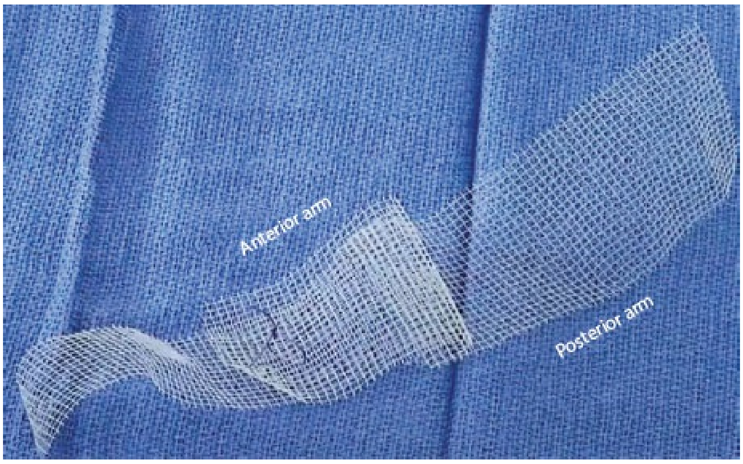

Figure 87.9 Preparation of Y-mesh with the anterior arm sutured to the sacrum arm of the mesh to assist with posterior arm mesh placement and suturing.

Once the appropriate tension is achieved, the excess sacral arm mesh is cut either using the robotic suture-cut or manually with scissors through the assistant port. CV-4 Gore-Tex sutures on a TH-26 needle are used to place two sutures perpendicular through the anterior longitudinal ligament and back through the mesh. Vaginal tension is further verified and the sutures are tied down (Figure 87.11). Next, using the already attached 0 monocryl suture, the remaining peritoneum is reapproximated to cover the mesh up to the level of the sacral promontory (Figure 87.12) [12,29].

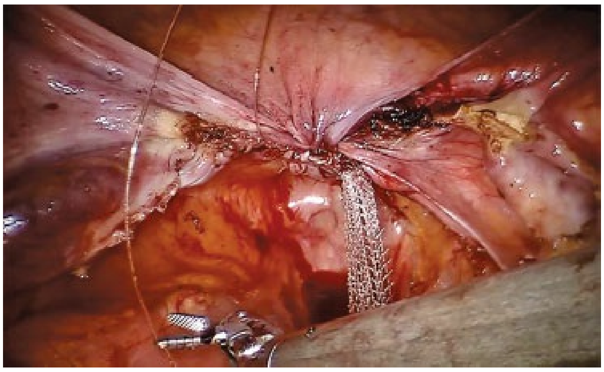

Figure 87.10 Completion of purse string suture in robotic-assisted laparoscopic sacrocolpopexy.

In posthysterectomy cases, the addition of a Breisky vaginal retractor is placed into the vagina to further delineate the anterior and posterior vaginal wall at the level of the vaginal cuff and apex. The remainder of the procedure is performed in the same fashion.

As with laparoscopic approach, a cystoscopy is performed at the end of the procedure.

Complications

The most common complications associated with these two approaches are the same as the complications sited for an abdominal sacrocolpopexy. Complications include injury to the ureter and bladder and injury to the bowel and rectum during lysis of adhesions and dissection. Overall risk for bleeding is quite low; however, when it does occur, it can be life threatening. There is also the risk of hematomas, pelvic abscesses, injury to the vertebral disc, infection in the sacrum periosteum due to suture placement, and potential mesh erosion [34–36].

Outcomes

Rozet et al. performed the largest case series of laparoscopic sacrocolpopexy during 1996–2002, which included 363 females. The authors concluded after 14-month follow-up, there was a 4% recurrence rate of POP and 1% vaginal erosion rate and reported a 96% satisfaction rate by the patient [35,37].

Claerhout et al. reported the largest prospective series of laparoscopic sacrocolpopexy including 132 patients. During the study, mean follow-up rate was 12 months and reported 98% objective cure rate. However, there was an 18% failure rate with recurrence of posterior prolapse and mesh erosion was seen in 4.5% of patients within 1 year of surgery [35,38].

Salamon et al. performed a single arm prospective study of 120 women with stage II or greater POP, undergoing robotic-assisted sacrocolpopexy. With interval follow-up at 6 and 12 months, the group reported an 89% anatomical success rate and 94% clinical cure rate. This study was able to accomplish a 98% follow-up rate at 1 year. Mean operative time for the procedure was 161 ± 29 minutes [39].

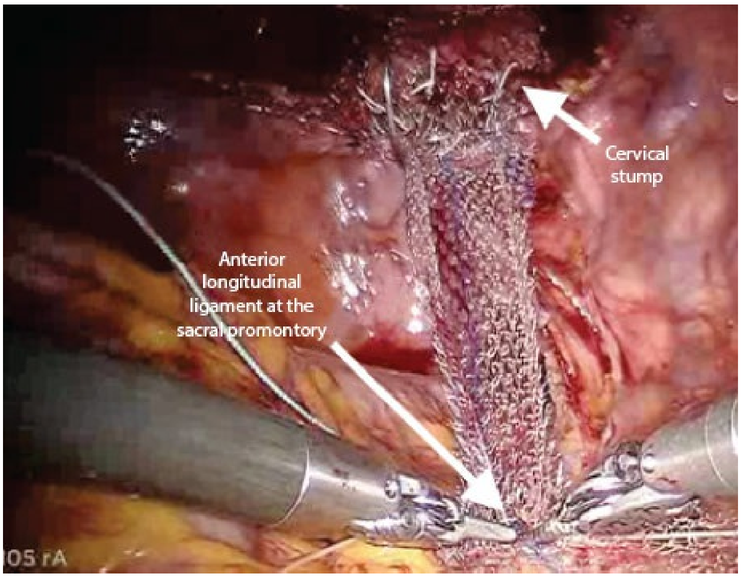

Figure 87.11 Tensioning of mesh prior to suturing down mesh onto the anterior longitudinal ligament.

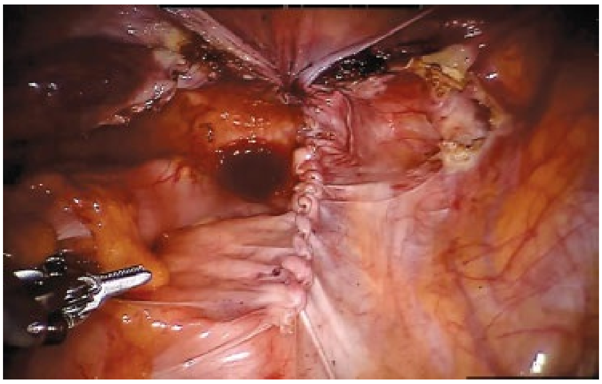

Figure 87.12 Completed robotic-assisted laparoscopic sacrocolpopexy with reapproximation of the peritoneum over the mesh.

Culligan et al. in 2014 performed a single-arm prospective study of 150 women with symptomatic POP who were scheduled to undergo robotic-assisted sacrocolpopexy. This study evaluated cure rates at 12 months postoperatively. They reported a clinical cure rate of 95% and an objective anatomy cure rate of 84% with no cases of mesh erosion or exposures. This study was also able to accomplish a 95% follow-up rate at 1 year. Mean operative for the procedure was 148 ± 27.6 minutes [30].

When comparing the two different approaches, Lee et al. performed a review encompassing 17 patient series between 1966 and 2013, which included 11 laparoscopic approach studies with a total of 1221 patients. The authors found the mean operative time was 124 minutes with a 3% conversion rate to an abdominal approach. The objective cure rate was 91% and a patient satisfaction rate of 92%. Additionally, 6 robotic-assisted sacrocolpopexy studies with a total of 363 patients were reviewed. They found the mean operative time to be 202 minutes; however, this ranged greatly by surgeon experience. They reported a 1% conversion rate to an abdominal approach, and the objective cure rate was reported to be 94% and a 95% subjective cure rate [35].

In 2014, Anger et al. performed a randomized controlled trial comparing the two minimally invasive approaches. This study included 78 randomized patients with stage II or greater POP. They reported, after deducting the initial cost of the robot at the facility, there was no significant difference in the cost between the two procedures. They also reported longer surgical times with the robot-assisted approach at 202 minutes compared to 178 minutes with laparoscopic surgery but no group differences in symptoms both in the PFDI-20 and POP-Q staging, or rate of adverse events [40].

MESH

In 2010, Osterguard discussed the importance of different mesh properties to include density, pore size, elasticity, filament size, surface area, and overall mesh load (Table 87.1) [41,42].

He also discussed potential mesh-related complications to include erosion and exposure, dyspareunia, and pelvic pain. Due to these basic mesh-related principles and complications, multiple studies have been performed focusing on mesh load, durability, and complications associated with mesh placement. Multiple studies have also been performed comparing native tissue mesh and the traditional polypropylene mesh outcomes.

The majority of studies examining mesh complications to date have been performed using Marlex (95 g/m^2) (C.R. Bard, Cranston, RI), as this was previously the gold standard. Kohli et al. performed a retrospective study over an 8-year period examining vaginal mesh erosions complicating abdominal sacrocolpopexy. They revealed an erosion rate of 8% when following patients up to 24 months postoperatively [43]. Recently, prospective studies using lighter mesh (18 g/m^2) have reported the same or better success rates with no mesh complications or erosion [39,44].

Table 87.1 Y-Mesh Products Available for Sacrocolpopexy

Brand Name	**Pore size (mm^2)**	**Density (g/m^2)**	**Thickness (μm)**
Restorelle Y	1.8	18	305
ALYTE® Y-Mesh Graft Vaginal flaps (CR Bard)	2.9	17	287
ALYTE Y-Mesh Graft Sacral flap (CR Bard)	2.9	34	400
Artisyn (Ethicon)	3.9	28	533
Upsylon (Boston Scientific)	2.8	25	200
IntePro (AMS)	1.6	52	527
Vertessa (Caldera)	1.4	22	325

Culligan et al. performed a study comparing the surgical outcomes using porcine dermis mesh and the current gold standard polypropylene mesh. In the 115 patients studied at 12 months follow-up, patients had an anatomic cure rate of 80% with porcine mesh and 86% with polypropylene mesh. The clinical cure rate was 84% and 89%, respectively [45]. However, a similar study performed by this group in 2005 comparing fascia lata and synthetic mesh in 100 patients demonstrated that polypropylene mesh was superior in postoperative POP-Q points, POP-Q stage, and objective and anatomic failure rates [46].

Due to the current media exposure associated with mesh erosions, multiple changes in surgical techniques have been explored to prevent such complications. Limited retrospective data have shown that a total hysterectomy at the time of sacrocolpopexy regardless of the approach relates to a 14%–23% erosion rate [47,48]. With the cervical stump left in place, there is the theoretical benefit of a buffer between the mesh and the vaginal apex, preventing both ascending infection and erosion into the vaginal wall [49]. This technique is controversial because the benefit of a supracervical hysterectomy versus the future challenges of trachelectomy due to pelvic pain or premenopausal cycle cervical bleeding and continued cervical screening has not been well studied.

CONCLUSION

Worldwide abdominal sacrocolpopexy continues to be the gold standard for the treatment of apical prolapse. However, with the evolving technology of laparoscopy and robotic-assisted techniques, we now have the opportunity to perform HUSLSs and sacrocolpopexy for our patients with the prospect of higher surgical success rates while also minimizing postoperative complications. This ultimately will improve both patient safety and satisfaction.

88 Uterine Prolapse

Miriam Seitz and Roger P. Goldberg

Uterine prolapse results from the descent of the vaginal apex, cervix, and surrounding connective tissue supports. It is a common problem that can significantly impair a woman's quality of life [1]. Women across the age spectrum are prone to this disorder, particularly those who have undergone vaginal delivery. Beyond meeting the technical challenge of reducing the prolapse bulge with successful long-term results, it is also important for the pelvic reconstructive surgeon to bear in mind that for many women, the uterus represents a valued symbol of sexual and reproductive identity. In this respect, uterine prolapse stands apart from other "hernias" that may occur throughout the body. Rather than adopting a uniform treatment approach for all uterine prolapse cases, surgeons should gain familiarity with a range of strategies, including the use of pessaries and traditional operative techniques that incorporate hysterectomy, and also uterine-preserving repairs.

PRINCIPLES OF NORMAL UTERINE SUPPORT

Based on our current understanding of normal pelvic anatomy, key anatomic elements contributing to uterovaginal support are (1) connective tissue supports at the vaginal apex including the cardinal–uterosacral complex and paracolpium (DeLancey level I) [2] and (2) the levator ani musculature, including a horizontally positioned levator plate. The levator plate extends from the sacrum to the anorectal junction and receives components of both the iliococcygeus and puborectalis muscles. The levator ani complex provides a foundation of pelvic support, which, with respect to the uterus, includes the critical upper vaginal/cervical region. The levator ani muscles, when well toned and anatomically intact, maintain closure of the urogenital hiatus and actively promote reflex hiatal closure during physical activity. The levator ani musculature is exposed to substantial risk of injury during vaginal birth, and levator defects are commonly found afterward due to avulsion injuries and denervation [3]. If the cervix and upper vagina remain well supported by an intact and horizontally oriented levator plate providing a base of support during physical exertion, then the development of prolapse is believed to be less likely [4], and the amount of strain on secondary and tertiary support structures (i.e., uterosacral ligaments) is decreased.

On the connective tissue level, a well-suspended and intact cervix serves as a central fusion point for the vaginal endopelvic connective tissues, an area of insertion referred to as the paracervical ring. When these anatomic connections are compromised, an enterocele and/or proximal rectocele and cystocele defects may occur. Whereas the pelvic floor musculature cannot be repaired with existing surgical techniques, restoring or preserving the connective tissue architecture of the upper vagina should represent an overarching goal when addressing uterine prolapse of any degree. These principles are illustrated in Figure 88.1.

The upper third of the vagina (level I) is suspended from the pelvic walls by vertical fibers of the paracolpium, which is a continuation of the cardinal ligament. In the middle third of the vagina (level II), the paracolpium attaches the vagina laterally to the arcus tendineus and the fascia of the levator ani muscles [5]. The cervix and vaginal apex should be regarded as central structures receiving numerous important connective tissue insertions including the proximal components of the pubocervical and rectovaginal septae and cardinal–uterosacral ligaments laterally and posteriorly. The overall architecture of the vagina largely relies on the integrity of these attachments and on a tethering of the vaginal apex and cervix to approximately the level of the ischial spines.

EPIDEMIOLOGY AND ETIOLOGY OF UTERINE PROLAPSE

Defining the rate of uterine prolapse in the general population, and its natural progression, is challenging due to varying ways to define and grade the condition, and differences observed across populations. According to the women's health initiative study of over 16,000 women with a uterus, prolapse of the uterus (of any degree) was recorded in 14.2%. Another study, by Nygaard et al. [6], recorded a 25.6% overall rate of prolapse among women with an intact uterus. Swift et al. [7] identified a twofold increased incidence of severe pelvic organ prolapse (POP) with each additional decade of life. A Swedish study including gynecological examination of 487 women aged 20–59 years found the prevalence of any degree of prolapse to be 31%; however, only 2% had a prolapse bulge reaching the vaginal introitus. Age, parity, pelvic muscle strength, and, among parous subjects, maximum birth weight were significantly associated with the presence of prolapse [8]. Nygaard et al. [9] published a cross-sectional analysis of 1961 nonpregnant women >20 years old who participated in the 2005–2006 national health and nutrition examination survey, including standardized physical examinations in a mobile examination center. The weighted prevalence estimates included 2.9% of women experiencing POP. Another study [10] of over 1800 women from a single small Dutch city identified an 11.4% rate of self-reported prolapse symptoms with a total population-attributable risk of 46%. Independent risk factors for prolapse symptoms included pregnancy, a maternal history of prolapse, and heavy physical labor. In the developed world, parity and childbirth represent the primary risk factors associated with uterovaginal prolapse. Samuelsson et al. [8] reported a 44% versus 6% prevalence of genital prolapse among parous and nonparous women, respectively. Another population-based study [11] found that prolapse risk was significantly increased in women with one (odds ratio [OR] 2.8), two (OR 4.1), and three or more (OR 5.3) vaginal deliveries compared with nulliparous women.

One analysis of 1.4 million women from a Swedish hospital registry identified an adjusted OR of 0.18 (0.16–2.0) when comparing the odds of a recorded prolapse diagnosis after cesarean versus vaginal birth [12]. Among nulliparous women, up to 99% demonstrate no appreciable prolapse (stage 0 or 1) when undergoing systematic gynecological exam [13]. Nonobstetrical risk factors for uterine prolapse include advancing age, obesity, chronic heavy lifting, straining due to constipation, chronic obstructive pulmonary disease, connective tissue disorders [14], including Marfan or Ehlers–Danlos, and neurological or spinal cord injury. Some research has indicated that Caucasian and Hispanic women have the highest rate of prolapse, while Asian women have lower rates and black women were reported to have symptomatic prolapse at less than half the rate of Caucasian women (OR 0.4, 95% CI 0.2–0.8) [11]. One population-based study of 1137 women included quantitative prolapse examinations (POP-Q) and concluded that white women had 1.4-fold higher risk of objective prolapse with the leading edge of prolapse at or beyond the hymen [15].

Although symptomatic uterine prolapse cases among nulliparous women appear to be rare in the developed world, in some developing countries, nonobstetrical risk factors including prolonged lifting from a young age, smoking, chronic obstructive pulmonary disease, and malnutrition appear to play a more important contributory role. As many women in the developing world then proceed to undergo childbirth at a young age, the impact of unattended deliveries and traumatic childbirth contributes to the development of uterine prolapse, leading to social isolation. For instance, in Nepal, uterine prolapse represents a women's health crisis, reflecting deep gender inequalities [16].

UTERINE PROLAPSE SYMPTOMS

Symptoms of uterine prolapse may include an external vaginal bulge, pelvic heaviness, and incomplete urinary emptying. Rates of symptomatic prolapse increase with advancing age, increasing from an estimated 6.6% among women aged 20–29 to 56% among those aged 50–59 [8]. Urinary retention may accompany uterine prolapse due to concomitant prolapse of the anterior vaginal wall and anatomic kinking of the urethra or obstruction of the bladder neck by the prolapsing cervix. Many women with uterine prolapse report no symptoms until the prolapse approaches the vaginal introitus and beyond. At this stage, common complaints include a palpable bulge, sensation of vaginal pressure or fullness, low back pain, and voiding difficulties. Low back pain has not been associated with POP [17]. Abnormal bleeding is not associated with uterine prolapse with the occasional exception of advanced prolapse causing cervical ulceration.

EVALUATION OF UTERINE PROLAPSE

Examination in the standing position, during maximal Valsalva or repetitive coughing, is often required to fully appreciate the degree of uterine descent. Cervical elongation, which may occur in up to one-third of women with pelvic prolapse [18], should be assessed with a bimanual examination to palpate the length of cervix protruding, while the apical vagina is maximally elevated with the examining fingers suspending each lateral fornix and then visually by using a full bivalve speculum to elevate the vaginal apex to the level of the ischial spines. If the cervix extends to the midvagina or beyond even with support of the apex, this suggests cervical elongation—the implication being that uterine-sparing surgery may be at higher risk for failing to relieve symptoms, even if the apex has been successfully resuspended (Figure 88.2).

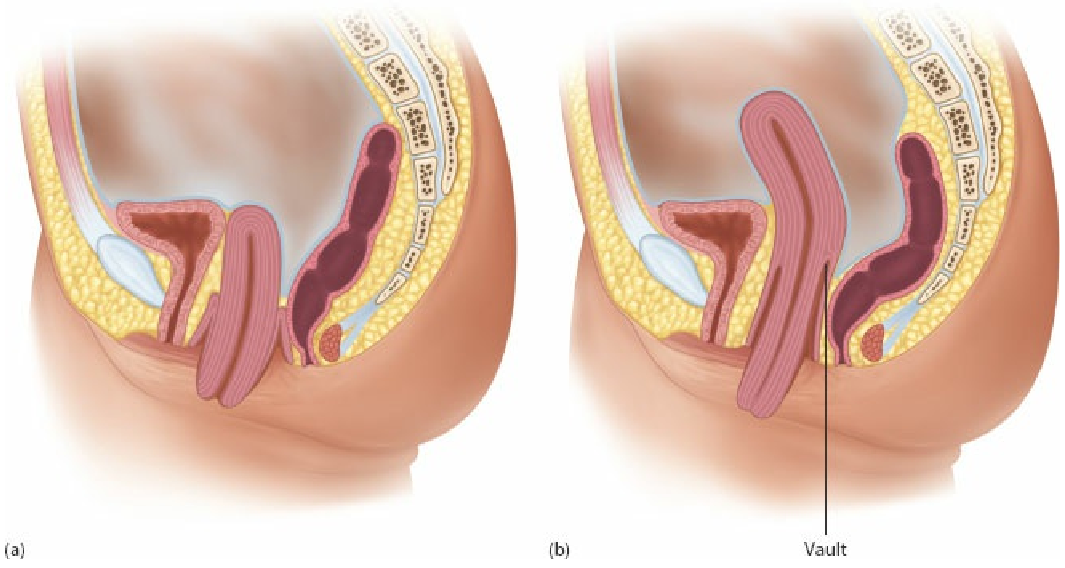

Figure 88.2 Example of cervical elongation versus uterine prolapse: (a) uterine prolapse, (b) cervical elongation.

The anterior and posterior vaginal compartments should be separately and carefully assessed using the posterior blade of a bivalve speculum or Sims speculum to retract the opposite vaginal wall while visualizing the prolapse during straining efforts. In particular, prolapse in the apical and anterior compartments tend to often occur concomitantly, thus achieving satisfactory anterior compartment support that requires attention to the apex, and vice versa. It is increasingly appreciated that apical support defects represent an important factor underlying cystoceles and also rectoceles [19].

The international continence society's pelvic organ prolapse quantitative (POP-Q) staging system [20], which creates a vaginal profile utilizing nine designated points along the anterior, posterior, and apical vaginal compartments, is covered elsewhere in more detail and can be utilized to describe the degree of uterine prolapse, with point C (cervix) describing the maximal prolapsed position of the most distal edge of the cervix during a straining effort. The POP-Q system provides a useful means for recording, comparing, and exchanging clinical findings, with acceptable intra- and interobserver reliability [21]. Alternatively, the Baden–Walker "halfway" system [22] may be used to describe the position of the cervix relative to the hymenal ring. Using this scale, second-degree uterine prolapse involves a cervix extending to the hymenal ring, third-degree prolapse extends beyond the hymenal ring, and fourth-degree prolapse represents complete procidentia with no appreciable support remaining. The most severe cases, referred to as complete procidentia, involve the uterus fully protruding through the genital hiatus.

TREATMENTS OF UTERINE PROLAPSE

Along with aging of the female population, the number of individuals requiring treatment for uterine prolapse is expected to substantially increase in the decades ahead [23]. As surgical treatments become less invasive and thus more appealing, demand for prolapse operations will most likely continue to increase. Wu et al. (2014) studied a U.S. population and published a lifetime risk of POP surgery of 12.6% (95% CI 12.4–2.7) by the age of 80 years [24]. Luber et al. [25] projected a 45% increase in demand over the next 30 years for treatment of female pelvic floor disorders including POP.

Pessary management remains an option that should be offered in almost all cases, although clearly, the percentage of women selecting this modality has declined in the recent decades as surgical procedures have become less invasive and more widely popularized. It is important for surgeons treating uterine prolapse to remain skilled in pessary management, to provide symptom relief for women with uterine prolapse who are poor surgical candidates or who wish to avoid or delay surgery.

Pessaries for uterine prolapse need to provide adequate drainage of cervical secretions and may cause ulceration, vaginitis, bleeding, and, if left unattended, more serious complications such as fistula formation with erosion into the bladder or rectum. Typically, the two most common "first-line" pessaries for uterine prolapse are the ring pessary with support and the Gellhorn pessary (Figure 88.3), with the latter being especially useful for women with advanced uterine prolapse and reduced introital and perineal support. For uterine prolapse during early pregnancy requiring symptom relief, the Smith–Hodge pessary is the most commonly cited; by 20 weeks gestation, however, uterine prolapse rarely persists as the gravid uterus elevates above the pelvic brim. Although nearly any pessary can be tried for uterine prolapse if monitored closely, cube and donut pessaries should be avoided with rare exception due to their tendency to trap secretions and cause ulcerations. Topical estrogen is commonly prescribed to postmenopausal women wearing a pessary to mitigate some of these risks. In addition to a benign leukorrhea that often occurs with pessary use, bacterial vaginosis is also relatively common and may occasionally require removal of the pessary. Most of the more serious complications result from pessaries that have been inadequately monitored [26,27]. Especially patients unable to remove the device on their own need to be prepared for periodic office visits in the range of every 6–12 weeks. Most complications can be avoided if the patient removes the pessary overnight, every night, or several times a week. Vaginal and cervical cancers associated with pessary use have been reported but are exceptionally rare [28].

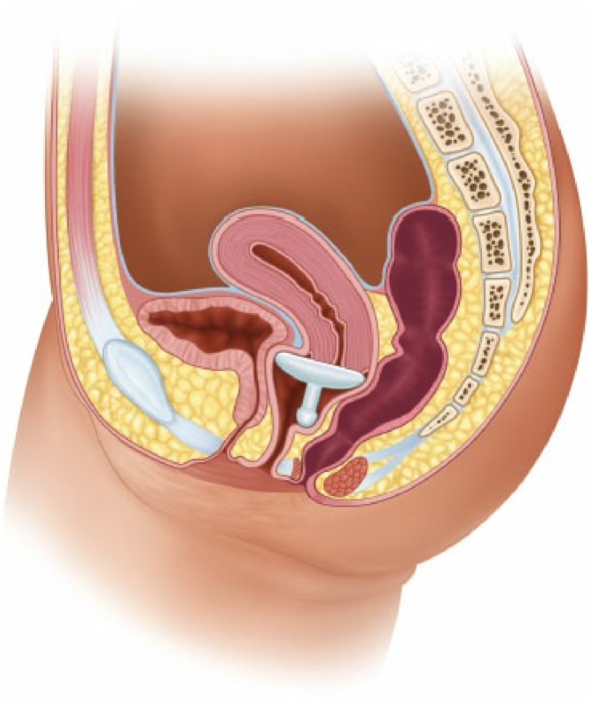

Figure 88.3 Gellhorn pessary in place, for the treatment of uterine prolapse.

Several surgical approaches are available, and each should be judged according to how effectively they achieve a successful anatomic outcome and an improved quality of life. There is no single "gold standard" surgical approach for the treatment of uterine prolapse. Vaginal surgery carries the advantage of its relative safety and efficiency, shorter recuperation times, and also the ability to efficiently address concomitant prolapse defects and stress urinary incontinence. Factors to be considered include perioperative risk, present and planned reproductive and coital activity, previous pelvic reconstructive surgery, and general health status. As the overall safety of a variety of surgical approaches has improved, age itself appears to play a lesser role in surgical decision-making. All techniques worth considering should achieve an effective suspension of the vaginal apex; this can be accomplished with or without removal of the uterus. This raises a key question: does hysterectomy tend to help, hinder, or not significantly impact our efforts to achieve a successful and long-lasting anatomic result and improved quality of life? This question should be considered from both patient and physician perspectives. On the one hand, uterine prolapse does not result from any abnormality of the uterus itself, but rather from relaxation or detachments involving the cardinal–uterosacral ligament complex and nearby vaginal apical supports. Moreover, hysterectomy involves purposeful detachment of what remains of these connective tissue supports and structures. In up to 12% of cases, hysterectomy performed for prolapse is associated with vaginal vault prolapse and enteroceles later on [22] and also may increase the susceptibility of the anterior compartment to subsequent prolapse defects [29]. An epidemiological study from Oxford [30] found that the risk of prolapse following hysterectomy was 5.5 times higher in women whose initial hysterectomy was performed for POP, as opposed to other reasons. Often, the repair of posthysterectomy prolapse may be even more challenging than the primary surgery, due to an absence of normal connective tissue structure and strength. On the other hand, vaginal hysterectomy is associated with a known track record and excellent success. Furthermore, removing the uterus eliminates the risk of future interventions for new pathology such as fibroids, cervical dysplasia, or endometrial hyperplasia. And aside from specific medical reasons, some women personally feel that they "want it out." We believe that if surgeons have the ability to offer both extirpative and uterine-sparing approaches, then satisfaction will be achieved for the largest number of patients.

Hysterectomy with Vaginal Vault Suspension

The most common surgical treatment for uterine prolapse is vaginal hysterectomy followed by vault suspension, along with repairing any significant concomitant defects of the vagina in the anterior, posterior, and lateral compartments. It is crucial to emphasize that the vault suspension and restoration of anterior and posterior compartment support are the components of this repair that restore pelvic support. In other words, at the moment the hysterectomy is completed and the uterine specimen is removed, the prolapse operation has just begun. The decision to perform hysterectomy is often more the result of surgical habit and residency training patterns than any scientific evidence. For most practitioners, uterine prolapse is considered an automatic indication for hysterectomy even for cases involving no intrauterine pathology, and this translates into roughly 17% of hysterectomy procedures being performed for the primary indication of prolapse [31].

Apical suspension at the time of hysterectomy is a critical step, as roughly 12% of women after hysterectomy may develop subsequent vaginal vault prolapse. The procedures most commonly performed during hysterectomy include uterosacral vaginal vault fixation, sacrospinous or iliococcygeus suspension, and McCall culdoplasty [32].

Uterosacral ligament suspension tends to be performed with varying techniques among surgeons, with fixation strengths and results varying accordingly. However, in our experience, a fixation stitch on the upper one-third of the ligament, near the ischial spine, provides consistent support and excellent restoration of vaginal length when each suture is passed through the ipsilateral vaginal cuff corner. Barber et al. reported success in 90% of women after high uterosacral ligament suspension at a median follow-up of 15 months, although some subjects had been followed for as little as 3.4 months in this cohort, and the technique was associated with a concerning 11% intraoperative ureteral injury rate. Shull et al. [33] reported good anatomic success among 89% of subjects at last follow-up, with only a 1% rate of ureteral kinking (a risk profile, which is reflective of our experience). Karram et al. [34] evaluated 168 of 202 women undergoing high uterosacral ligament suspension after 6 months to 3 years follow-up. Eighty-nine percent of this cohort expressed satisfaction with the procedure. Figure 88.4 illustrates a typical high uterosacral vaginal fixation. Rardin et al. reported that laparoscopic uterosacral ligament suspension achieved similar results to the transvaginal technique.

The McCall culdoplasty is a variation of the uterosacral ligament suspension, wherein the detached uterosacral ligaments are shortened and fixed to the vaginal cuff; this operation usually includes closure of the peritoneal cavity by reefing a suture across the posterior peritoneum at the rectal reflection. This operation utilizes the uterosacral ligaments at a somewhat more distal location—where they are mobile and closer to the ureters. When performing any uterosacral ligament suspension technique, intraoperative cystoscopy is necessary to demonstrate ureteral patency.

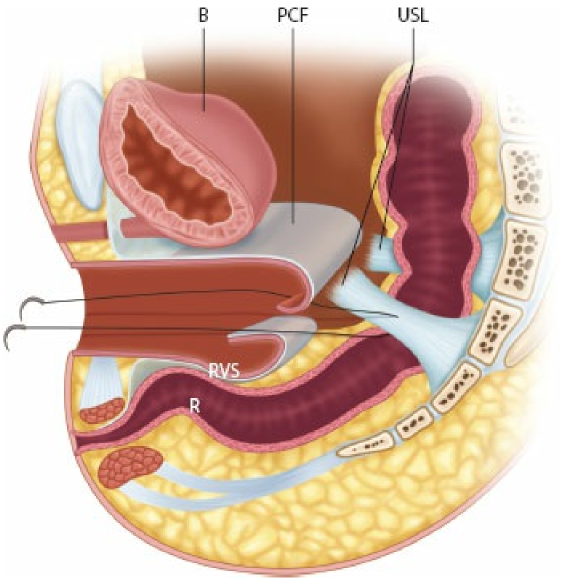

Figure 88.4 Uterosacral vaginal vault fixation following hysterectomy. *Abbreviations*: PCF, pubocervical facia; USL, uterosacral ligament; PS, pubic symphysis; B, bladder; RVF, rectovaginal fascia; R, rectum.

Sacrospinous colposuspension has traditionally been described as a unilateral fixation of the vaginal apex, performed by a posterior (rectocele) approach. As detailed by Richter, Nichols [35], Morley and

DeLancey [36], and others, the vagina is usually suspended to the patient's right side to avoid the rectosigmoid anatomy. The vaginal apex is attached, using either permanent or absorbable sutures, to the midportion of the sacrospinous ligament with care, as the most serious complications from this repair are traumas to the pudendal neurovascular structures and inferior gluteal vessels. At our center, although self-limited peripheral nerve injuries have been encountered, pudendal vascular injuries have been completely avoided by adhering to one simple principle: suture into, never over, the ligament. This translates into a fixation point located one to two fingerbreadths directly medial to the ischial spine. Excellent results have been reported for the classical sacrospinous suspension, but the operation also has clear limitations. First, the vagina deviates to one side, creating an esthetic but not usually functional disadvantage. Second, the traditional sacrospinous fixation technique appears to confer a significant risk of recurrent anterior vaginal wall relaxation [37]. Colombo et al. concluded that unilateral sacrospinous fixation did not offer an advantage over McCall culdoplasty when performed at the time of vaginal hysterectomy [38].

For the past 15 years, our center has utilized an approach whereby the sacrospinous ligaments are accessed through the anterior (cystocele) rather than posterior (rectocele) dissection, and the vagina is affixed bilaterally. For the vast majority of cases, fixation into the sacrospinous ligament is performed with no vaginal retractors, utilizing a push-and-catch suturing device. We have found the bilateral anterior approach to anchoring the vaginal apex to the sacrospinous ligament allows the surgeon to address the anterior compartment with the same dissection, hopefully decreasing the higher rates of cystocele recurrence associated with the traditional technique utilizing native tissues. For larger cystoceles, this may include augmenting the anterior compartment with a biograft or polypropylene mesh, a topic beyond the scope of this chapter.

The iliococcygeus fascial suspension is similar to the sacrospinous suspension; however, here the apex is attached to the prespinous musculature (iliococcygeus or obturator internus fascia). Because the operation utilizes a fixation point that is less cephalad, it may achieve slightly less vaginal depth; however, it carries less risk of neurovascular injury than the sacrospinous repair and has demonstrated good anatomic success. There are no major vascular structures of concern in the high iliococcygeus area, and so it can be considered an excellent secondary choice for surgeons not fully comfortable with placing a fixation suture at the sacrospinous level, or for cases involving distorted or challenging anatomy in and around the ischial spine and sacrospinous ligament.

All cases of uterine prolapse are inherently associated with an enterocele, which may occur because of the descent of the posterior peritoneal cul-de-sac along with the prolapsed uterus ("traction" enterocele) and/or because of separation of the pubocervical and rectovaginal connective tissue at the vaginal apex away from the pubocervical "ring." Past teaching tended to emphasize the surgical separation of the peritoneal sac from the vagina and ligation and excision of this redundant tissue. However, many surgeons, ourselves included, have found that ligation or purse-string closure of the peritoneum may be unnecessary, as long as the operation restores continuity of the anterior (pubocervical) and posterior (rectovaginal) connective tissue planes to the pubocervical ring at the vaginal apex and suspension of this apex to a reliable source of apical support.

Uterine prolapse may also be treated with an abdominal approach, although this is less commonly performed for the nonenlarged prolapsed uterus. Proper fixation of the vaginal vault is no less essential when operating abdominally, but it appears to be emphasized less during abdominal cases. High uterosacral ligament suspension and abdominal sacral colpopexy with sutures through the presacral fascia are appropriate techniques, as they reinforce the vaginal apex to an appropriate cephalad-anchoring point. Nygaard et al. [39] published a 7-year follow-up of the Pelvic Floor Disorders Network multicenter randomized masked trial (Colpopexy and Urinary Reduction Efforts trial). By year 7, the estimated probability of failure was 0.27 (abdominal sacrocolpopexy [ASC] and urethropexy) and 0.22 (ASC alone) of anatomic failure (treatment difference of 0.050; 95% CI −0.161 to 0.271). Mesh erosion at 7 years was 10.5% (95% CI 6.8%–16.1%).

Some authors have identified higher rates of mesh erosion when abdominal sacral colpopexy is performed at the time of hysterectomy for uterine prolapse, leading some surgeons to perform a supracervical hysterectomy followed by sacral cervicopexy. However, other studies have indicated no excess risk from a baseline mesh erosion rate of approximately 3.4%–4.2%, even when the operation is performed by experienced subspecialists [40,41].

Laparoscopic sacral colpopexy or uterosacral ligament suspension may be performed following laparoscopic hysterectomy. The scientific evidence regarding the outcomes of these vault suspension procedures is limited but growing more robust with the introduction of robotic-assisted techniques, which may offer a greater number of surgeons to truly replicate the open abdominal repair.

Uterine-Sparing Techniques

Uterine-sparing prolapse repairs have been described as far back as the 1880s, and for years, influential gynecological surgeons have suggested that the uterus plays a passive, rather than an active role, in uterovaginal prolapse [42].

Alwin Mackendrot (1859–1925) provided an early description of prolapse and an accurate description of the cardinal and uterosacral ligaments. Thomas Watkins (1898) described an interposition operation for postmenopausal women, involving cervical amputation and fixation of the bladder against the posterior uterine wall, thereby elevating the lower uterine segment. Dr. Watkins advised against uterine removal for prolapse, unless the organ was diseased. By the end of the nineteenth century, several techniques had been proposed for ventral fixation of the uterine fundus to the abdominal wall by surgeons including Harris, Murphy, and Kocher, and in the early twentieth century, a combined vaginal and abdominal procedure included dilatation and curettage, trachelorrhaphy, anterior and posterior colporrhaphy, and abdominal uterosacral plication with uterine suspension. Dr. David Nichols, in his classic textbook on *Vaginal Surgery*, described the uterus as an innocent bystander, "…the result of genital prolapse and not the primary cause of the symptomatology" [43]. Diwan et al. [44], in reviewing the subject of uterine preservation, concluded that hysterectomy has not been proven to improve durability of the repair and may carry several disadvantages including increased morbidity, blood loss, operative and recovery times, and increased pelvic neuropathy and disruption of natural support structures. The authors cited a potential risk for new-onset urinary incontinence, bladder dysfunction, prolapse, and possibly adverse effects on sexual identity. Altman et al. [45] compared 162,488 Swedish women with hysterectomy to 470,519 matched controls and found that 3.2% (n = 5270) of women after hysterectomy needed to undergo prolapse surgery versus 2.0% of the controls (n = 9437), with the highest risks observed in women having had vaginal hysterectomy (hazard ratio 3.8; 95% CI 3.1–4.8). The authors concluded that hysterectomy was associated with increased risk of subsequent prolapse surgery. Likewise, Blandon et al. [46] studied a cohort of 8220 women with prior hysterectomy and found that a cumulative incidence of subsequent prolapse surgery was 5.1% by 30 years (study period 1965–2002). Prolapse surgery was more likely among women with an original diagnosis of prolapse, who underwent vaginal hysterectomy (hazard ratio 4.3; 95% CI 2.5–7.3). With respect to bowel function, Karasick et al. [47] studied 354 women undergoing defecography and concluded that hysterectomy was associated with a higher risk of enterocele (40% vs. 25%, $p = 0.009$) and pelvic floor descent (25% vs. 15%, $p = 0.04$) and may contribute to the development of defecation disorders.

Patient choice is often the driving factor leading to uterine preservation. For younger women, this decision may be fueled by a general desire to feel young, intact, and fertile; it is certainly understandable that many women—younger women in particular—have a psychological attachment to this reproductive organ. For the advanced elderly, a desire to avoid hysterectomy may relate to fear over the perceived invasiveness of the operation, surgical risks, and/or length of recuperation. In theory, effective hysteropexy procedures may preserve the architecture of the vaginal apex better than hysterectomy, *suspending rather than transecting* the cardinal–uterosacral ligament complex and envelope of connective tissue attachments surrounding the paracervical ring. Before performing a hysteropexy, abnormal bleeding patterns and/or undiagnosed gynecologic symptoms should be addressed. Additionally, the presence of cervical or uterine pathology (i.e., dysplasia and undiagnosed bleeding) would serve as contraindications to uterine preservation, and up-to-date cervical cytology must be confirmed.

Uterine preservation operations fall into two major categories: (1) *hysteropexy procedures* that attempt to reconstruct normal anatomy and (2) *obliterative procedures* designed to resolve the prolapse bulge and not preserve the normal anatomy of the vagina.

Hysteropexy Procedures

Sacrospinous Hysteropexy

It is interesting to note that uterine-sparing techniques were promoted well before hysterectomy was popularized as a procedure of choice for prolapse. In the modern gynecologic literature, open abdominal, vaginal, and laparoscopic techniques have been described. Hysteropexy techniques vary significantly among the scattered centers that have taken an interest in uterine preservation and published their technique and results.

The feasibility of sacrospinous hysteropexy was suggested by several early case series [48,49], all of them involving a posterior approach and unilateral fixation of the apex, suggesting short operative time and encouraging rates of success. Cruikshank et al. reported successful long-term support even among four of five younger women who reported a subsequent pregnancy and childbirth. Maher et al. [50] compared 70 women aged 23–87 years old, who underwent either sacrospinous hysteropexy (*n* = 34) or vaginal hysterectomy" (*n* = 36). Standardized questionnaires and blinded postoperative examinations were performed at a mean follow-up of 33 months. Recurrence rate after hysteropexy was 3.6%, no higher than what was observed in the vaginal hysterectomy group. Additionally, uterine preservation was associated with shorter operative time (59 vs. 91 minutes) and less estimated blood loss (198 vs. 402 mL). Rates of patient satisfaction were high for both groups (85% for hysteropexy and 86% for vaginal hysterectomy).

Other comparative studies include Hefni et al. [51], who compared 61 sacrospinous hysteropexy cases to 48 hysterectomies and reported 95% versus 95% success, respectively. van Brummen et al. [52] compared 54 sacrospinous hysteropexy cases to 49 vaginal hysterectomies and found equivalent anatomic results for the two operations with quicker recuperation after hysteropexy. Interestingly, vaginal hysterectomy was associated with up to threefold higher rates of urge incontinence and overactive bladder symptoms, raising speculation as to whether the dissection of bladder base during hysterectomy may increase the likelihood of denervation injury and subsequent lower urinary tract dysfunction.

Dietz et al. [53] evaluated 133 women after sacrospinous hysteropexy at a mean follow-up of 22 months; 99 completed questionnaire, but only 60 followed up for the postoperative exam. Eighty-four percent of respondents were highly satisfied. The authors recorded only a 2.3% recurrence rate for uterine descent; however, 35% of subjects developed a subsequent cystocele. A separate analysis [54] on functional outcome among 72 of these subjects, 1 year after sacrospinous hysteropexy, included validated symptom and quality-of-life questionnaires. Scores on all domains of urogenital symptoms and defecatory symptoms, except for the pain and fecal incontinence domain, improved significantly. Self-reported quality of life was improved for all domains, and no major complications were encountered in this cohort.

The same authors performed a separate randomized trial including 71 subjects undergoing either sacrospinous hysteropexy or vaginal hysterectomy for stage 2 to 4 uterine descent [55]. With respect to subjective outcomes, sacrospinous hysteropexy and vaginal hysterectomy were equally effective in improving urogenital/defecatory symptoms. No differences were found in quality-of-life scores and self-reported urogenital/defecatory symptoms at 1-year follow-up between the two procedures. Sacrospinous hysteropexy was associated with better mean apical support than vaginal hysterectomy as measured by C and D points on POP-Q testing at 1 year. However, among women presenting with stage >2 uterine prolapse, the risk of apical recurrence was 17% lower after vaginal hysterectomy compared with those undergoing sacrospinous hysteropexy. Women who had presented preoperatively with advanced stage uterine prolapse were especially prone to objective recurrent prolapse 1 year after sacrospinous hysteropexy in this study. Repeat surgery for prolapse was performed in 11% of women after sacrospinous hysteropexy versus 7% after vaginal hysterectomy. Alshaikh recently compared sacrospinous hysteropexy and uterosacral ligament suspension at the time of hysterectomy and found similar subjective results although there was a trend toward more objective recurrences in the hysteropexy group [56].

Mesh-augmented sacrospinous hysteropexy procedures have been utilized as a means to simplify the technical steps of the surgery and also to concurrently address both the anterior and apical compartments. Vu et al. (2012) published 1-year recurrence rate of 1.89% (no anterior and one apical [C ≥ 1]) when mesh was used to augment sacrospinous hysteropexy, defining recurrence as POP-Q stage ≥2 in the anterior and/or apical compartments. Pelvic Floor Distress Inventory (PFDI) scores were improved in all domains postoperatively [57]. There were no surgeries performed for recurrence, and when patients were asked if they would choose the surgery again, 93% said they would. Additionally, the risk of vaginal mesh erosion associated with this repair was 1.9%, consistent with previous reports suggesting that uterine-preserving prolapse repairs may be associated with low rates of mesh complications [58]. The use of mesh has triggered substantial controversy in recent years, and at the present time, large multicenter trials are in progress to better delineate the risks and benefits of mesh-augmented hysteropexy in comparison with the alternative of vaginal hysterectomy (Figure 88.5).

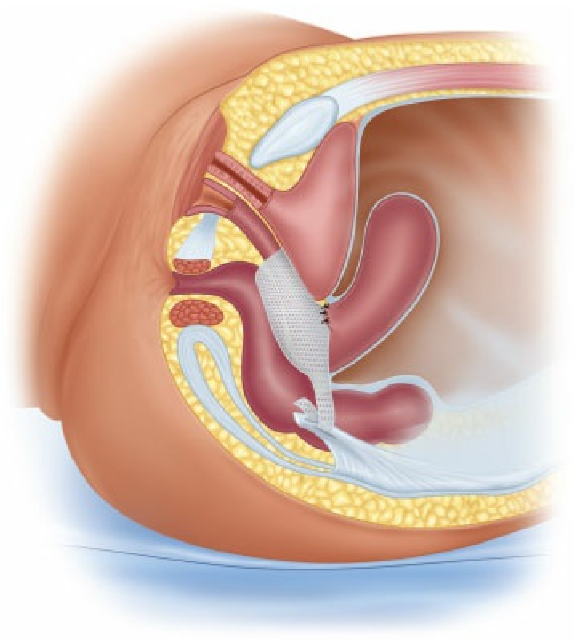

Figure 88.5 Mesh-augmented sacrospinous hysteropexy for uterine prolapse and combined cystocele.

Abdominal and Laparoscopic Sacrohysteropexy

Open abdominal sacrohysteropexy involves suturing the uterus to the anterior longitudinal ligament with a graft and more recently polypropylene mesh. Studies have demonstrated favorable anatomical cure rates and improved quality of life and sexual function. Abdominal hysteropexy is an approach that has been established by both observational series showing long-term (0 > 1 year) apical failure rates in the range of only 1%–7% [59–61].

Roovers et al. [62] performed the only randomized controlled trial (RCT)-comparing abdominal sacrohysteropexy and Burch ($n = 31$) to vaginal hysterectomy, uterosacral ligament suspension, anterior and posterior colporrhaphy, and needle suspension ($n = 31$). Anatomical outcomes were similar with regard to apical (95%) and posterior (85%–95%) success, but anterior defects recurred in 61% and 64% of women. There were more physician visits and more reoperations in the abdominal sacrohysteropexy group.

Costantini et al. [63] performed a prospective, cohort study on 72 consecutive subjects undergoing repair of uterovaginal prolapse by the abdominal approach; 34 were treated with abdominal hysteropexy and 38 with abdominal hysterectomy, followed by sacrocolpopexy. The sacrocolpopexy was performed with two pieces of rectangular mesh, and hysteropexy was performed with one posterior rectangular and one anterior Y-shaped mesh. Mean operative time, estimated blood loss, and hospital stay were significantly lower in the hysteropexy group ($p < 0.001$). At a mean follow-up of 51 (12–115) months, success rates were similar for uterine and vaginal apical support (100%). Recurrent low-grade cystoceles were observed in 1/38 (2.6%) after sacral colpopexy and 3/34 (8.8%) after hysteropexy (p = NS). There were no surgeries performed for recurrent vault or uterine prolapse, and the majority of subjects in each group (91% after hysteropexy, 87% after hysterectomy) were “satisfied and would do (this) again.”

Uterosacral and Round Ligament Hysteropexy

Hysteropexy techniques involving the uterosacral ligaments have also been described, including one by Maher et al. [64] in which laparoscopic suture hysteropexy was performed on 43 women. The Moschcowitz closure of the posterior cul-de-sac was combined with uterosacral shortening and fixation of the ligaments into the posterior cervix and then fixation to the contralateral uterosacral. At a mean interval of 12 ± 7 months, 81% remained symptom-free, and objective prolapse cure was achieved in 79%. Eventually, 16% underwent repeat surgery, all performed for uterine prolapse. Bedford et al. [65] compared hysterectomy with laparoscopic uterosacral colpopexy to laparoscopic hysteropexy and found with a median follow-up of 2.5 years that the failures at the apex were 27% for the hysteropexy group and 11% for the hysterectomy group ($p < 0.2$). It appears that the uterosacral approach has not matched the efficacy of sacrospinous and sacral hysteropexy techniques.

Likewise, varieties of “round ligament” uterine suspensions have been proposed and have performed rather poorly in comparison with the alternatives. These have included laparoscopic [66,67] techniques and also open techniques including that reported by O’Brien and Ibrahim [68] who observed uterine prolapse recurrence in eight of nine postmenopausal patients after 3 months. The round ligament is generally not regarded as a pelvic support structure or a reliable anatomic anchoring point for uterine prolapse surgery.

In summary, preserving the prolapsed uterus is a strategy receiving increased attention as we face an expanding “toolbox” of surgical options including mesh-augmented repairs and tissue fixation systems offering alternatives to standard suture-based approaches. New techniques appear to provide greater operative ease and show highly promising results in both the apical and anterior compartments. In particular, sacrospinous hysteropexy and abdominal sacrohysteropexy have established credible track records from the standpoints of anatomic outcomes, morbidity, and patient satisfaction. Uterine preservation now plays a more central role in the treatment of symptomatic uterovaginal prolapse.

Obliterative Procedures: Lefort Colpocleisis and the Manchester Operation

The Manchester/Fothergill procedure was described in 1888 by Archibald Donald of Manchester, England. The Manchester procedure involves shortening and reattachment of the uterosacral and cardinal ligaments, combined with either partial or complete cervical amputation. Up to 20% recurrence rates have been described within the first few months, and additionally, functional concerns including dyspareunia and dysmenorrhea have been cited. A recent retrospective observational study evaluated 204 younger women (mean age 34.68 ± 4.24 years) with grade 2–3 uterine prolapse; 95.1% had associated cystoceles and 51.3% had associated rectoceles. Postoperatively, 27 patients (13.2%) had febrile morbidity, urinary retention occurred in 45 patients (22.0%), and cervical stenosis occurred in 23 patients (11.3%). Within the first year, one patient underwent abdominal hysterectomy because of unsuccessful cervical dilatation, and at a mean of 3.6 years following the operation, eight patients had undergone a vaginal hysterectomy for recurrent uterine prolapse. The authors noted a mean satisfaction/acceptance score for the operation of 8.52 ± 2.13 (range, 2–10).

The Manchester operation is no longer used widely but may still represent a consideration for select cases of prolapse in women wishing to retain their uterus.

Lefort Colpocleisis

Colpocleisis represents an excellent alternative for a select group of older, nonsexually active women with severe prolapse who wish to undergo a low-morbidity repair with extremely quick recuperative times. The Lefort (partial colpocleisis) operation, first described by its namesake in 1877, results in closure of the vagina, leaving small (pencil-width) lateral channels on each side, and therefore is only appropriate for women who are completely certain they do not ever want to have penetrative sexual intercourse again.

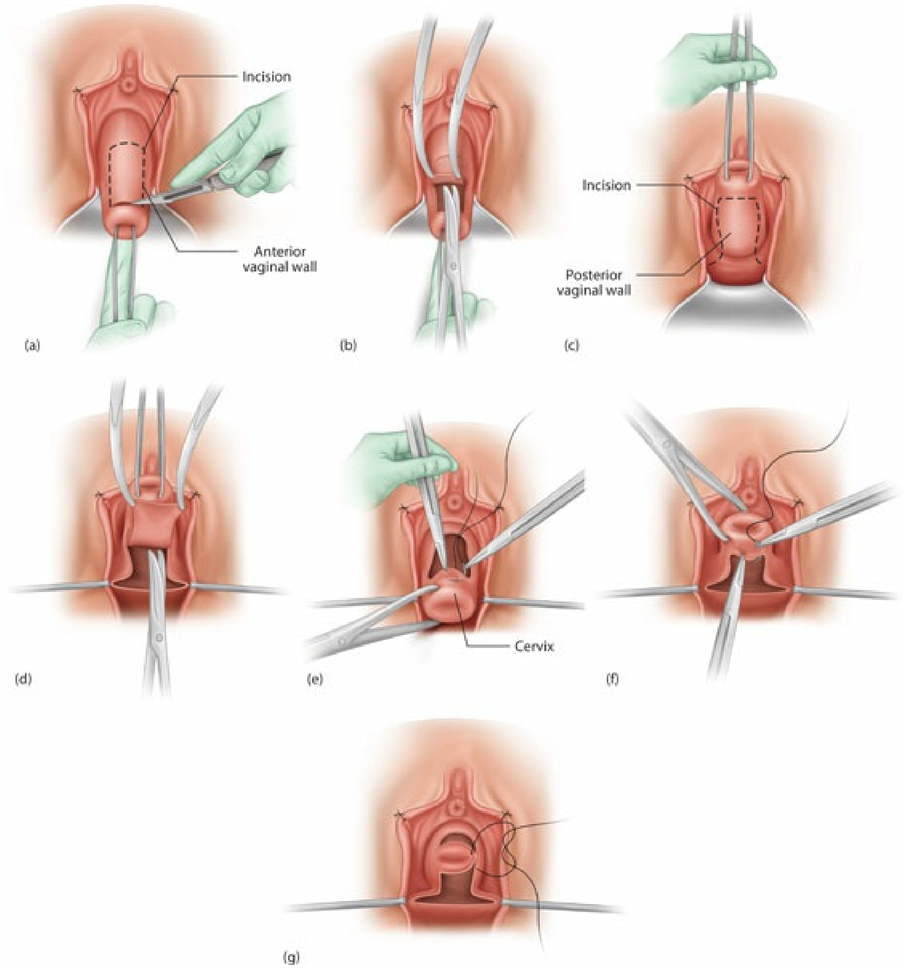

Figure 88.6 (a) anterior vaginal incisions, (b) anterior dissection, (c) posterior incision, (d) posterior dissection, (e) anterior suture placement, (f) posterior suture placement, (g) sutures tied, creating lateral tunnels.

The operation can be performed under local anesthesia if desired and is associated with minimal postoperative pain, high rates of patient satisfaction, and exceptionally low rates of failure [69,70]. With this technique, trapezoidal patches of vaginal epithelium are removed from both anterior and posterior vaginal walls, followed by placement of interrupted absorbable sutures approximating the anterior and posterior edges of the retained vaginal epithelium “strips” running along each lateral side of the prolapse. As the sutures are sequentially tied, the effect is to fold the pubocervical and rectovaginal connective tissue surfaces onto each other, which reduces the cervix and vaginal apex and eventually inverts the entire prolapse bulge, while obliterating the vaginal canal. The repair should include a robust perineorrhaphy to significantly narrow the vaginal introitus. Although the operation retains epithelialized “tunnels” allowing for cervical and uterine secretions to discharge, there is a risk of future difficulty sampling the cervix and endometrium should vaginal bleeding later occur, and patients need to be counseled about this. Cases of cancer and hematocolpos have been reported [71], and these cases may introduce difficult diagnostic and treatment challenges.

Before performing this operation, normal cervical cytology screening should be verified according to age-appropriate guidelines, and either ultrasonography or endometrial sampling may be a consideration in some cases (Figure 88.6).

CONCLUSIONS

Uterine prolapse is common among our patients and remains a challenging surgical condition even in experienced hands. Pessary management remains an important and often effective strategy that should be offered as an alternative to surgical repair. Vaginal hysterectomy followed by apical suspension remains a surgical mainstay, although the scientific evidence suggests that the removal of the uterus, in anatomic terms, may contribute no structural benefit to a prolapse repair in many cases. Hysterectomy is still commonly performed with prolapse repairs, but it is important to emphasize that uterine prolapse is most often a result of the disease process rather than its cause—in other words, an "innocent bystander." Hysteropexy repairs are an alternative whose efficacy has been established by an increasing amount of research, although one recent comparative trial found hysteropexy to be associated with higher rates of objective failure than hysterectomy for the treatment of advanced prolapse cases; the same trial, however, found rates of patient satisfaction to be identical. Although numerous questions remain open for future research, the current evidence suggests that favorable results can be achieved using both the "traditional" hysterectomy-based approach and the uterine-preserving surgery. As new and improved minimally invasive hysteropexy techniques emerge, uterine preservation may have the potential for increased appeal among both surgeons and patients.

Choosing the "right" treatment strategy for uterine prolapse, whether surgical or nonsurgical, should take into consideration the individual patient's sexual and reproductive activity, personal feelings, sites and degrees of pelvic prolapse, concurrent pelvic pathology, and overall health status. By offering several treatment alternatives, clinicians can help to ensure that the largest number of symptomatic women achieves their personal goals.

89 Biological Grafts in Reconstructive Pelvic Surgery

Alexis M. Tran and Peter K. Sand

Successful repair of pelvic floor defects remains one of the greatest challenges facing pelvic reconstructive surgeons. The recognized high rate of recurrence following anterior vaginal wall repairs has led pelvic floor surgeons to augment these repairs with various materials. A variety of prostheses have been used: allografts, xenografts, and absorbable and permanent synthetic mesh. Among the most important advances in this field has been the utilization of new lightweight synthetic mesh and biological grafts into the surgical armamentarium. One of the arguments for using a biological graft versus a synthetic mesh is to theoretically minimize the risk of graft exposure, extrusion, infection, or new-onset dyspareunia. A recent American Urogynecologic Society (AUGS) survey reported that transvaginal mesh use decreased from 90% in AUGS survey responders to 61% after the FDA safety update in 2011 [1]. Biological grafts represent an important option in transvaginal pelvic reconstruction, especially following heightened public and governmental scrutiny of synthetic materials and the subsequent declining utilization of transvaginal permanent mesh.

BASIC SCIENCE OF BIOLOGICAL GRAFTS

The purported function of biologics is to provide a regenerative framework for extracellular matrix and remodeling with new collagen deposition, resulting in new tissue formation with eventual replacement of the graft.

The initial reaction after implantation is adsorption of host proteins to the implant creating a biofilm. This process does not require a cellular response and is initiated within seconds of implantation. After this initial response, low-molecular-weight proteins such as albumin and fibrinogen, immunoglobulins, and extracellular matrix molecules are adsorbed to incorporate the implant within the host tissue. Once the proteins undergo conformational changes, the host-implant complex becomes immunogenic and sets off an inflammatory response including the complementary system.

A cascade of events follows graft implantation. First, an acute inflammatory response occurs. This is the same foreign body response that occurs in wound healing after any insult. Mononuclear cells (macrophages, mast cells) populate and penetrate the graft scaffold. The following typical sequence of wound healing follows this with mononuclear cells secreting signaling factors such as cytokines and growth factors. Fibroblasts are attracted to the site to initiate synthesis of collagen, predominated by type 3 collagen initially. Eventually, matrix proteins are produced, which begin the remodeling process. Early cellular and vascular infiltration of a graft scaffold is critical for fibroblast proliferation and new collagen deposition. In the absence of angiogenesis, tissue remodeling does not occur and instead scar formation results. In a rodent animal model, neocellularity was seen at 3 months after alloderm implantation [2]. This was also observed in a primate model 1 month after human dermal graft implantation [3].

The initial inflammatory response can promote either graft integration, excessive scarring, graft encapsulation, or graft degradation. This balance between normal wound healing and a disproportionate inflammatory response is largely controlled by the action of chemical signaling molecules at the host/graft interface. In vitro studies demonstrated alloderm (acellular cadaveric dermis) inducing a smaller cytokine response than non-cross-linked porcine dermal grafts and porcine intestinal submucosa [4,5]. Animal models have also showed that cross-linked porcine dermal grafts are associated with a heightened foreign body response and pronounced early inflammatory response. Similar tissue response has been observed in humans. Our histopathological analysis of cross-linked, nonperforated, porcine dermal grafts used as transvaginal suburethral slings in recurrent stress incontinent patients demonstrated an increased lymphocytic cell reaction and multinucleated giant cells infiltrating the specimen at 42 weeks post graft implantation with no graft material detected thereafter. The consequences of eventual loss of the graft on the structural and functional integrity of the surgical repair in pelvic reconstructive procedures need to be determined [6] (Figure 89.1).

When scaffold degradation of the graft is accompanied by cellular infiltration, extracellular matrix deposition, and neovascularization, tissue remodeling occurs [7]. If this process fails to take place in the host, the graft, instead of being replaced by new regenerated tissue, is replaced by a scar. Vaginally, this can result in unwanted outcomes such as vaginal shortening, constriction, or dyspareunia. It has been suggested that rapid degradation of the graft scaffold without deposition of new collagen can predispose to implant failure. The biomechanical properties (strength, elasticity, stiffness, and strain) and histopathological characteristics of a graft in vivo have been studied largely in vitro with animal models.

In the New Zealand white rabbit model, the histopathology and biomechanical properties of four biological grafts: human dermis, porcine dermis, porcine collagen–coated polypropylene mesh, and autologous fascia at two anatomical sites were investigated. Elastic modulus and ultimate strength decreased in dermal collagen grafts. Vaginal site graft implantation was associated variably with decreased strength, with more shrinkage, and with less stiffness and erosions. Histologically, cadaveric and xenograft dermal grafts promoted more inflammation and demonstrated less collagen ingrowth than autologous fascia or porcine collagen–coated synthetic material. Longer-term outcomes (9 months) in this model demonstrated cross-linked porcine dermal graft–induced variable host tissue responses. Some grafts demonstrated encapsulation with minimal host tissue infiltration into the graft. Others showed a severe foreign body reaction [8,7].

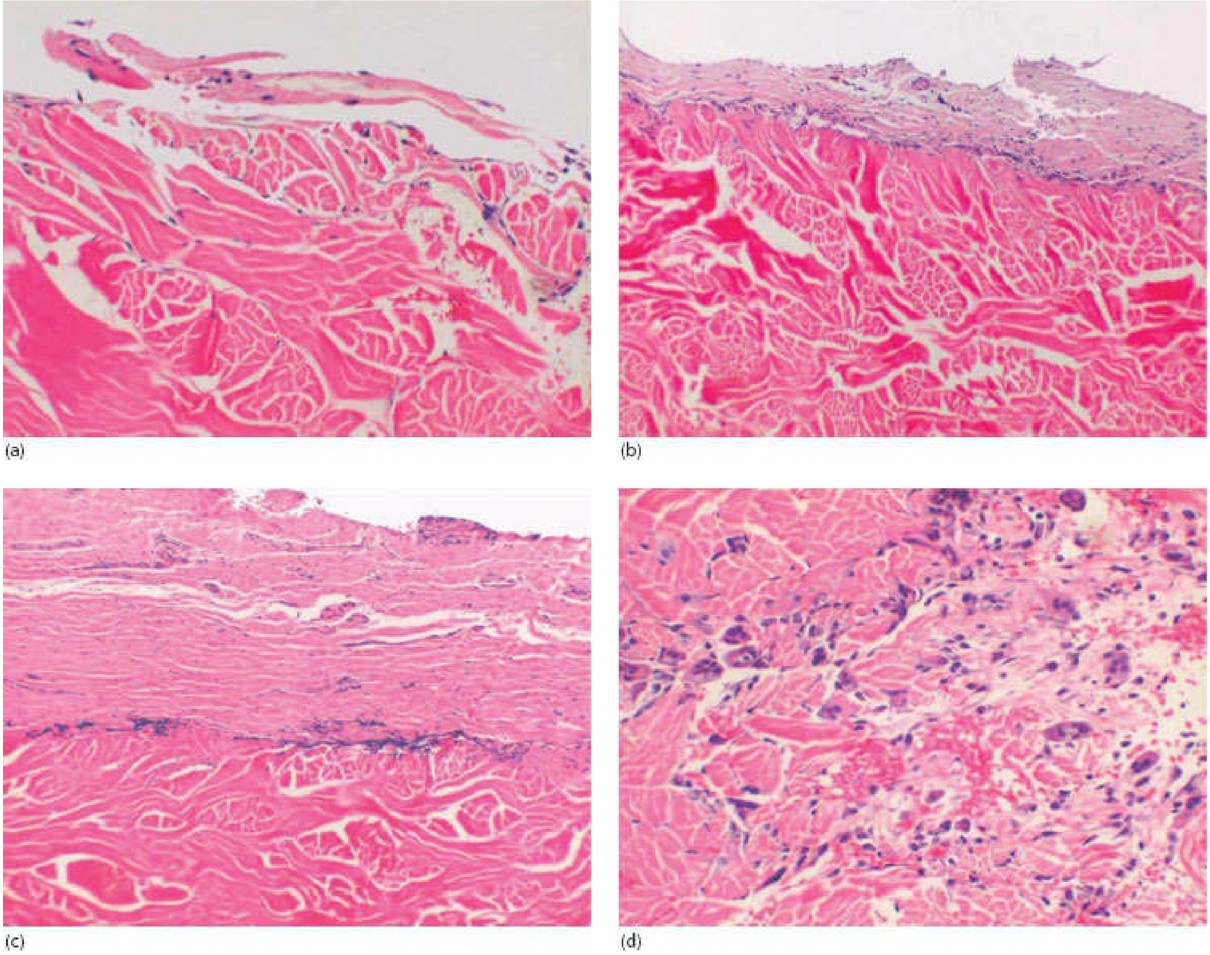

Figure 89.1 Hexamethylene diisocyanate cross-linked porcine dermal implants may integrate or encapsulate and undergo degradation and not be incorporated into host tissue. (a) Suburethral graft 15 weeks after implantation. The periphery of the graft demonstrates a thin layer of new collagen formation with minimal fibroblast infiltration. (b) Suburethral graft 19 weeks after implantation. Graft demonstrates mild fibroblast proliferation with neovascularization at its periphery. There is a mild lymphocytic reaction at the interface of the graft and new collagen formation. (c) Suburethral graft 21 weeks after implantation. Graft demonstrates moderate fibroblastic proliferation and collagen formation with a more prominent lymphocytic reaction at the

interface. (d) Suburethral graft 42 weeks after implantation. Graft demonstrates histiocytes and multinucleated giant cells infiltrating the thickness of the specimen (a, d, hematoxylin and eosin, 20× magnification; b, c, hematoxylin and eosin, 10× magnification). (From Gandhi S et al., *Am J Obstet Gynecol*, 192, 1643, 2005. With permission.)

The mechanical properties of grafts changed after implantation.

Preimplantation graft properties did not predict postimplantation biomechanical graft behavior. Human dermal graft displayed more strength and stiffness at the start, but these properties diminished with time. The investigators concluded that in this animal model the dermal graft did not offer more mechanical support than autologous fascia or synthetic mesh.

As shown in both animal models and clinical studies, porcine dermis cross-linked grafts induce inconsistent long-term response in different hosts. Some behave more as a resorbable material with degradation and total loss of mechanical strength at the graft site during remodeling, and some behave more as a synthetic implant without any tissue ingrowth. Suburethral tissue specimens in patients with recurrent SUI after sling surgery with hexamethylene diisocyanate (HMDI) cross-linked porcine dermis showed some specimens with limited collagen remodeling and minimal inflammation, while others induced a strong foreign body response. Gandhi et al. reported unpredictable tissue reactions with this adjuvant graft in stress urinary incontinence surgery [6,7].

In animal models, we have seen that vaginal site implantation displays different behaviors than abdominal site implantation of prosthetic grafts. Vaginal grafts underwent degradation at a more rapid rate. Erosion rates were minimized by decreasing graft size.

GRAFT TYPES

The use of biological grafts dates back to 1917 in anti-incontinence procedures [9]. These consisted of autologous grafts. Allografts were the first biological mesh type to be introduced to North America in the 1990s. Dermis is the most common tissue due to the size of the graft, which may be obtained. These dominated the market and literature until the introduction of xenografts. Xenografts quickly gained popularity as a result of its reduced cost, improved availability, and reduced regulatory restrictions.

In female pelvic reconstruction, biological grafts consist of three types: autologous grafts, and allograft and xenografts [10]. Autologous grafts consist of fascia lata, dura mater, split-thickness skin grafts, or rectus fascia harvested from the host recipient. Allografts consist of cadaveric sources of dermis or fascia lata. Xenografts consist of porcine dermis, small intestinal submucosa (SIS), bovine dermis, and pericardium and xenograft synthetic composites (acellular cross-linked porcine dermis with polypropylene mesh) (Table 89.1).

The differences observed in graft behaviors are likely a result of the host response, tissue types, and processing methods. Tissue processing can alter the immunogenic and foreign body response to these grafts. Perforation of biological grafts has been shown to be beneficial as it promotes angiogenesis and more rapid host infiltration of fibroblasts for collagen deposition. The porosity of the graft material also seems to reduce seroma formation and the risk of infection.

Table 89.1 Commercially Available Biological Grafts for Reconstructive Pelvic Surgery

Tissue	Brand name	Processing
Cadaveric fascia lata	Suspend Tutoplast (Mentor, Santa Barbara, CA)	g irradiated Solvent dehydrated Preserved
	FasLata (C.R. Bard, Covington, GA)	g irradiated Freeze-dried
	ReadiGRAFT (LifeNet, Virginia Beach, VA)	Freeze-dried, Allowash (removes cells, bacteria, virus, fungi, and spores)
Cadaveric dermis	Alloderm (LifeCell Corp., Branchburg, NJ)	Freeze-dried
	Repliform (Boston Scientific, Natick, MA)	Cryopreservation without ice crystal Damage
	Bard Dermal Allograft (C.R. Bard, Murray Hill, NJ)	g irradiated Freeze-dried

	Axis Tutoplast Processed Dermis (Mentor, Santa Barbara, CA)	g irradiated Solvent dehydrated
Porcine dermis	Pelvicol Acellular Collagen Matrix (C.R. Bard, Murray Hill, NJ)	g irradiated Hexamethylene diisocyanate HMDI cross-linked
	PelviSoft Biomesh (C.R. Bard, Murray Hill, NJ)	g irradiated HMDI cross-linked Fenestrated
	PelviLace Biourethral Support System (C.R. Bard, Murray Hill, NJ)	g irradiated HMDI cross-linked
	Intexen (American Medical Systems, Minnetonka, MN)	Freeze-dried
Porcine SIS	Symphysis Smart Remodeling Matrix (Cook Urological, Inc., Bloomington, IN)	Solvent dehydrated Freeze-dried Non-cross-linked
	Surgisis Soft Tissue Graft (Cook Urological, Inc., Bloomington, IN)	Solvent dehydrated Freeze-dried Non-cross-linked
	Stratasis Tension-Free Urethral Sling (Cook Urological, Inc., Bloomington, IN)	Solvent dehydrated Freeze-dried Non-cross-linked
	FortaGen (Organogenesis, Canton, MA)	g irradiated 1-ethyl-3-[(3-dimethylamino)propyl]-carbodiimide hydrochloride cross-linked
Bovine pericardium	Veritas (Synovis Surgical Innovations, St Paul, MN)	Non-cross-linked
Bovine dermis	Xenform Soft Tissue Repair System (Boston Scientific, Natick, MA)	Non-cross-linked

Allografts carry a potential risk of one to two per million for viral transmission and one in eight million for HIV transmission. Xenografts carry a theoretical prion risk although no cases have been reported.

Autologous grafts offer the benefit of avoiding the effects of processing, of graft rejection, and of transmissible infections. Because the patient serves as her own donor, these grafts induce very little foreign body reaction, and there is usually good incorporation of the graft into the native tissue. These grafts, unlike others, may also be used for infected surgical sites.

The harvesting of autologous fascia lata has been described in various pelvic floor reconstructive surgical procedures. With the patient's leg rotated medially in a dorsal lithotomy position, a 4 cm incision is made between a point 2 cm above the lateral epicondyle and directly superior to the medial aspect of the patella. The vertical fibers of the iliotibial tract and the oblique and horizontal fibers of the dorsal fascia lata are exposed with blunt and sharp dissection. A similar 4 cm incision is made 15–20 cm superior to the previous incision in the line of the lateral epicondyle and greater trochanter. With a special stripper, an extended transverse fascial thigh graft is excised. The skin is reapproximated with sutures and the leg is wrapped in an elastic bandage. Leg compression is necessary for hemostasis but may increase the risk of deep venous thrombophlebitis.

Procurement from the patient's own body eliminates the concerns about transmissible infections, but harvesting the tissue may be associated with surgical morbidity. Pain, infection, weakness, and unsatisfactory cosmetic outcomes have all been cited as disadvantages to harvesting autologous grafts. In a retrospective review of 71 patients undergoing either a pubovaginal sling or abdominal sacrocolpopexy using autologous fascia lata, Walter reported one case of a hematoma requiring draining and five cases of incisional cellulitis requiring oral antibiotics. Nineteen percent of patients also reported persistent thigh numbness with a mean follow-up time of 25 months [11].

Since their first use in pelvic reconstruction, the popularity of autologous grafts has been surpassed by the use of other materials as a result of questions regarding the durability of autologous grafts [12]. More recently, a reanalysis of a 5-year data on apical repair with cadaveric fascia lata reported success rates exceeding 90% when a composite score was used to define success [13,14]. This was markedly higher than the 68% success rate at 5 years when only anatomic outcomes were measured. The limitation of this analysis from this randomized controlled trial was that the subjective query of patients was not blinded nor utilized validated instruments. It has been suggested, from in vitro study, that differences in horizontal or vertical graft orientation significantly affects the graft's bursting strength.

Xenografts and allografts must undergo decellularization and sterilization to prevent antigenic responses and infection. Sterilization methods include freeze-drying, solvent dehydration, and irradiation. Each is purported to have an effect on the donor tissue. Previous studies of biological implants used as slings reported that freeze-dried cadaveric fascia lata demonstrated the most diminished biomechanical properties and intratissue consistency after graft implantation [12,15].

Xenografts may also undergo supplemental cross-linking. Possible cross-linking agents are HMDI, carbodiimide, glutaraldehyde, or photooxidizing agents. Although cross-links exist in native collagen present in dermal grafts, additional processing increases the amount of collagen cross-links, resulting in supplemental cross-linking. Supplemental cross-linking is purported to prolong the lifespan of the implant. The 3D structure of the collagen mechanically strengthens the matrix and impedes degradation by enzymatic collagenase.

The effect of supplemental cross-linking on xenograft behaviors appears to play the largest role on host tissue responses. Even though in vitro studies report generally improved graft resistance to enzymatic degradation to host collagenases with increased collagen cross-links, this has not always correlated to clinical efficacy [2]. Long-term tissue reinforcement to serve host tissue regeneration is a purported benefit of cross-linked biological grafts. Cross-linked biologics in the plastic surgery literature were found to behave more as a permanent synthetic. In both translational animal models and in vivo, supplemental cross-links may have a significantly higher immunologic disadvantage, which may result in graft rejection. In the hernia literature, cross-linked dermal grafts were found to be completely degraded in infected wounds. In uninfected implants, no evidence of tissue remodeling was seen. In vivo, cross-linked porcine dermal can behave more as a permanent foreign body or a synthetic due to its lack of integration into host tissue and likely resultant fibrous encapsulation [6]. Non-cross-linked implants facilitate tissue ingrowth without encapsulation and promote tissue remodeling.

The balance between extracellular deposition and scaffold degradation is necessary for effective tissue graft reinforcement during tissue remodeling. While some study investigators have reported deposition of new matrix at the site of biological graft implantation, tissue regeneration within a degrading scaffold can be mimicked by fibrotic scar formation. The distinction between these two states is not always histologically apparent.

One of the major limitations of biological graft research is the common animal models used. Most investigations in the female pelvic medicine and reconstructive surgery literature have used the New Zealand white rabbit model. In the general surgical literature, rodents, guinea pigs, or minipigs have been utilized. Those animals are used due to relative ease of graft implantation and low cost. Tissue responses in different species do not directly compare to humans—especially in the long term. We have shown this in the vaginal rabbit model.

Failure of grafts may be due to a rapid or an unbalanced degradation of the graft scaffold without the necessary time for proper support from the deposition of the components of the extracellular matrix. Gradual tissue remodeling of an implanted tissue graft is essential for success in pelvic reconstructive procedures.

CLINICAL USE OF BIOLOGICAL GRAFTS

Anterior Compartment Defects

Biological graft augmentation in the anterior compartment has been an area of scientific interest as reflected by the largest number of prospective, retrospective, and randomized controlled trials to support its use. This interest is because anterior compartment repairs with native tissue have very high anatomic failure rates in excess of 40% [16]. Studies have shown that anterior compartment defects benefit from graft-reinforced repairs. It is well established that repairs with polypropylene monofilament mesh result in higher long-term anatomic success rates compared to traditional native tissue repairs (46% vs. 14%) [17]. However, the anatomic benefit of synthetic permanent reinforced repair must be balanced against its increased potential risk of mesh erosion, exposure, pelvic pain, and dyspareunia.

To minimize the risk of exposures with synthetic mesh, Sand et al., in a prospective, randomized, controlled trial, used a polyglactin 910 mesh imbricated into an anterior application of the endopelvic connective tissue compared to a native tissue repair with a midline colporrhaphy for vaginal repair of the anterior compartment. Anatomic success (less than grade 2) was significantly increased with absorbable synthetic mesh after 1 year (75% vs. 57%, $p = 0.02$) [16].

Long-term follow-up (greater than 18 months) of prospective work by Clemons et al. demonstrated that when cadaveric dermal grafts were attached adjacent to the arcus tendineus fascia bilaterally, the anatomic recurrence (POP-Q stage ≥ 2) rate was 58.3%. Among these recurrences, only 28.6% were symptomatic. They concluded that alloderm graft has good subjective success despite a moderate rate of objective failure within 24 months of placement [18]. In Clemons' initial study, 33 patients had a 59% objective success rate and a 97% subjective success rate.

Conversely, in a retrospective comparative study, Botros et al. reported a significantly higher success preventing recurrent anterior prolapse (greater than or equal to stage 2) when using a human dermal graft for a paravaginal repair (attached directly to the arcus tendineus fasciae) in addition to standard anterior colporrhaphy when compared to only anterior colporrhaphy alone (19% vs. 43%, $p = 0.004$) [19]. Favorable subjective outcomes were reported, but limited by response. The differences in outcomes between these two trials using barrier grafts of human dermis may be attributed to the surgical technique. While many studies have described tension-free placement of biological grafts or anchoring to sites along the pelvic wall, Botros et al. described the fixation of the graft to the arcus tendineus fasciae pelvis with minimal tensioning.

The 2013 Cochrane meta-analysis of two randomized controlled trials of primary prolapse repair with or without HMDI cross-linked porcine dermis in the anterior compartment concluded that anterior colporrhaphy has a nearly twofold (RR 1.7) risk of recurrence as compared to using an adjuvant acellular porcine dermal implant (CI 1.1–2.6) [20,21].

Two other well-designed randomized controlled trials by Natale et al. and Menefee et al. demonstrated lower recurrence rates with adjuvant synthetic meshes compared to porcine dermis. Natale et al. reported a 72% anatomic success rate (less than or equal to stage 2) with polypropylene vs. a 56% in the porcine dermal graft group. Extrusion was only seen in the synthetic mesh group (6.3%). Both groups reported improvement in QOL [22]. Menefee et al. compared success between polypropylene, porcine dermis, and native tissue anterior colporrhaphy in a randomized controlled trial with blinded postoperative outcomes [23]. They reported the highest success rate with polypropylene (82%) versus porcine dermis (54%) and 42% with native tissue repairs. Extrusion rates were higher in the polypropylene group (14%) versus 4% in the porcine dermal group and with none in the native tissue group. Higher extrusion rates have also been noted in other trials with synthetic grafts [17].

When anterior colporrhaphy with native tissue repair was compared to using an adjuvant porcine dermal graft in three randomized trials, the objective failure was significantly higher in the native tissue group (27%) compared to the porcine dermis group (16%) [20,21,23].

When used in the anterior compartment for vaginal reconstructive surgery, it seems that how allografts are implanted may impact their success of preventing recurrence. In a prospective, randomized, controlled trial, Gandhi et al. reported that a 2 × 4 cm cadaveric fascia lata graft overlay did not reduce the rate of recurrent cystocele. At 13 months, the objective (>stage 2) and subjective failure rates of the anterior colporrhaphy were not statistically significantly different: 29% and 21% from the 10.5% and 10.9% noted in the fascial patch group, respectively [15]. In a study using adjuvant cadaveric fascia lata grafts, which were attached using transvaginal bone anchors, only 2 out of 132 patients at 12 months had recurrent cystoceles of greater than second degree. Only one case of osteitis pubis was reported [24].

A randomized controlled trial of standard native tissue anterior colporrhaphy compared to utilizing adjuvant small intestine submucosa grafts reported a 59.3% anatomic cure rate vs. 86.2%, with the adjuvant small intestine submucosa intestine grafts. No differences were noted in QOL measures or subjective outcomes [25]. No inflammatory complications were reported—as had been reported in single case with porcine small intestine submucosa transobturator slings [26]. Guerette et al. compared native tissue repairs with bovine pericardium graft–reinforced repairs in the anterior compartment. They reported a 78.4% versus 85.7% success rate, respectively at 1 year. At 2 years, the bovine pericardium graft group's success rate dropped to 76.5% vs. 63% with native tissue. Both groups demonstrated improvements in subjective outcomes. No statistically significant differences in subjective or objective outcomes were noted with use of bovine pericardium adjuvant grafts in the anterior compartment [27].

Reanalysis by Barber et al. of the original work suggested that when subjective outcomes are considered, the failure rates of graft-augmented repairs are comparable to native tissue. Surgical success defined as anatomic support proximal to the hymen had the lowest treatment success (19.2%–57.6%).

When surgical success was defined as the absence of bulge symptoms, the cure rate was 92.1%. If success was defined as absence of retreatment then the success rate was 97.2%. These wide variations in reported success were also demonstrated in apical prolapse compartment repairs. Utilization of a composite definition (subjective and objective outcomes) of success may alter the success of various biological adjuvant grafts in anterior compartment repairs. Adjuvant biological grafts have demonstrated superior anatomical outcomes when compared to native tissue repairs in the anterior compartment. However, no change was seen in subjective outcomes compared with native tissue anterior compartment repairs [13].

Posterior Compartment Defects

Posterior vaginal wall prolapse is commonly associated with functional symptoms of vaginal bulging, obstructed defecation, and sexual dysfunction. Repair of posterior compartment defects should theoretically work to restore normal anorectal caliber and support to improve anorectal symptoms. However, studies have reported variable functional responses to anatomic correction [28–30]. Although transvaginal use of biological grafts for posterior compartment defects is proposed to reinforce repairs, there is a paucity of studies to support this hypothesis. When cadaveric dermal grafts were used to augment site-specific defect repairs in the posterior compartment, Kohli reported that 93% of patients had a POP-Q point Ap measurement of <−0.5 at 13 months in his prospective trial [31]. There are three randomized controlled trials evaluating biological graft–augmented repairs in the posterior compartment [16,28,29]. But mostly the literature is limited to retrospective comparative studies [28,29]. Paraiso et al., in a double-blinded, randomized controlled trial, compared posterior colporrhaphy, site-specific repair in the posterior compartment, and site-specific defect repairs augmented by porcine SIS. At 1 year, the authors reported a failure rate (greater than or equal to stage 2) of 14%, 22%, 46%, respectively [28]. In a secondary analysis by Gustilo-Ashby at 1 year, it was determined that although defecatory symptoms improved after posterior repair with and without graft augmentation, they persisted or worsened in up to 35% of patients. No difference was observed in sexual function [30]. Sung et al. also performed a randomized, controlled trial comparing native tissue repairs with small intestine submucosa augmented repairs. At 1 year, there was no difference in anatomic or subjective failures (notice of vaginal bulge symptom or defecatory symptom failure). These authors concluded that small intestine submucosa graft augmentation was not superior to native tissue for either measure at 1 year. The rate of dyspareunia was comparable to the control group (12.5% vs. 7%) [29]. Novi et al., in a prospective cohort trial examining sexual function at 6 months, determined that the porcine dermis–reinforced posterior repair group had a significant improvement in the Pelvic Organ Prolapse/Urinary Incontinence Sexual Questionnaire scores vs. the site-specific native tissue posterior repair group (19.9 vs. 6.9, respectively). Interestingly, both groups demonstrated a significant and comparable improvement in dyspareunia (decrease of 8% vs. 10%, respectively) [32].

Based on the available data, biological graft–reinforced repairs in the posterior compartment demonstrate similar or worse anatomic outcomes when compared to native tissue repairs. Mild improvements in functional outcomes were seen; specifically, there was a positive impact on sexual function. This benefit possibly represents the only reported potential benefit of graft-reinforced repairs in the posterior compartment.

Apical Prolapse

Abdominal sacrocolpopexy (ASC) has been considered the gold standard abdominal approach for prolapse of the vaginal apex with variable cure rates that depend on the definition of success employed (19.2% if perfect anatomic support to 97.2% if no reoperation) [13,33,34]. Although most of the long-term studies utilized synthetic mesh with an open approach, there exists a concern about adverse events such as mesh erosion with these grafts [33–35]. The 7-year outcomes from the extended CARE trial estimate the probability of mesh erosion to be 9.9%–10.5%, depending on whether the last censoring time was based on the last clinic visit or the last telephone interview [35]. These authors maintain that these results cannot be extrapolated to estimate outcomes in other surgical approaches for apical prolapse repair. However, the 2012 publication by Siddiqui et al. is promising. They retrospectively compared robotic-assisted laparoscopic sacrocolpopexy (RSC) to the historical abdominal sacrocolpopexy cohort from the CARE trial. They determined that at 1 year, both groups had comparable improvement in pelvic floor outcomes and quality of life measures. As consistent with Nygaard et al., the mesh erosion was higher in the ASC group (5.3% vs. 2.4%). These authors attribute their decreased rate of mesh erosion in the RSC cohort with the advent of lighter polypropylene mesh and performance of supracervical hysterectomy at the time of concomitant hysterectomy [36]. To date, the majority of extant studies support the use of synthetic mesh with the durability outweighing the potential risks. In a double-blinded, randomized, controlled trial comparing the use of cadaveric fascia lata and polypropylene mesh for abdominal sacrocolpopexy, synthetic mesh demonstrated superior durability with sustained support of the anterior and apical segments of the vagina utilizing the pelvic organ prolapse quantification (POP-Q) points Aa and C. The objective failure rate was significantly worse (32%) in the fascial graft cohort versus 9% in the polypropylene mesh cohort. Mesh exposures occurred in 2 of the 54 subjects [37]. Five-year data determined that objective recurrence was higher in the fascial group at 38% vs. 6.8% in the synthetic mesh group for any (POP-q stage greater than or equal to 2) [14]. When a composite score was used to define success, the failure rates were less for both cohorts, 10% vs. 3.4%, respectively.

In our center, Letko et al. retrospectively reported on sacrospinous hysteropexy augmented with an acellular cadaveric dermis versus polypropylene mesh for apical compartment defects in post-hysterectomy patients. The dermal graft group demonstrated an objective recurrence (defined as greater than or equal to stage 2) at 1 year of 27.1% and the recurrence rate was 18.5% when polypropylene mesh was used [38].

Currently, the evidence supports that synthetic mesh is best for transabdominal procedures for pelvic reconstructive surgery, but the ideal choice of graft material for vaginal reconstructive surgery is less clear. The role of the site of graft implantation, size of graft, tension or tension-free placement, variable host responses, variability across graft procedures and anchoring methods, and the effect of graft processing are all aspects of biological adjuvant grafts, which may affect its clinical efficacy after implantation. The ideal graft material would be biocompatible with a minimal inflammatory response and offer long-term stabilization to allow for normal wound healing for the duration of tissue remodeling by the host. These are areas for future study to identify ideal biological grafts for use in reconstructive pelvic surgery. Novel research on the use of engineered biomaterials may herald a new area for biological graft in pelvic reconstructive surgery [39].

90 Synthetic Grafts in Pelvic Surgery

William Barone and Pamela Moalli

INTRODUCTION

Synthetic meshes, which were originally designed to repair abdominal hernias, have been used since the 1950s to repair pelvic organ prolapse (POP) via sacrocolpopexy and since the 1990s for repair of stress urinary incontinence (SUI) [1,2]. In both applications, the overarching goal of biomaterial use has been to improve the perceived low success rates of native tissue repairs and minimize morbidity associated with harvesting a patient's own tissue. The type of mesh used for urogynecological procedures directly mirrors products introduced into the market for hernia repair, though initially surgeons simply cut the mesh into the desired shape for sacrocolpopexy or suburethral slings. Over time, hernia meshes were designed to have lighter weight with wider pores based on clinical outcomes and the work of Klinge, with the urogynecology community quickly adopting the same materials. For example, Ethicon's Prolene Soft hernia mesh was remarketed for sacrocolpopexy as the prototype prolapse mesh Gynemesh PS (Figure 90.1).

By the time the tension-free vaginal tape (TVT) was introduced into the market in 1996, the use of lighter-weight materials had been widely adopted [3]. The TVT transformed the surgical treatment of SUI into a minimally invasive, highly effective procedure with minimal patient morbidity. Based on its tremendous success and perceived demand for a less invasive approach to prolapse repair, manufacturers introduced transvaginal mesh (TVM) procedures for POP using mesh kits in 2002. TVM kits were developed and aggressively marketed by numerous companies. Surgeons, seeking materials to improve the long-term durability of surgical repair for POP with a less invasive approach relative to sacrocolpopexy, were instructed in TVM procedures, resulting in the rapid escalation of TVM kit use after 2005. Indeed, mesh repair showed improved anatomical success of POP repairs but was also associated with increased reports of complications [4].

Reports of these complications in the Manufacturer and User Facility Device Experience database and in small studies prompted the FDA to issue a public health notification in 2008 warning that complications associated with the use of TVMs had been observed [5]. In 2011, after observing a fivefold increase in POP mesh medical device reports (1503 reports), the FDA revised its warning stating that complications associated with TVMs were not rare [6]. Moreover, long-term follow-up (7 years) from studies of meshes implanted for sacrocolpopexy, a procedure previously thought to be associated with a low rate of mesh-related complications, revealed that mesh complications after these repairs were more common than previously thought (10.5%) and increased with time [7]. As a result, decisions regarding POP surgical management have become complex, as the purported lack of durability of native tissue repairs is weighed against the potential benefits and complications of a mesh-augmented repair, and whether the repair is performed abdominally or vaginally. In this chapter, our current understanding of the importance of textile and mechanical properties of a synthetic mesh in driving the host response to synthetic grafts will be discussed as it relates to our current understanding of the pathogenesis of mesh-related complications. In addition, environmental considerations for application of synthetic grafts will be discussed in regards to the vagina.

MESH COMPLICATIONS

Synthetic mesh complications include mesh erosion, mesh exposure, infection, dyspareunia, and pain. Mesh exposure is identified as the visualization or palpation of mesh through the vaginal epithelium (Figure 90.2), while mesh erosion is defined as the perforation of mesh into adjacent structures (bladder, rectum, etc.). Typical management of mesh-related complications, such as exposure, includes repeat surgery to remove mesh [8–11], though symptoms may persist even after mesh is removed [6,11–13]. While prevous generations of SUI slings were found to have complication rates ranging from 0.3% to

23%, contemporary studies focusing on current lightweight, wide-pore meshes such as TVT report reduced complication rates, with an erosion rate of ~1% [14,15]. However, complication rates for synthetic mesh for prolapse repair remain a cause for concern, highlighted by recent FDA notifications citing complication rates up to 15% and 10.5% for transvaginal procedures and sacrocolpopexy, respectively [16–19]. It was not until just recently that studies began to explore the mechanisms by which these complications arise.

CHARACTERIZING MESH: TEXTILE AND STRUCTURAL PROPERTIES

In order to differentiate their products vendors often promote various textile and structural characteristics (Table 90.1). Textile characteristics refer to physical properties of the product and include filament material and size, weight, pore size, and porosity. Structural properties define the mechanical behavior of meshes and include ultimate load, ultimate elongation, stiffness, and energy absorbed. Prior to discussing synthetic mesh for prolapse repair, the definition or interpretation of these textile and structural properties will be provided.

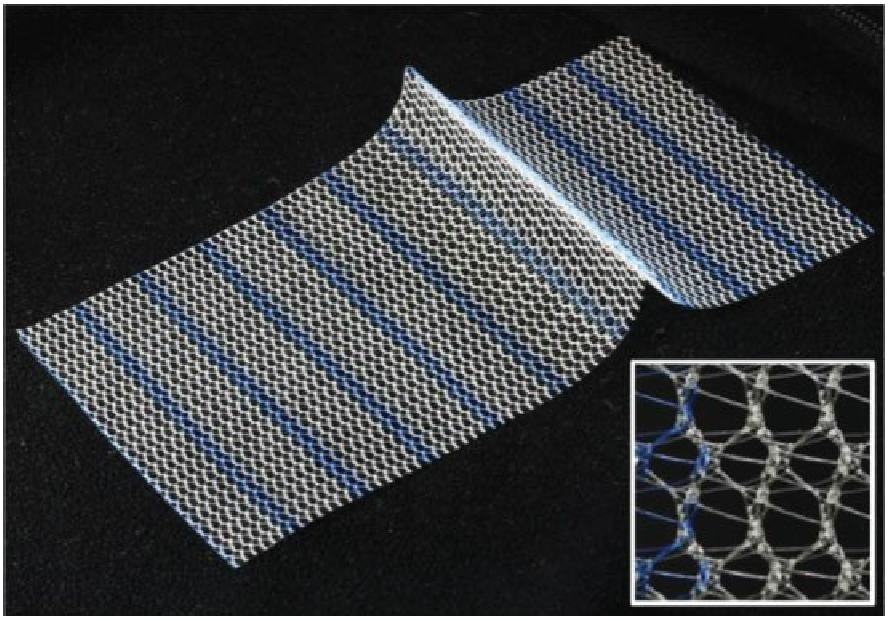

Figure 90.1 Use of synthetic mesh for prolapse repair has drastically increased in recent decades. Following the introduction of the tension-free vaginal tape, nearly all synthetic meshes for urogynecologic applications have been constructed from polypropylene utilizing a knitted, wide-pore, low-weight design. Gynemesh PS (shown here) is the representative of the current generation of products. While the pore geometry (insert) widely varies among contemporary devices, the material and construction techniques are nearly constant.

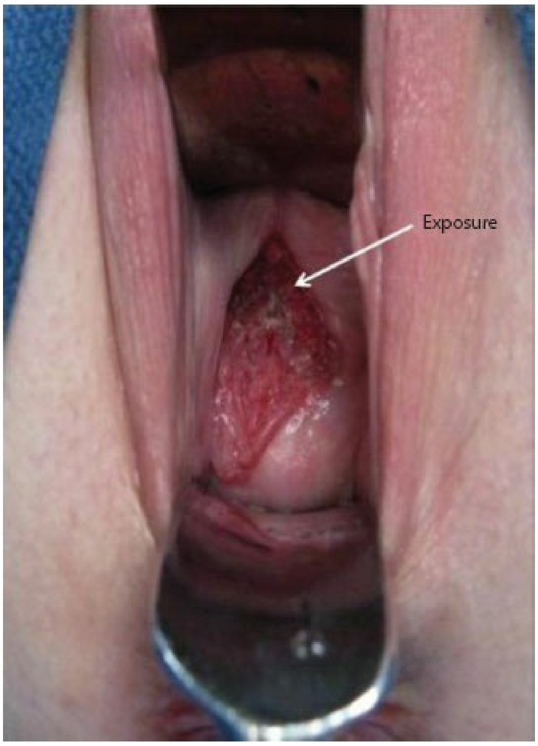

Figure 90.2 One of the most devastating complications following implantation of prolapse mesh is exposure. As shown here in the anterior vaginal wall, exposure occurs when mesh is visible in the vaginal lumen.

Textile Properties

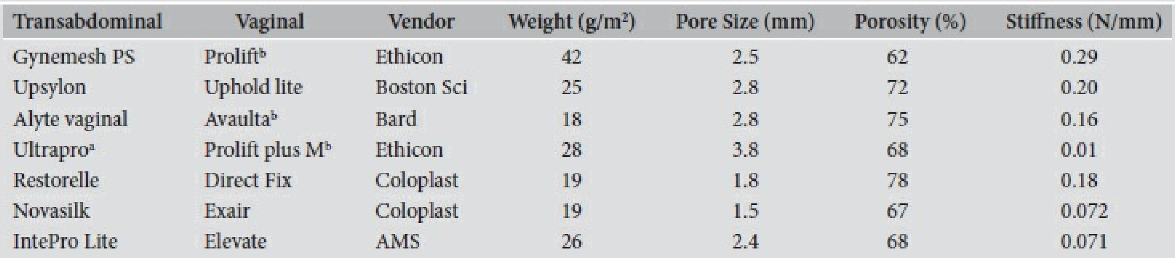
Material: The mesh material refers to the substances from which a mesh is constructed. Mesh materials can be classified as synthetic, biologic, or composite (a combination of synthetic and biological components). Biological materials include autografts and allografts, as well as xenografts. Though biological grafts have been utilized for urogynecological materials, failure rates ranging from 20% to 40% for such devices have significantly limited their use [20,21]. Synthetic meshes are typically comprised of polymeric materials, which have been extruded into thin filaments. Reproducible properties, low morbidity rates, and nondegradable features, in addition to improved anatomical outcomes, have led to the dominance of synthetic materials for urogynecological procedures.

Mesh weight: Mesh weight refers to the area density of the mesh, given in units of g/cm^2. Mesh weight is similar to a measure of density or specific gravity, though given the planar geometry of synthetic meshes, a planar measurement of density is used as opposed to a volumetric measure. More simply, mesh weight provides a measure of the amount of material present in a given area. Given the porous nature of many contemporary synthetic meshes, lower mesh weight is achieved by utilizing greater pore diameters, adding void space to lower the amount of mesh material per unit area.

Pore size: Pore size refers to the maxiumum diameter of the repeating unit pore found in synthetic mesh (Figure 90.1). It must be stressed that mesh vendors typically report the maximum diameter of the largest repeating unit pore, ignoring cross fibers in most cases. In addition, the typical pore geometry is polygonal and thus, a range of diameters may be reported depending on which transverse points are chosen to measure. Further, synthetic meshes often have small pores, which arise from the knit or woven constuction of filaments. However, these smaller pores are generally included in measures of pore size.

Porosity: The porosity of a mesh is defined as the ratio of mesh material to the amount of void space present in a given area, typically constrained to the boundaries of the mesh device. A porosity of 1 refers to a solid “mesh” (i.e. a solid piece of material with no openings), while a porosity of 0 refers to no mesh material present.

Table 90.1 Characteristics of Prolapse Meshes with Names when Applied Transabdominally vs. Vaginally



Transabdominal	Vaginal	Vendor	Weight (g/m^2)	Pore Size (mm)	Porosity (%)	Stiffness (N/mm)
Gynemesh PS	Prolift[b]	Ethicon	42	2.5	62	0.29
Upsylon	Uphold lite	Boston Sci	25	2.8	72	0.20
Alyte vaginal	Avaulta[b]	Bard	18	2.8	75	0.16
Ultrapro[a]	Prolift plus M[b]	Ethicon	28	3.8	68	0.01
Restorelle	Direct Fix	Coloplast	19	1.8	78	0.18
Novasilk	Exair	Coloplast	19	1.5	67	0.072
IntePro Lite	Elevate	AMS	26	2.4	68	0.071

[a] UltraPro (aka Artisyn), measurements made after absorbable component absorbed; stiffness determined in a uniaxial load to failure test.

[b] No longer available on the market.

Structural Properties

In mechanics, structural properties refer to nonnormalized measures of mechanical behavior and describe the load–elongation behavior of structures. Structural properties are dependent on the amount of material present, unlike mechanical properties, which are constant for a given material (Figure 90.3). For instance, a steel rod with a greater diameter will take more force to break relative to a smaller diameter steel rod of equal length. While the structural properties of these rods are different (load and elongation), the mechanical properties (stress and strain) are the same. Due to the porous nature of synthetic mesh, only strucutral properties should be reported. For uniaxial tensile testing, important strucutral properties include ultimate load at failure, ultimate elongation, and stiffness (Figure 90.3). These parameters are defined as follows.

> *Ultimate load*: The load, or force, at which mesh fails (breaks, tears, etc.), reported in Newtons or pounds of force. As a structural property, ultimate load is dependent on the dimensions of the mesh sample tested. Further, this property is dependent on the mechanical test used. The ultimate load is analogous to ultimate stress or tensile strength, where ultimate stress is defined as the ultimate load divided by the specimen's cross-sectional area.
>
> *Ultimate elongation*: The maximum elongation or distension a mesh undergoes until failure occurs, typically reported in units of mm. Similar to the ultimate load, ultimate elongation is dependent on both the dimensions of the tested sample and the mechanical testing protocol used to analyze the mesh. Ultimate elongation is similar to ultimate strain, where ultimate strain is defined as ultimate elongation divided by the initial length of the samples.
>
> *Stiffness*: The slope of the load–elongation curve reported in units of N/mm. Intuitively, stiffness is the resistance of a material to deformation or elongation (i.e., stiffer materials require more force to elongate or deform). Stiffness can be calculated at any point along the load–elongation curve, although often the maximum slope is reported. It is important to note that many mesh products exhibit nonlinear load–elongation behavior; thus, the slope of this line changes along the curve (Figure 90.3). As such, it is best practice to report the elongation at which the slope is calculated. While many different stiffness values can be reported for a mesh, it is ideal that a range of stiffness or the stiffness at the anticipated in-vivo elongation be provided. Whereas stiffness refers to the slope of the load–elongation curve, the slope of a stress–strain curve is referred to as the tangent modulus. Intuitively, the tangent modulus is similar to stiffness but relates the normalized measures of stress and strain rather than load and elongation.

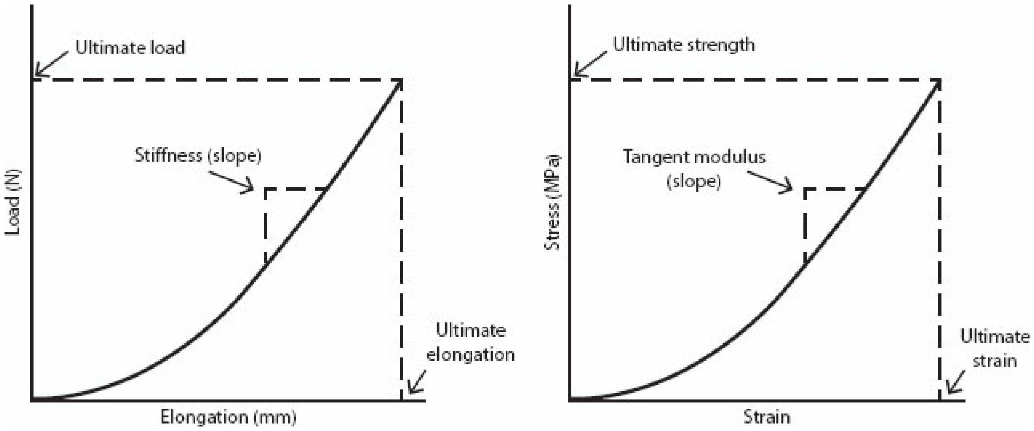


Figure 90.3 Materials testing can be classified as either (a) structural or (b) mechanical. Structural testing measures include ultimate load, ultimate elongation, and stiffness. These parameters are obtained directly from load–elongation curves and do not account for variations in sample dimensions. Mechanical testing properties include ultimate strength, ultimate strain, and tangent modulus. These measures are normalized by specimen dimensions and are used to characterize the mechanical behavior of continuous materials. While materials such as single filament of polypropylene can be characterized using mechanical properties, porous textiles such as synthetic mesh must be characterized by structural properties.

HOST RESPONSE TO SYNTHETIC GRAFTS IN THE VAGINA

To date, few have considered the role of the host tissue response as a significant or causative variable in prolapse mesh outcomes, despite the host response playing a key role in patient outcomes in virtually all other biomaterial applications. In addition, the lack of knowledge concerning the cause of mesh-related complications (erosion, exposure, infection, dyspareunia, and pain) highlights the necessity for examining the host response to grafts in the vagina. Such an understanding is imperative to improve patient outcomes following mesh implantation.

Recent studies have begun to enhance our understanding of the impact of mesh implantation on the morphology, composition, and biomechanical behavior of the vagina. In a rhesus macaque model, Liang et al. compared the host response of the heavier-weight, lower-porosity, high-stiffness prototype prolapse mesh, Gynemesh PS (Ethicon) to two lower-weight, higher-porosity, lower-stiffness meshes, UltraPro (aka Prolift plus M or Artisyn, Ethicon) and Restorelle (Coloplast), following implantation by sacrocolpopexy after a hysterectomy. After 3 months, Gynemesh PS, the stiffest mesh, dramatically altered the histological appearance and functional behavior of the vagina. While all meshes examined were found to disrupt the organization of the vaginal tissue, Gynemesh PS had the greatest negative impact Specifically, Gynemesh PS resulted in atrophy of the smooth muscle layer, with a 55% decrease in the thickness of the muscularis relative to sham-operated controls (Figure 90.4) [22]. Further, Gynemesh significantly increased the number of apoptotic cells in the subepithelium and adventitia layers, rising from 0.43% and 1.56% of cells to 7.22% and 32.49% compared to sham. Overall the impact of mesh was apparent, as a majority of apoptotic cells were located around the individual mesh fibers. Interestingly, changes in vaginal morphology and apoptosis were less pronounced following the lower-stiffness UltraPro and Restorelle implantation.

Gynemesh also negatively impacted the composition of the extracellular matrix, decreasing collagen and elastin content by 20% and 43%, respectively. While UltraPro and Restorelle were not detrimental to collagen content, UltraPro induced a decrease in elastin content by as much as 49%. Finally, sulfated glycosaminoglycan (GAG) content, a marker of tissue injury, was increased by 20% relative to sham samples, while collagenase activity increased by 135% following Gynemesh PS implantation [22]. Overall, these results clearly demonstrate that the vagina undergoes a maladaptive remodeling response following mesh implantation with heavier-weight, lower-porosity, and higher-stiffness meshes elicite the most detrimental changes. The degenerative response was the most consistent with a phenomenon referred to as stress shielding, a mechanosensitive phenomenon in biological tissues, which results in thinning of the tissues associated with a prosthesis. Alternatively, degradation could be the end result of chronic inflammation associated with a foreign body response. Indeed, the increase in sulfated GAG content following synthetic mesh implantation is consistent with acute soft tissue injury and tissue turnover [23]. Regardless of the mechanism, these findings are consistent with processes that result in degradation of the vagina, predisposing vaginal tissue to mesh exposure.

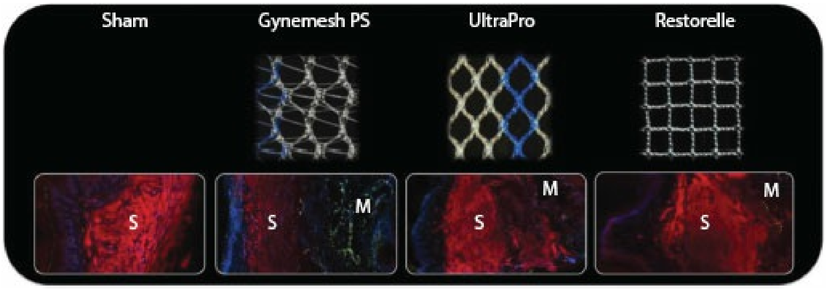

Figure 90.4 Immunofluorescent labeling (bottom) demonstrates the effect of various synthetic mesh products (top) on the vaginal tissue. Here, the red signal represents positive staining of alpha-smooth muscle actin, the green signal represents apoptotic cells, and the blue signal represents nuclei. Gynemesh, the stiffest of all meshes implanted by Liang et al., found to significantly reduce the thickness of the smooth muscle layer (layer designated by S). Further, increased apoptosis was observed surrounding the mesh (mesh designated by M). (From Liang R et al., *Br J Obstet Gynaecol*, 120(2), 233, 2013.)

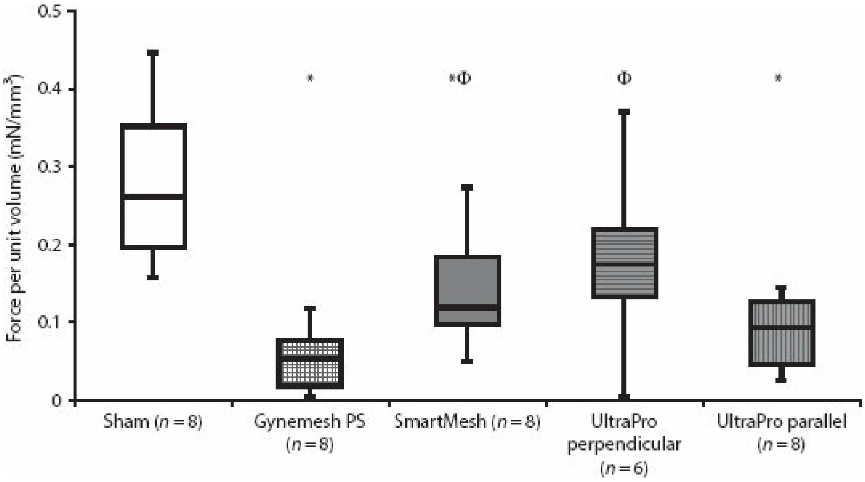

Figure 90.5 Using biomechanical assays to examine smooth muscle contractility, Feola et al. found that synthetic mesh implantation dramatically reduces the active properties of the vagina. Nearly all meshes groups tested reduced smooth muscle contractility relative to sham samples. Significant difference relative to sham is indicated by*. Φ indicates significant differences relative to Gynemesh PS. (From Feola A et al., *Br J Obstet Gynaecol*, 120(2), 224, 2013.)

Functionally, mesh implantation has been found to deteriorate both the active and passive mechanical properties of the underlying and associated vagina (Figure 90.5) [24]. In agreement with morphological findings, Feola et al. reported that Gynemesh eliminated nearly all smooth muscle contractility relative to sham [22,24]. UltraPro and Restorelle also interfered with smooth muscle contractility; however, such negative effects were much less than that observed with Gynemesh. Passive properties, typically representing the mechanical integrity of fibrillar extracellular matrix proteins (collagen and elastin), were evaluated via ball burst testing, as typical planar mechanical tests are invalid for composite mesh–tissue structures of these dimensions. Accounting for the combined stiffness of both mesh and tissue, Gynemesh significantly reduced the passive mechanical integrity of the tissue, decreasing the estimated stiffness of the vagina to almost 0 N/mm, nearly a 10-fold reduction [24]. This result suggests that Gynemesh implantation nearly abolishes the mechanical integrity of underlying and associated vagina in agreement with reports of decreased total collagen and elastin content following mesh implantation [22]. Overall, mesh implantation appears to be detrimental to the mechanical properties of the vagina, particularly with the heavier-weight, lower-porosity, and higher-stiffness devices. This is concerning as degradation of the vaginal smooth muscle, collagen, and elastin (key constituents of vaginal tissue) are already thought to be compromised in women with prolapse [25]. Ideally, mesh implantation would enhance or, at minimum, maintain the supportive capabilities of the vagina, though synthetic mesh, as currently utilized, has the potential to damage native vaginal tissue.

FACTORS INFLUENCING THE HOST RESPONSE TO SYNTHETIC MESH

To date, much of our understanding of urogynecologic mesh products has been derived from the hernia mesh literature, which is not surprising given that the design of current prolapse meshes were originally developed for hernia repair [20]. Thus, the majority of current data in the literature, as well as vendor marketing pamphlets, use legacy methods to demonstrate biocompatibility of prolapse mesh products, by implanting synthetic mesh in the abdominal wall. While there is great utility in such studies, namely, verifying a lack of outright host rejection, the abdominal wall and pelvic floor are quite dissimilar in regard to the biologic environment and the mechanical demands placed on a mesh implant. Because the current generation of synthetic mesh is based on the technology developed for abdominal hernia repair, it is deemed compatible for prolapse repair based on premarket characterization, yet the transfer of this technology from abdominal use to reconstruction of the pelvic organ support leaves much room for optimization. As such, current urogynecologic mesh is largely a prototype solution rather than an optimal one, as evident by the complications associated with mesh implantation. Despite the distinct differences between the abdominal wall and the vagina, many of the design changes responsible for recent reductions in prolapse mesh complications have directly resulted from findings in the abdominal wall. Perhaps the most important concepts shown to impact the host response to synthetic meshes in urogynecologic applications are material type, filament type, and pore size.

Material Type

Since the introduction of the first synthetic nylon sling in the 1950s, urogynecological grafts have been constructed from a variety of materials, resulting in a wide range of outcomes [2]. These materials include polyethylene terephthalate (Mersilene), polypropylene (Marlex), polytetrafluoroethylene (Teflon), and expanded polytetrafluoroethylene (Gore-Tex) [20]. Ex vivo and in vitro studies have shown that these materials are nontoxic and have a high tensile strength, demonstrating their ability to be used in reconstructive pelvic surgeries. Though the material chosen for mesh construction likely plays a role in dictating the host response, additional structural features of a mesh design have confounded the impact of many graft materials.

For instance, Teflon and Gore-Tex experienced disastrous results as prolapse meshes. The distinctive trait for these materials was poor integration with host tissues, and while the ease of removal was initially touted as a benefit, Gore-Tex was plagued with numerous complications of alarming severity [21]. Gore-Tex slings were reported to have a removal rate of at least 35%, with a significant number of sinus tract formations (10%), in addition to infections and reports of vaginal exposures [26]. Similarly, in a large prospective multicenter trial, Gore-Tex was found to be a significant risk factor for mesh exposure into the vagina following sacrocolpopexy [19,27]. Still, the failure of Gore-Tex is likely due to the small pore size (<10 μm) used in this product rather than the polymer itself. Discussion of pore size is included later in this chapter.

Another material that has been linked to poor clinical outcomes is polyethylene terephthalate, a polyester polymer. This polymer was used to construct a graft using a woven, multifilament construction technique and manufactured as Mersilene. Although Mersilene was associated with increased rates of exposure and infection relative to other meshes, surgeons continued to use this material until recently. Interestingly, Mersilene slings also had numerous complications including infection, exposure, erosion, and fistula formation, though manufacturers and surgeons failed to appreciate the problems associated with the use of polyester attempting to overcome the problem by coating it with silicone (marketed as the Protegen sling) [28]. As more data was published on the problems associated with this material, it was gradually been pushed out of the market. Our current understanding of host response to mesh suggests that the adverse host response to Mersilene is likely due to interstices as small as 1 μm that arise from the woven textile construction, rather than the use of polyethylene terephthalate per se. It is thought that such small spaces harbor bacteria because immune cells cannot easily pass into these areas, leading to chronic infection, inflammation, mesh exposure, erosion, and fistula formation.

In the recent decades, polypropylene has become the primary material for synthetic mesh used in incontinence and prolapse surgeries. Unlike the woven construction used for polyethylene terephthalate, polypropylene mesh is most often knitted. Initial studies found polypropylene to elicit a strong inflammatory response including fibrotic tissue formation and multinucleated giant cells (i.e., foreign body response) around mesh filaments [29]. In addition, polypropylene mesh was found to encourage tissue ingrowth, providing a scaffold for tissue penetration. Clinically, polypropylene grafts were found to have relatively low complication rates relative to other material types; however, it was not until the overwhelming success of the TVT that polypropylene became the dominant material for mesh construction [3]. Still, polypropylene's success may be attributed to structural features such as knit construction and large pore sizes, rather than specific properties of polypropylene. However, the publication of large case series and other clinical trials (eCARE) highlights the significant rate of complications associated with both the transvaginal and transabdominal insertion of polypropylene grafts [7]. Given that current mesh products are almost exclusively comprised of polypropylene, the variable success of synthetic grafts suggests that factors other than material selection are responsible dictating the host response.

Filament Type

Often, materials selected for mesh construction are extremely stiff and rigid making them unsuitable for implantation on soft, low-stiffness tissues such as the vagina. For instance, the tangent modulus for polypropylene is 1.5–2 GPa, which is 1000 times greater than that of most soft tissues in the body. In order to reduce the overall product stiffness and provide flexibility to synthetic grafts, materials such as polypropylene are extruded into a thin diameter thread, known as a filament. The structure of the filament has also been linked to the host response of a mesh, specifically its impact on infection. Filaments are classified as either mono- or multifilament, where multifilament fibers are braided or interwoven. Studies have found significantly higher bacterial presence in multifilament meshes, which is believed to result from an increased surface area of ~1.57 for multi-filament fibers, relative to monofilament fibers [30]. The increased amount of surface area is thought to provide more space for bacteria adhesion and, in turn, greater bacterial proliferation [30]. In addition, multifilament structures have inherent spaces between the filaments, which are typically less than 10 μm in diameter. Such diameters allow for the passage of bacteria, yet macrophages are unable to infiltrate these areas, providing a harbor for bacterial proliferation [20].

Fiber Pattern

Individual fibers, whether monofilament or multifilament, provide the basic unit of construction for mesh, yet the manner in which filaments are arranged greatly impacts the behavior of synthetic materials. The two common methods for constructing synthetic grafts are knitting and weaving. Weaving utilizes a simple interlacing technique, with two perpendicular filament orientations. Styles of weaving include plain, twill, and satin. Woven meshes provide superior mechanical strength and shape memory; however, these devices fray when cut and conform poorly to boundaries [31]. In addition to high infection rates (Mersilene), woven mesh is not suitable for the complex geometries of the vagina and its supportive tissues. Unlike woven mesh, knit mesh is constructed by looping of a single fiber. Types of knit structures include warp-lock, interlock, and circular knit, though the latter is uncommon for urogynecologic meshes. Knitted meshes are flexible devices and can easily be manipulated or conformed to the adjacent anatomical structures. Notably, woven mesh has a significantly greater number of mesh-related complications relative to knitted mesh. The impact of construction method is easily illustrated by comparing Marlex, a woven, heavyweight polypropylene mesh, and Prolene, a knitted, heavyweight polypropylene mesh. When first used to treat abdominal hernias, Marlex exposure rates were nearly 44%, while Prolene exposure rates were minimal (<5%), despite similar mesh weights (Prolene ~85 g/m^2 and Marlex ~95, ~85 g/m^2) and identical material selection [31].

In addition to filament type, the fiber pattern, or pore geometry, greatly impacts the mechanical behavior of mesh, highlighted by the wide range of mechanical behaviors (characterized by structural properties in mechanics literature) for type I meshes [32–34]. The importance of mechanical deformation of pores is highlighted by the significance of pore dimensions, which is discussed in the following section. While woven mesh is generally stiff due to high filament alignment and little filament translation with loading, knitting allows for filament rotation and variable behavior along differing axes. Alterations in knit patterns allow for type I polypropylene devices to have a wide range of mechanical behaviors, including manipulation of stiffness and anisotropy. As such, the geometric differences greatly impact the load–elongation behavior of contemporary mesh products [32].

Pore Size

Another characteristic of mesh believed to impact the host response is porosity. Porosity is defined as a ratio of void or empty space in a mesh to the amount of mesh material. A porosity of 0 signifies a solid piece of material (no pores), while a porosity of 1 indicates that no material is present. It is generally accepted that high-porosity meshes reduce complication rates, a belief that is reflected in the movement toward lower-weight meshes. Porosity provides a simple, two-dimensional measure of the amount of mesh in a given area; however, this value is subject to change with mechanical loading, as will be discussed in the succeeding text.

Though recent products have sought to increase mesh porosity, studies suggest that pore size, not porosity, is the most important factor for improving the host response to mesh. In the hernia literature, the impact of pore size has been well characterized, specifically for polypropylene mesh. Larger pores have been shown to improve the mechanical integrity of the resulting mesh–tissue complex, increasing both strength and collagen deposition relative to complexes following implantation of grafts with smaller pore dimensions. Smaller pores restrict and reduce tissue ingrowth relative to larger pore structures, yielding mesh–tissue constructs with limited vascular growth and less mature collagen [35,36]. In addition, the foreign body response is greatly reduced with increasing pore size [37–39]. Importantly, pores with dimensions less than 10 μm allow for the passage of bacteria yet are too small for macrophages and neutrophils to pass through, providing regions for bacterial proliferation and persistent infection [40].

While bacterial proliferation is dependent on the dimensions of openings in a mesh, each individual mesh fiber elicits a foreign body response surrounded by cells and fibrous tissue (granuloma) regardless of size (Figure 90.6) [41–43]. Decreasing pore size reduces the distance between these perifiber inflammatory reactions, and once sufficiently close, adjacent foreign body reactions can overlap with neighboring fibrous granulations, leading to a phenomenon referred to as “bridging fibrosis.” Bridging fibrosis results in the formation of a continuous scar plate or encapsulation, sealing the graft from the body and preventing tissue ingrowth [37,44]. Further, Klinge et al. have found that the foreign body response to fibers is dependent on the hydrophobicity of the polymer used to extrude the filaments [45]. As such, differing materials have dissimilar pore dimensions at which bridging fibrosis will occur. Specifically, it has been shown that effective tissue ingrowth for polypropylene mesh occurs in mesh pores with a diameter of 1000 μm or greater [46], where effective tissue ingrowth is defined by the quality of the tissue, which forms around mesh fibers, with no bridging fibrosis. For polypropylene grafts, pore sizes less than 1000 μm elicit greatly enhanced inflammatory and fibrotic responses [47,48]. It should be noted that studies regarding pore size were performed in an abdominal wall model. While these findings have proven useful in guiding synthetic graft design for abdominal wall and vaginal meshes, extrapolation of such data requires the assumption that the environmental conditions between these sites are similar. The appropriateness of this assumption is questionable and will be highlighted later in this section. Still, there is likely a critical pore diameter for urogynecologic meshes that minimizes scar plate formation, though it may be distinct from that found in abdominal wall studies even for the same material.

Given the importance of pore size, it is not surprising that this design feature is often considered the primary method for mesh characterization, originally outlined by Amid et al. in the late 1990s [40]. The Amid classification divides meshes into four classes [10]:

Type I: Macroporous, with pore sizes greater than 75 μm in diameter
Type II: Microporous, with pore sizes less than 75 μm
Type III: Predominately macroporous with microporous components (e.g., Mersilene and polytetrafluoroethylene)
Type IV: Submicroscopic pore size (<1 μm)

In light of the previous discussion on pore diameter, it is not surprising that type II, type III, and type IV meshes have been met with poor clinical outcomes citing little tissue formation and no adhesion to surrounding tissues, in addition to high infection rates [10,21,26]. While the Amid classification was useful for past mesh devices, nearly all contemporary products are characterized as type I rendering this characterization ineffective for distinguishing products. With nearly all contemporary meshes classified as type I, the Amid classification must be supplemented to guide mesh selection and graft design.

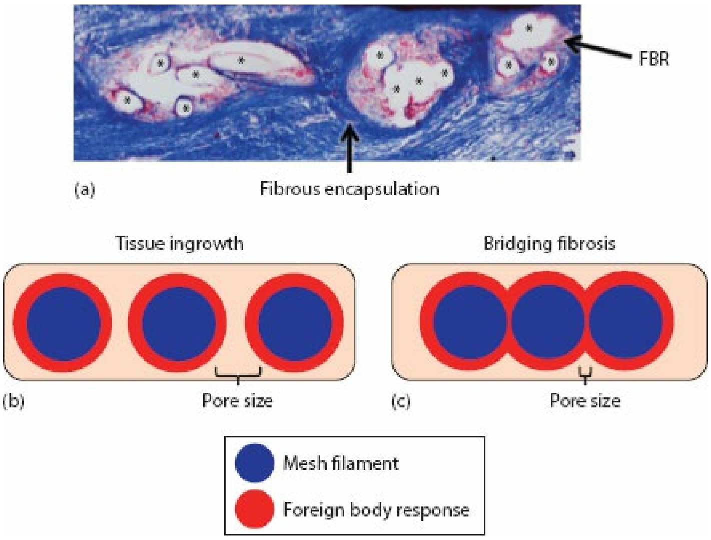

Figure 90.6 (a) Masson trichrome staining of vaginal tissue with mesh embedded demonstrates the fibrous encapsulation associated with individual mesh filaments. * represents polypropylene mesh filaments and FBR represents foreign body reaction to mesh fibers. (b) While each filament is encased in fibrotic tissue, large pore sizes allow for tissue to grow in between separate foreign body responses. (c) However, if filaments become too close to one another, the foreign from individual filaments joins creating bridging fibrosis.

Mesh Burden

Finally, it should be mentioned that the area density of the mesh, referred to as mesh weight, is not a significant factor in dictating the host response. Often, heavyweight meshes (>1 g/cm^2) are constructed to have small pore sizes, thereby increasing their mesh weight, while lower-weight meshes (<1 g/cm^2) are often constructed with a large range of pore sizes. Thus, the negative effects of heavyweight meshes are likely due to small pore dimensions rather than the specific gravity of the device. Weyhe et al. demonstrated the concept that pore size, rather than mesh weight, is more predictive of the host response as a lightweight, microporous mesh was found to provoke a more intense foreign body response with poor tissue integration compared to heavyweight meshes with larger pore sizes [47]. Given these results, it appears that the relative density or spatial distribution of material has a greater impact on the host response than the total amount of material implanted. The spatial distribution, or mesh per unit volume, of a device is defined by the term “mesh burden.” Mesh burden is directly derived from the concept that mesh fibers are encapsulated in fibrous granulations, which may form bridging fibrosis if mesh fibers are sufficiently close. Increases in mesh burden imply that mesh filaments have been brought closer together in three-dimensional space, increasing the likelihood of encapsulation and scar plate formation. Data regarding this characteristic is limited, though understanding the distribution of mesh material in 3 dimensions may prove useful in guiding future mesh designs.

CONSIDERATIONS FOR VAGINAL MESH IMPLANTS

Much of the advancement in prolapse mesh can be attributed to knowledge gained from hernia mesh studies. Yet this criterion is merely a starting point, as optimization of grafts for the vagina requires a greater understanding of the environment in which these devices are placed and the function they are being asked to perform. Relative to the abdominal wall, the environment of the vagina is much more complicated from a biological and mechanical perspective, requiring consideration of the role of the implant in this anatomic location. As such, the requirements for mesh repair are not translatable from the abdominal wall to the vagina.

Biological Environment

Importantly, synthetic meshes are directly fixed to the vagina, an organ that is heavily colonized with bacteria, creating a clean-contaminated surgical field for transvaginal procedures. Generally, the vagina and its supportive tissues are metabolically active as their tissue compositions dramatically change with normal aging and during hormone driven events such as pregnancy, menstrual cycle, and menopause [49,50]. The activity of these tissues is an important consideration for implantable devices.

Several studies have found mesh implantation to elicit a markedly different host response in the vagina compared to the abdominal wall. Using a rabbit model, Pierce et al. found that implanted polypropylene mesh elicited no mesh exposures abdominally, yet exposure rates for the same mesh were 27% at the vaginal site [51]. In addition, the authors stated that the graft length was often decreased upon explanation from the vagina—a phenomenon commonly referred to as “shrinkage.” Additionally, histological analysis revealed increased inflammation and fibroblast proliferation scores for vaginal implants relative to those in the abdominal site, further emphasizing the disparate biologic environments. Pierce et al. also examined the outcomes of cross-linked collagen grafts in the abdominal wall versus the vagina of rabbits. Cross-linked grafts were noticeably degraded in 37% of abdominal implants, while 70% of grafts implanted on the vagina were degraded. Degradation at the vaginal site was so dramatic that nearly half of all grafts were found to be missing upon sample harvesting [51]. Similarly, using a sheep model, Manodoro et al. found no exposures in the abdominal wall, while 30% of vaginal implants resulted in exposures [52]. Interestingly, Manodoro et al. reported increased folding and nearly twice the amount of mesh “contraction” or “shrinkage” in vaginally placed mesh samples. It is important to note that in each of the mentioned studies, mesh was simply sutured to the vagina and not tensioned as is done for prolapse and incontinence surgeries utilizing mesh. As such, these studies ignore the impact of mechanics on mesh outcomes and highlight that the biological response to a material is vastly different in the vagina relative to the abdominal wall.

Overall, the vagina is a harsher biologic environment for mesh implantation compared to the abdomen. Still, questions regarding vaginal graft implantation remain. For example, no studies have considered the impact of route of delivery in TVM placement. Surgical entry for transvaginal procedures may potentially contaminate the mesh via vaginal microflora, resulting in subclinical infection, and intensifying the host response. The failure to acknowledge the biologic environment in the development of urogynecologic meshes has likely resulted in high complication rates of polypropylene mesh; however, the mechanical demands place on synthetic meshes used for prolapse repair is another significant factor that must be considered.

Mechanical Environment

Mechanical Demands of Mesh

Pelvic organ support is a complex mechanical system in which support to the vagina is provided by the levator ani muscles and connective tissue attachments to the pelvic sidewall. The vagina, in turn, orchestrates support to the pelvic organs by maintaining static equilibrium and resisting transient changes in abdominal pressure. Given the interactions between these components, imbalance or degradation of any tissue may lead to dysfunction or conditions such as prolapse. Current synthetic graft repair attempts to restore support, mimicking the mechanical role of connective tissue, as current meshes have no active properties. While it may seem inconceivable to truly recreate native pelvic organ support, understanding nonpathological support and the mechanical behavior of both grafts and healthy native tissues would greatly improve outcomes of reconstructive surgery in the soft tissues of the pelvis.

During prolapse repair, synthetic meshes are typically attached to the vagina and then secured to the sacrum (sacrocolpopexy) or to structures along the pelvic sidewall (transvaginal procedure). Under these conditions, mesh devices assume the role of suspension cables, maintaining the position of the vagina while resisting the downward forces of abdominal pressure and the weight of other pelvic floor viscera. This function results in a predominately uniaxial tensile loading condition, which is quite dissimilar from in vivo loading for hernia repair. During a hernia repair, the mesh is often fixed along its perimeter in the abdominal wall, over the defect. This scenario, analogous to the wall of a pressure vessel, places hernia mesh in tension along all axes simultaneously, much like the surface of a balloon upon inflation. The omniaxial loading in the abdomen helps maintain geometric features of mesh, such as geometry and pore size. While stable graft geometries are expected in the abdominal wall, tensile loading conditions of the vagina provides an increased likelihood of mesh deformation highlighted by reports of significant mesh contraction (Figure 90.7) [10,52]. Thus, for urogynecological meshes to function as intended, it is necessary to understand how mesh products deform under loading conditions similar to those in the pelvic floor.

Many studies have evaluated the mechanical behavior of mesh in response to uniaxial loading, often reporting structural properties such as ultimate elongation, ultimate load, and stiffness [32–34]. While these studies are useful for comparing mesh behavior, often the focus is placed on the failure criteria for grafts, with loads typically exceeding 30 N. Yet, structural failure of synthetic mesh is extremely rare clinically. Rather, focus should be placed on mesh behavior at loads that are experienced in vivo [53,54]. Perhaps the greatest impact of mechanical loads on mesh behavior is on the mesh porosity and pore size, properties that dictate the host response. Indeed, uniaxial loads dramatically decrease the maximum pore size and porosity of nearly all current synthetic meshes [32,34,42].

Uniaxial loading of composite, porous materials results in elongation of the graft in the direction of applied force and causes individual filaments to rotate and reorganize to resist the applied force. The degree of reorganization is largely governed by the geometry of a mesh and contributes to the nonlinear behavior observed for mesh products. Meshes whose filaments are highly aligned with the loading axis exhibit little nonlinear load–elongation behavior, while the same mesh tested with filaments offset 45° from the loading axis have elongated toe regions and significant pore deformation before resisting applied forces. For most materials, elongation along one axis results in narrowing of the axis perpendicular to the applied force. This phenomenon is known as Poisson’s effect for continuous materials, though a similar occurrence is observed for porous materials. Typically for porous structures, this narrowing results from a reduction in pore size as pores collapse during filament reorganization. Uniaxial tension dramatically reduces pore size for most mesh products, as pores in a tensioned mesh are often less than 1 mm in diameter even at low levels of force (Figure 90.8) [55]. Given the importance of pore size on the host response, one would anticipate a diminished potential for tissue ingrowth and a high likelihood of bridging fibrosis for meshes implanted under tension. This mechanical deformation provides a potential mechanism for the clinical observation of mesh “shrinkage” or “contraction” after implantation, specifically for TVM products [10,52]. Though mesh shrinkage may also involve contraction of fibrotic tissue or other biological mechanisms, tensile forces have the potential to cause large alterations in mesh dimensions and induce fibrosis. Factors including tissue ingrowth and the boundaries imposed by the vagina may help to limit pore size reduction in vivo to some extent. Nonetheless, mesh deformation must be considered when “tensioning” or placing a mesh surgically, as well as during in vivo loading conditions both before and after host tissue integration occurs, as this dictates the initial host response following implantation.

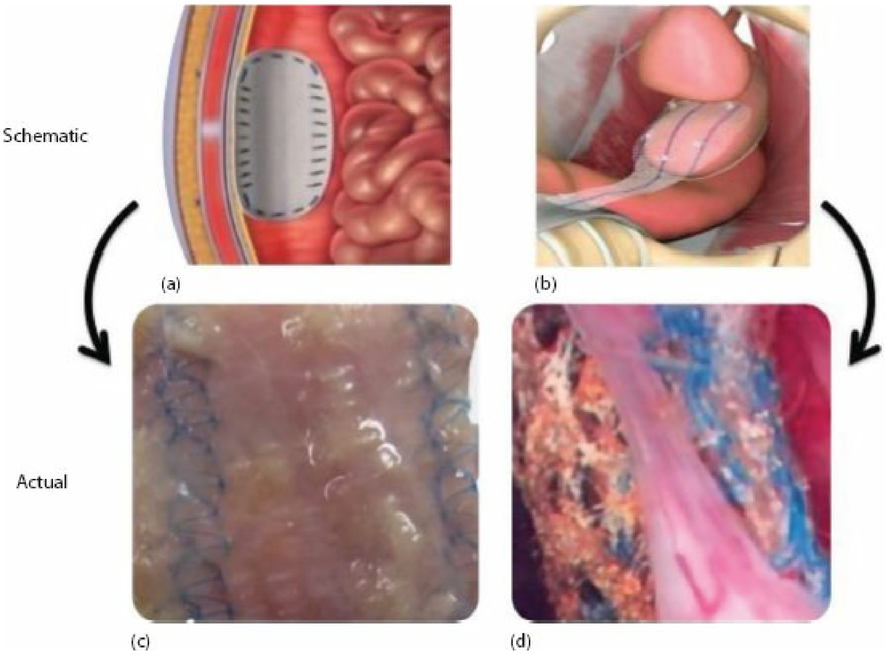

Figure 90.7 The mechanical function of synthetic mesh is quite distinct between (a) hernia mesh repair and (b) prolapse repair. For hernia repair, mesh is placed in the abdominal wall and loaded along all axes simultaneously to resist expansion of the abdominal cavity resulting from internal pressure. Vaginally, mesh arms are placed in tension, acting as support cables to hold the vagina in place. This disparity in mechanical loading leads to notably different deformation of mesh products in vivo. Explanted hernia mesh is typically flat and pore geometries appear similar to the preimplanted state (c), while prolapse mesh is often bunched with dramatic alterations in pore geometry and decreased pore size (d).

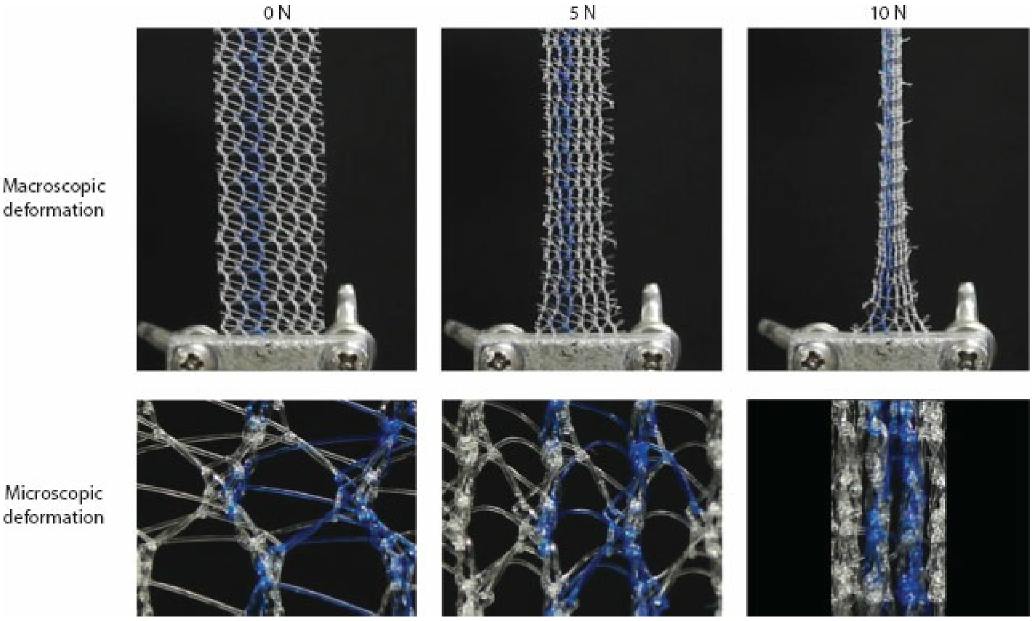

Figure 90.8 Uniaxial tensile loading dramatically alters the pore size and pore geometries of nearly all mesh products. As shown here, Gynemesh, representative of current wide-pore, low-weight polypropylene synthetic meshes, experiences significant deformation at forces well below its ultimate load. Macroscopically (top), the mesh undergoes lateral contraction, similar to that shown in Figure 90.7. Microscopically (bottom), pore dimensions are drastically reduced bringing filaments closer together. (From Shepherd JP, Feola AJ, Abramowitch SD, Moalli PA. Uniaxial biomechanical properties of seven different vaginally implanted meshes for pelvic organ prolapse. *Int Urogynecol J Pelvic Floor Dysfunct* 2012;23(5):613–620.)

Boundary Conditions

Additional boundary conditions, such as the tissue substrate or the method of mesh anchoring, also have significant effects on the mesh deformation under application of force. To date, nearly all ex vivo structural testing of prolapse mesh have utilized clamps to applied forces to mesh, forcing mesh deformations to occur in plane only. Though the assumption of planar deformation is necessary for measurement of structural properties such as stiffness, clamped restraints at the boundary are not representative of mesh fixation in vivo. Recently, discrete suture fixation of mesh products was found to significantly increase the amount of folding and wrinkling that occurs upon application of tensile forces. Inclusion of suture attachments resulted in a 15-fold increase in surface curvature for tested mesh devices at just 10 N of force, relative to traditional mechanical testing boundary conditions (Figure 90.9) [56]. Increased folding of the mesh provides an additional mechanism by which filaments can be brought closer (increasing mesh burden), increasing the likelihood of bridging fibrosis. Given these results, it is clear that the number and placement of sutures used to fix mesh in vivo greatly impacts the manner in which forces are transferred throughout a graft, creating regions that are at increased risk of complication.

When considering the interface between two materials, such as the vagina and implanted mesh, the properties of the each material must be considered. Mechanically, material interfaces are subject to stress concentrations, with the magnitude of stress proportional to the difference in stiffness between the materials [57,58]. This principle is quite noticeable in many biological structures. Examination of tendons, tissues that transfer force from the compliant muscle to the stiff bone, reveals a variable stiffness along their length. Tendons have increased stiffness at the boney insertions, relative to the muscular attachments, which are quite compliant (low stiffness). Such a distribution of stiffness is created by variable tissue composition and functions to minimize stress concentrations at the respective boundaries [58,59]. The importance of this interface has also been demonstrated in other medical implants, as increased implant stiffness was found to induce a maladaptive remodeling response through a phenomenon known as “stress shielding” [60–62]. This common mechanical phenomenon occurs in composite materials (i.e., device–tissue complex) when a stiffer material is the primary load-bearing structure, “shielding” surrounding tissues from in vivo forces. When prothesis bear are the primary load bearing structure, biological tissues, which respond to mechanical stimuli, may atrophy. Stress shielding was detrimental to soft tissues following hip arthroplasty, resulting in increased periprosthetic breakdown of both collagen and elastin upon implantation of implants of increasing stiffness [63–66].

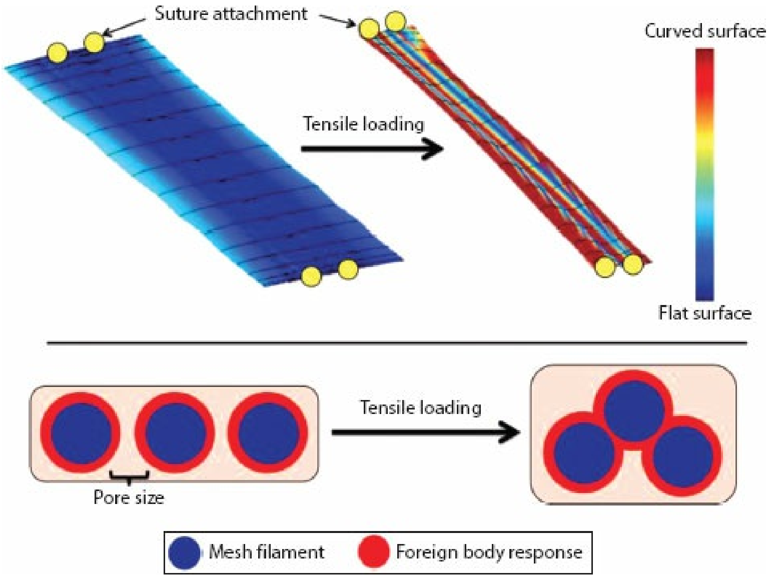

Figure 90.9 The boundary conditions applied during mechanical loading greatly influence the deformation of mesh products. When examining the surface curvature of synthetic mesh (top), discrete placement of sutures (yellow circles) results in significant curvature or bunching of mesh upon application of tensile loads. Bunching of mesh brings mesh fibers closer together, including fibers that have deformed out of plane (bottom). Similar to the planar deformations shown in Figure 90.6, bunching of mesh allows for individual

foreign body responses to join, creating bridging fibrosis. (From Barone WR et al., *J Biomech*, 2015;48(9):1566–1574.)

Vaginal tissue, like most biological tissues, has been shown to respond to mechanical stimuli. When a prothesis, such as mesh, alters mechanical stimuli, homeostatic processes may be impacted. Previously it has been found that matrix metalloproteinase (MMP) activity of fibroblasts from full-thickness vaginal biopsies is significantly altered by application of mechanical forces. Specifically, MMP activity increases of 76% and 188% were observed in fibroblasts after undergoing repetitive mechanical stretching to 8% and 16%, respectively [62]. Interestingly, fibroblasts cultured with 17β-estradiol and progesterone returned collagenase activity to control levels despite the presence of mechanical stimulation. Clearly, mechanical stimulation is important for vaginal tissues, though the effects of such forces may have increased importance in postmenopausal women, the primary demographic for prolapse mesh implantation.

SUMMARY

Support to the vagina and, hence, the pelvic organs is a complex, poorly understood system, with numerous components vital for maintaining the anatomy and its proper function. It is understandably difficult to mimic the natural support system of the vagina and urethra as connective tissues and muscles provide a wide base of support with broad attachments. However, as a community, it is important to recognize deficiencies in our understanding of this complex highly orchestrated system. Advancements in hernia mesh technology has provided significant advances in the design of synthetic grafts for prolapse repair, yet the complications arising from such materials provide a strong reminder that synthetic meshes were not designed with the vaginal support system in mind. The success of future generations of synthetic grafts is dependent on creating devices specifically designed for the unique biological and mechanical environment of the vagina. These considerations, alongside advanced knowledge of native support, are key to designing more effective grafts for prolapse repair.

91 Complications of Synthetic Mesh Used to Repair Pelvic Organ Prolapse

Mickey Karram and John B. Gebhart

INTRODUCTION

Pelvic reconstructive surgery for genital prolapse usually results in improved quality of life. However, numerous complications from mesh-augmented prolapse repairs have been reported in the literature. This chapter is aimed at discussing these various complications and how best to manage them.

Pelvic organ prolapse (POP) and stress urinary incontinence are common and often comorbid disorders in women that can greatly impact quality of life. Population-based studies report an 11%–19% lifetime risk of women undergoing surgery for one of these conditions with a recurrence of symptoms common in both groups. Six to twenty-nine percent of women who undergo a pelvic floor repair have additional surgery for recurrent prolapse, stress incontinence, or related complications [1,2].

The success initially observed with the use of surgical mesh in general surgery combined with the perceived high failure rates for traditional native tissue suture repairs for prolapse initially led gynecologic surgeons to implement surgical approaches that utilize prosthetic materials. Medical device manufacturers have estimated that in 2006 and 2007, approximately 30% of POP repair procedures utilized adjuvant materials. However, recently, there have been concerns raised around the safety of transvaginal mesh due to a variety of outcomes related to mesh erosion, pain, vaginal constriction, and other complications. While similar types of complications have occurred with native tissue suture repairs, the perception is that graft-related complications have been more severe and difficult to manage.

Historically, loss of pelvic floor support resulting in POP has been compared to a hernia. In 1973, Dr. Stanley Birnbaum [3] described a novel technique for treatment of vaginal prolapse in which fixation of the vaginal vault with a Teflon mesh bridge anchored the vagina to the hollow of the sacrum. This was the initial description of a sacrocolpopexy using a synthetic material. A follow-up article 6 years later noted 20 of 21 patients treated with this technique maintained good support and vaginal function.

Over the last 15 years, there has been a significant refinement and improvement in surgical mesh materials. Early on, there were problems with some surgical meshes, which increased erosion and infection rates. In most cases, these meshes were microporous multifilament materials, which require complete explantation for symptom improvement [4]. Fortunately, the majority of these products have been taken off the market. Currently utilized meshes are type 1 mesh, meaning they are macroporous monofilament polypropylene with a pore size greater than 75 μm. They can further be divided by weight (heavy-, mid-, or lightweight) [5,6].

Synthetic mesh utilized for prolapse repairs can be placed abdominally (abdominal sacral colpopexy) or transvaginally. Transvaginal mesh can be self-fashioned, cut to order, or packaged in a kit. The first synthetic mesh kit for prolapse was FDA approved in 2001 and the first trocar-based kit was approved in 2004 [7].

FDA WARNINGS

On October 20, 2008, the FDA issued a public health notification regarding the use of mesh in gynecologic surgery titled “Serious Complications Associated with Transvaginal Placement of Surgical Mesh in Repair of Pelvic Organ Prolapse and SUI.” This was done in response to over 1000 reports of these complications involving nine different surgical mesh companies. These reports were reported through the manufacturer and user facility device experience (MAUDE) database. The most common complications reported were mesh erosion, infection, pain, and urinary symptoms. Serious injury to the bowel, bladder, and blood vessels did also occur albeit rare. Several general recommendations were made by the FDA at that time based on these reports. These included the following:

1. Physicians seek specialized training for procedures involving the use of mesh and should be alert and recognize complications early.
2. Physicians should inform patients of the permanent nature of surgical mesh and that some complications associated with implanted vaginal mesh may require subsequent surgery that may or may not correct the complication.
3. The physicians were advised to inform patients about the potential for serious complications and the effect on quality of life including pain during intercourse and scarring and narrowing of the vagina after prolapse repairs.

The FDA continued to investigate mesh complications and, based on an updated analysis of reported adverse events and complications described in the scientific literature, released a scientific communication on July 13, 2011: “Update on Serious Complications Associated with Transvaginal Placement of Synthetic Mesh for Pelvic Organ Prolapse and SUI.” They noted that the use of surgical mesh for transvaginal repair of prolapse is an area of continuing serious concern and concluded that “serious complications associated with surgical mesh for transvaginal repair of prolapse are not rare.” They did not find clear evidence to support increased efficacy of mesh repairs when compared to traditional native tissue repairs, and patients undergoing mesh placement may be exposed to greater risk. It was also noted that mesh placed abdominally for the treatment of POP via sacrocolpopexy had a lower rate of mesh complications when compared to vaginally placed mesh.

In the light of these FDA findings, it is important to understand the current FDA approval process for new materials, as there is a proposed reclassification of surgical mesh used for transvaginal repair of POP. Currently, mesh products on the market were allowed to bypass a rigorous FDA approval process that mandates premarket testing called a “premarket analysis.” In lieu of this process, they were allowed to proceed with a much more simplified regulatory process called a “510K.” This process allowed new medical devices that were similar to a currently approved FDA device to be approved based on what is been termed as a “predicate” device eliminating the need for the companies to provide specific efficacy and safety data on a new product prior to obtaining FDA approval. Historically, transvaginal mesh kits were considered class II devices and able to use a 510K process with synthetic midurethral sling as the predicate device, even though the mesh utilized for prolapse repairs involved significantly increased volumes of mesh and utilized a different space in which the mesh was placed. Currently approved synthetic midurethral slings were approved by the same process based upon a prior product, “the Protegen sling,” which is no longer on the market due to a poor safety profile.

The FDA is considering a reclassification of vaginal meshes from a class II to a class III medical device, which would require premarket approval through a scientific review to ensure safety and efficacy prior to going to market. If this truly occurred, then it would require a significant investment to bring new mesh kits to the market. On January 4, 2012, the FDA did issue what have been termed 522 orders requiring postmarket surveillance studies for transvaginal mesh devices currently being sold for POP. These required studies are ongoing and will most likely ultimately decide the long-term fate of permanent transvaginal mesh.

PROFESSIONAL SOCIETY GUIDELINES

The American College of Obstetricians and Gynecologists and the American Urogynecologic Society (AUGS) issued a statement in December 2011 regarding vaginal placement of surgical mesh for POP repair. They advised that

- Surgeons placing vaginal mesh should undergo training specific to each device and have experience with reconstructive surgical procedures and a thorough understanding of pelvic anatomy
- Use of reconstructive materials by surgeons experienced with the specific procedure is a reasonable option for women with factors that increase the risk of prolapse recurrence (e.g., recurrent prolapse, medical comorbidities that preclude more invasive and lengthier open and endoscopic procedures) (Such use should be individualized and surgeons should counsel patients about the lack of efficacy and safety data and about alternative treatments.)
- Patients should provide their informed consent after reviewing the risks and benefits of the procedure, as well as discussing alternative repairs

In addition, the Society of Gynecologic Surgeons (SGS) issued a statement in July 2011, advising the following:

- SGS is in agreement with the interpretations and recommendations made in the FDA Safety Communication. The general consensus is that this reservation should not apply to synthetic midurethral sling procedures or sacral colpopexies utilizing the same mesh materials, but further longer-term evaluations of all of these procedures is important.
- For now, thoughtful, discriminant use of transvaginal mesh to augment vaginal defects should be performed by trained surgeons with experience in complex reconstructive surgery, and only on patients who are perceived to have an unacceptable risk of clinical failure when other procedures are performed.
- We should all follow outcomes when we employ new procedures, and should feel comfortable about the benefits versus the risks before employing them. It is important that patients are informed of the risks and benefits of any surgical procedure, as well as the specific potential adverse events associated with transvaginal mesh use, including outcomes that may still be unclear and require further investigation. Alternative treatments should be explained.

The International Urogynecological Association (IUGA) convened a Grafts Roundtable regarding transvaginal graft use in 2010 [8] and advised the following:

- Individual patient characteristics have to be included in the risk/benefit ratio when counseling patients regarding transvaginal mesh repair.
- Informed consent for vaginal reconstructive surgery with mesh should include verbal and written review with the patient of expected benefits, therapeutic alternatives, and potential risks.
- Manufacturers should provide detailed product description, data on biologic properties, cadaveric studies, and well-designed prospective clinical trials to support the claimed benefits of the new product.
- A process of added surgeon qualification for transvaginal mesh placement is desirable.

The AUGS issued guidelines for providing privileges and credentials to physicians for transvaginal placement of mesh for POP.

In the past, there were minimal guidelines for this process and physicians usually attended an industry sponsored 1- or 2-day course to learn these procedures using cadaveric trainers. The new AUGS recommendations call for documentation of each of the following: (1) knowledge of pelvic anatomy, (2) surgical skill, (3) surgical experience, and (4) internal audits for quality assurance. Informed consent should highlight potential benefits and complications of transvaginal mesh, alternatives including nonsurgical options and other surgical treatments, and potential complications of transvaginal mesh, which may require additional interventions, as well as the fact that symptoms may not be completely resolved with mesh removal. The article addresses surgeons who are not performing transvaginal mesh repairs but would like to begin, as well as those currently performing these procedures. The surgeon who approaches management of mesh complications after pelvic surgery should possess a comprehensive understanding of materials utilized in POP repair, pelvic floor anatomy, and advanced surgical skills in order to individualize the management of such complications specific to each patient. Patients should also understand that removal of mesh may not completely resolve all symptoms.

TERMINOLOGY

In response to increasing complications associated with mesh use in gynecologic surgery, the IUGA and the International Continence Society recently agreed on standardized terminology and a classification method for complications associated with insertion of mesh [9]. Terminology is specifically defined in the article and the classification system is based on three items: category, time, and site (CTS) (Appendix D).

Category includes seven complication types (vaginal without epithelial separation, vaginal with <1 cm epithelial separation, vaginal with >1 cm separation, urinary tract, rectal/bowel, skin/musculoskeletal, and patient compromise). Each has lettered modifiers for patient symptoms and infection (A, asymptomatic; B, symptomatic; C, infection; D, abscess).

Time includes four time periods (T1, intraoperative to 48 hours; T2, 48 hours to 2 months; T3, 2 months to 12 months; T4, over 12 months).

Site has five categories (S1, vaginal area of suture line; S2, vaginal area away from suture line; S3, adjoining viscus [bladder or bowel]; S4, other skin or musculoskeletal site; S5, intra-abdominal). As an example, a patient with mesh fiber exposure in the lateral vagina on her 6-week post-op check whose partner describes discomfort with intercourse would be classified as B1/T2/S2. Although somewhat complex, when broken down, it is a simple way to classify mesh complications with the CTS system intended to be an improved method for standardizing reporting of complications associated with graft placement. This classification system will also allow for identification and classification of all complications from minor, asymptomatic problems to complex pathology.

AVOIDING SYNTHETIC MESH COMPLICATIONS

Patient Selection

To date, there has been no systematic evaluation of which patients with POP should undergo transvaginal mesh repairs to correct POP. Some have argued that use of transvaginal mesh be restricted to patients who fail native tissue suture repairs. The stage or grade of POP is also a commonly cited reason to proceed with a transvaginal mesh repair. While intuitively these indications may make sense, there are no published data to support either rationale. Other commonly cited indications for mesh augmentation include patients who are not sexually active or patients who are felt to be at high risk for failure of a native tissue repair secondary to lifestyle, body habitus, etc. Unfortunately, there are also no data to support any of these rationales. Regardless, it seems prudent to avoid transvaginal mesh procedures in patients with underlying pelvic pain disorders, for example, pelvic floor tension myalgia, interstitial cystitis, or vestibulitis. Pelvic surgeons should be aware of the high prevalence of female sexual dysfunction in the community and should preoperatively screen patients for a history of dyspareunia, pelvic pain, and sexual abuse. Abnormalities of the pelvic tone or sensation should be elicited during the preoperative physical exam by palpating the levators, obturator internus, and vaginal sulci and evaluating for signs of vulvodynia. Patients who have these findings should be referred to physical therapy in the hope of treating the underlying condition prior to any surgical intervention. In addition, they should be explicitly informed that surgery, if undertaken, is not meant to improve these symptoms and may make them worse. Patients that are chronically immunosuppressed (e.g., due to medication for other systemic diseases or due to underlying disease) or who are current smokers should be similarly approached with caution. Finally, patients with severe atrophy, vaginal ulcers due to severe prolapse, or chronic pessary use should receive preoperative estrogen therapy for at least 4 weeks or until the aforementioned symptoms or signs resolve. Ideally, they should continue local estrogen therapy for the foreseeable future following surgery. The optimal time to start postoperative local estrogen therapy has not been studied; however, we recommend starting about 3 weeks following surgery to avoid inadvertent disruption of any suture line during insertion of the applicator.

Surgical Technique and Mesh Selection

Expert opinion states that the key distinction between mesh- and suture-based repairs is the tissue plane and thickness of the dissection. In traditional plication repairs, which most gynecologists are familiar with, the vaginal epithelium is dissected from the underlying pubocervical connective tissue, which is subsequently plicated in the midline with a delayed absorbable suture. Conversely, mesh repairs require a “full-thickness” dissection. Successful “full-thickness” dissection requires adequate hydrodissection (not typically used with traditional repairs) and dissection in a deeper surgical plane that leaves the pubocervical connective tissue attached to the epithelium. This allows, in theory, for decreased risk of vaginal mesh exposure, maintenance of better vascular supply to the epithelium and improved healing, with the goal of diminishing graft exposure. It is also felt that although the mesh is “suspended” tension-free via the arms, the mesh body needs to be trimmed and even possibly secured to the underlying tissue to prevent rolling or bunching, as this phenomenon has been observed in patients who experience mesh exposure and/or pain (Hurtado et al., 2009) [10]. Finally, it is felt that the mesh needs to be deployed in a tension-free fashion. Excessive tension on the arms has been associated with tight vaginal bands, pain, and exposures [11]. It is unclear if overtensioning results from mesh shrinkage (less likely as this phenomenon has not been documented with sacrocolpopexy) or inadvertent tensioning at the time of implantation (more likely) or a combination of factors. A thorough understanding by the treating surgeon of the nuances of mesh-based repairs is of the utmost importance to reduce these complications. In fact, there is evidence that complications are higher among providers with less experience. As a result, new providers should seek proctoring by experienced, unbiased providers until achieving a level of expertise needed to safely perform these types of procedures. Additionally, documentation and tracking of complications should be mandatory for all new implanters to ensure patient safety.

Modifiable Risk Factors for Mesh-Related Complications

There are several modifiable risk factors that may diminish mesh-related complications (Table 91.1). A major determinant is material selection. As previously discussed, Amid type II (e.g., microporous materials) and type III (e.g., grafts with microporous components or with multifilament weave) synthetic meshes should be avoided because of increased risk of mesh-related complications [12]. These materials undergo an encapsulation response and are more prone to erosion, sinus tract formation, and infection.

A recent secondary analysis of the colpopexy and urinary reduction efforts (CARE) trials showed that Gore-Tex mesh use was associated with a 4.5-fold increased risk of exposure compared to macroporous polypropylene [13]. Previous devices (ObTape and IVS Tunneler), which utilized materials that are encapsulated, have been removed from the market due to the increased risk of mesh-related complications. Mesh-related complications associated with these materials require complete excision of the mesh and are not the focus of this chapter.

Smoking increases the risk of mesh erosion by nearly fivefold presumably by inhibiting wound healing. Current tobacco users had a 5.2- and 3.2-fold increased risk of mesh exposure following sacrocolpopexy and vaginal mesh, respectively [13,14]. It would seem prudent for surgeons to recommend that patients should stop smoking for at least 1 month before and after elective procedures with mesh. Similarly, increased blood loss during the index surgery greatly increased the risk of mesh exposure. In a case-controlled study, patients who experienced excessive blood loss had a 7.3-fold increase in mesh exposure compared to patients who did not experience excessive blood loss [14]. When excessive blood loss is encountered during these procedures, surgeons should consider suture-based repairs or simply aborting the case. Tissue ischemia due to tobacco use or hematoma formation may lead to impaired wound healing.

MESH-RELATED COMPLICATIONS AFTER SACROCOLPOPEXY

Sacrocolpopexy is an abdominal, laparoscopic, or robotic procedure that involves attaching a Y-shaped graft (usually synthetic mesh) to the anterior and posterior vaginal wall and securing it to the anterior longitudinal ligament of the sacrum. Mesh complications after abdominal sacrocolpopexy are fairly rare and primarily center on mesh or suture erosion (Figure 91.1). A comprehensive review of abdominal sacrocolpopexy revealed an overall mesh erosion rate of 3.4%. Polypropylene had the lowest erosion rate at 0.5%, while Teflon had the highest rate of erosion at 5.5% [15]. A more recent follow-up of the CARE trial noted the probability of mesh erosion at 7 years increased to 10.5% [16]. There are mixed data regarding the risk of mesh erosion when sacrocolpopexy is performed with concomitant hysterectomy. Culligan et al. [17] reported an increased erosion rate with concomitant hysterectomy; however, this study had a small sample size ($n = 11$). While Brizzolara and Pillai-Allen [18] reported no increased erosion rate in 60 women undergoing sacrocolpopexy with concomitant hysterectomy when compared to 61 women undergoing sacrocolpopexy alone, another study compared mesh erosion rates after sacrocolpopexy with concomitant supracervical hysterectomy as compared to sacrocolpopexy alone. A total of 277 patients were included in this study, 195 with concomitant supracervical hysterectomy with sacrocolpopexy and 82 with sacrocolpopexy alone. There were three patients with mesh erosion diagnosed at a mean follow-up of 8 months, 1 (0.5%) in the supracervical hysterectomy with sacrocolpopexy group and 2 (2.4%) in the sacrocolpopexy alone group. There was no statistical difference in mesh erosion rates among the two groups [19].

Table 91.1 Suggestions to Decrease the Risk of Erosion or Exposure after Reconstructive Pelvic

Surgeries Using Synthetic Grafts

Patient centered

- Stop smoking before and after surgery.
- Appropriately use vaginal estrogen in postmenopausal women before and after surgery (authors' opinion).
- Have regular postoperative follow-up visits with your surgeon.

Physician centered

Preoperative

- Understand technical aspects and surgical anatomy of the planned procedure that involves mesh placement; gain as much experience as possible with the procedure.
- In a patient with uterovaginal prolapse, consider a uterine-preserving procedure or a supracervical hysterectomy.
- Educate patients preoperatively on the importance of avoiding the future development of urogenital atrophy.

Intraoperative

- Utilize lightweight large-pore polypropylene.
- Use hydrodissection to facilitate the appropriate plane of dissection.
- Avoid mesh bunching, taking care to make sure that the mesh lies flat.
- Trim mesh appropriately to the specific prolapse repair to limit mesh load.
- Consider abandoning mesh placement if excessive blood loss is encountered.
- Consider abandoning mesh placement if inadvertent injury to the urethra (sling placement), bladder, or bowel (mesh-augmented prolapse repairs) occurs.
- Avoid overzealous trimming of vaginal mucosa.

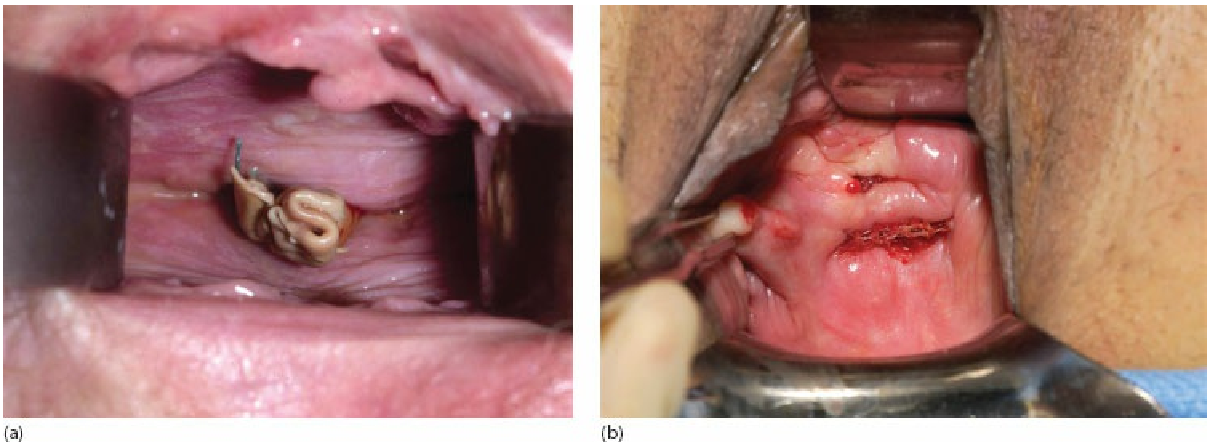

Figure 91.1 Vaginal mesh erosion after abdominal sacrocolpopexy. (a) Gore-Tex mesh erosion seen transvaginally after abdominal sacrocolpopexy. (b) Polypropylene mesh erosion seen transvaginally after abdominal sacrocolpopexy.

A variety of risk factors have been identified for mesh and suture erosion after sacrocolpopexy. A secondary analysis from the CARE trial evaluated mesh and suture erosion rates among the 322 women who underwent sacrocolpopexy [20]. They identified 20 women with mesh/suture erosion within 2 years of surgery, 3 were suture only, and 17 had exposed mesh. Three identifiable risk factors were found, which included concurrent hysterectomy, which increased erosion rate from 4% to 14% in this study population; also, the use of expanded polytetrafluroethylene (ePFTE; Gore-Tex, GORE Medical, Newark, NJ) had a fourfold higher risk (19% vs. 5%) of mesh erosion when compared to those with non-ePTFE mesh, and finally, smoking was associated with a fivefold increased risk of mesh erosion. No other significant factors were identified as risk factors for mesh erosion including estrogen status, diabetes, and prior surgery. The management of the three women with suture erosion included simple suture removal and two of the three had confirmed complete healing. Four of the 17 mesh erosions were managed without surgery and no resolution was noted in any of these 4. While 1 had 2 surgeries and 1 had 3 surgeries, 13 underwent at least one surgery. Of these 13, 2 had symptom resolution, 6 had persistent mesh erosion, and 5 were lost to follow-up.

Managing mesh erosion after sacrocolpopexy may only require observation and topical estrogen; however, in the authors' experience, it almost always requires surgical excision. Surgical management of mesh erosion after sacrocolpopexy can be technically challenging, partially due to the usually high location within the vaginal canal, the amount of mesh used in the procedure, and the ingrowth of the tissue into the mesh making surgical dissection difficult. Vaginal and abdominal routes for mesh excision have been described. In the authors’ experience, most mesh exposures can be successfully managed vaginally utilizing a technique of sharp dissection of the exposed mesh away from the surrounding tissue, with aggressive downward traction on the mesh. The mesh is cut away as high as possible and the vaginal defect closed (Figure 91.2). Vaginal entrance into the peritoneum significantly facilitates successful removal of the mesh.

South et al. [21] published their experience with excision of mesh in 31 patients after sacrocolpopexy, including a novel method for endoscopic-assisted transvaginal excision of mesh. Vaginal excision is described as sharp dissection of the vagina around the area of erosion and excision of the mesh with closure of mucosal edges with suture. Endoscopic-assisted transvaginal excision was used for patients with a sinus tract at the vaginal apex. The sinus tract opening was extended using a scalpel, if needed, to accommodate a 17-French cystoscope. The endoscope was placed into the sinus tract and advanced toward the sacrum to view the extent of the mesh. The scope was used for direct visualization during dissection of mesh from retroperitoneal tissues and during mesh excision. Abdominal excision of mesh was done by laparotomy and the presacral space was entered and mesh was detached from the sacrum and removed from the vaginal apex. Fourteen women underwent transvaginal mesh excision and this was successful in 9, while 17 women underwent endoscopic-assisted transvaginal mesh excision and this was successful in 7. The overall success rate for vaginal excision was 53%. However, multiple attempts at vaginal excision were required on several patients for symptom resolution. Seven patients underwent abdominal excision, each having failed one of the two transvaginal excision methods. All had symptom resolution and no severe complications were noted. The abdominal group had two intraoperative bowel injuries during lysis of adhesions: one wound infection and one readmission for fever requiring antibiotics. They concluded that complete removal of mesh may improve outcomes and decrease persistent symptoms, although significant morbidity can occur.

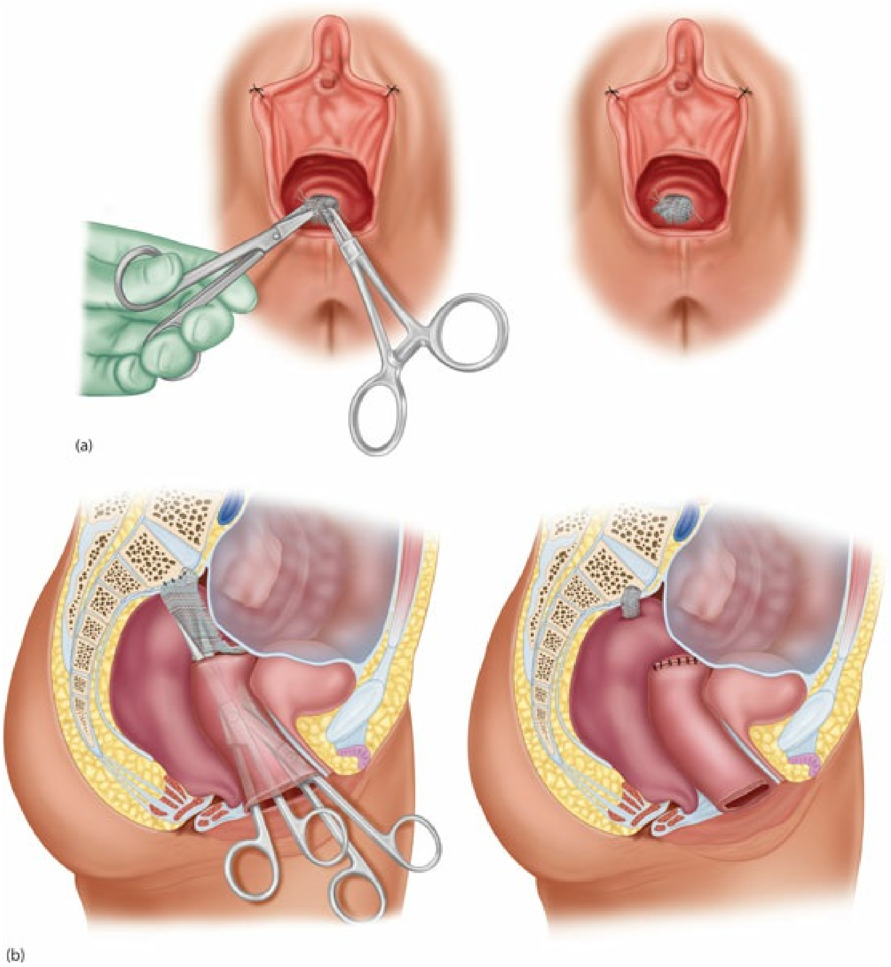

Figure 91.2 The technique of vaginal removal of an eroded synthetic mesh after abdominal sacral colpopexy. (a) Note that the mesh is undermined and grasped (usually with Kocher-type clamps), with aggressive downward traction applied on the mesh. (b) The mesh is sharply dissected away from the vaginal tissue and any other tissue that it is adherent to, and, with aggressive downward traction, it is excised as high as possible. The goal is to create as much distance as possible between the closed vaginal cuff and the cut edge of the mesh (see insert). COMPLICATIONS AFTER TRANSVAGINAL MESH PLACEMENT FOR PELVIC ORGAN PROLAPSE

There are potential benefits and risks with the use of transvaginal mesh for the treatment of POP. Proposed benefits include improved anatomic outcomes. These benefits must be weighed against potential complications, which include vaginal mesh erosion or extrusion, pelvic pain, and dyspareunia [22]. Also reported, albeit very rarely, are bladder and bowel perforation and/or injury.

A complete history and examination of all patients with suspected mesh-related complications should be completed. On pelvic examination, one should attempt to identify urogenital atrophy, palpation/visualization of any exposed mesh, mesh under tension, location of mesh arms, pain with palpation of the mesh (note location), bunching of mesh or palpable abnormalities beneath the epithelium, pain with palpation of pelvic floor musculature, or evidence of fistula. Rectal exam should be performed and cystoscopy and proctoscopy may be indicated in select cases. In patients with urogenital atrophy, the authors prefer to aggressively treat patients with local estrogen cream prior to any surgical intervention.

Mesh Erosion/Extrusion

This is the most common mesh-related complication after transvaginal placement of mesh for the management of POP (Figure 91.3). Common presenting symptoms of women with vaginal extrusion include vaginal drainage/bleeding, pelvic pain, and dyspareunia. On examination, pain with palpation of the mesh, visible mesh exposure, and vaginal shortening/tightening may also be seen. Published rates for mesh extrusion range from 3% to over 30% with large review articles suggesting overall rates between 10% and 15% [23,24]. Risk factors include concomitant hysterectomy, smoking, total mesh volume, young patient age, early resumption of sexual activity, diabetes mellitus, and surgeon experience. Local injection with lidocaine plus epinephrine at the time of mesh placement has not been shown to increase the risk of mesh extrusion [25]. Conservative management with topical estrogen and/or topical antibiotics can be attempted; however, little evidence of success exists with this treatment. Often, partial or complete excision is necessary for symptom improvement [26]. Both office-based and operating room excisions are options for management. Office-based excision should be reserved for those with small exposures (usually <1 cm), adequate access to the exposed mesh, and healthy vaginal tissues. Similar to the description of office-based management of synthetic midurethral sling exposure, local anesthetic is injected around the extrusion and the adjacent vaginal epithelium is mobilized. The mesh can be excised and the vaginal epithelium brought together in a tension-free fashion with interrupted sutures.

The operating room affords the surgeon improved visibility, better patient anesthesia, and a wider array of instrumentation for managing meshes' extrusions. The question that continues to be unanswered is how much mesh should be excised? There seems to be a balance, with an increased risk of repeat surgery for mesh excision when partial excision is undertaken and an increased risk of recurrent prolapse as well as more intraoperative morbidity with complete excision [27]. For extrusions that are small and straightforward, mobilization of the surrounding epithelium to cover the mesh or simple excision of a small amount of mesh and closing the epithelium is usually all that is needed. If pain and a large-scale extrusion are noted, then more aggressive resection is usually performed. Techniques for surgical excision revolve around dissection of the overlying vaginal epithelium away from the mesh, followed by the dissection of the mesh away from the adjacent organ (bladder or rectum) (Figure 91.4). Margulies (2008), Ridgeway et al. [28], and Muffly and Barber [29] each describe in detail surgical techniques for transvaginal mesh removal. Many mesh kits consist of a body of mesh and with arms used for anchoring the mesh. After implantation and incorporation of the mesh, these arms may become vascularized. When a more complete excision is desired and the mesh body has been mobilized satisfactorily, the authors advocate for clamping and tying of the mesh arms prior to transection to decrease the risk of bleeding. After mesh removal, when possible, midline plication of underlying connective tissue is performed to help resupport the prolapsed tissue and possibly decrease the risk of recurrent prolapse. Also, if appropriate, a native tissue suture suspension of the vaginal apex to the uterosacral ligaments or sacrospinous ligaments can be performed. If mobilization of the vaginal tissue does not allow for a tension-free closure of the vaginal epithelium, a porcine small intestine submucosa graft (Surgisis Biodesign®, Cook Surgical, Bloomington, IN) can be secured in place over the vaginal defect [30]. It acts as a scaffold and encourages host response to mediate the healing process. It can be used as a patch to close a vaginal defect. Biodesign will ultimately convert to normal skin in the majority of cases assuming a good blood supply is maintained (Figure 91.5). Vulvar skin flaps may also be used in instances where large defects are present after mesh removal.

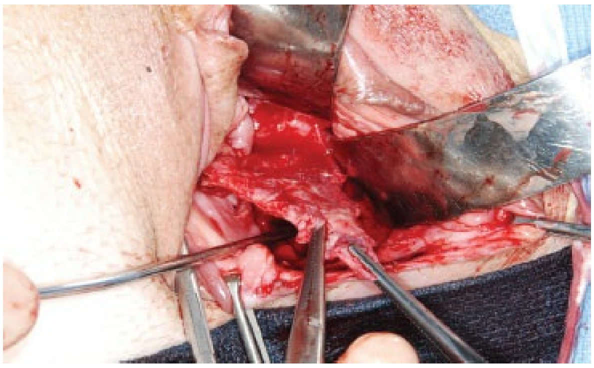

Figure 91.4 Technique for transvaginal removal of mesh; note the synthetic mesh is sharply dissected off the underlying viscera and overlying vaginal epithelium.

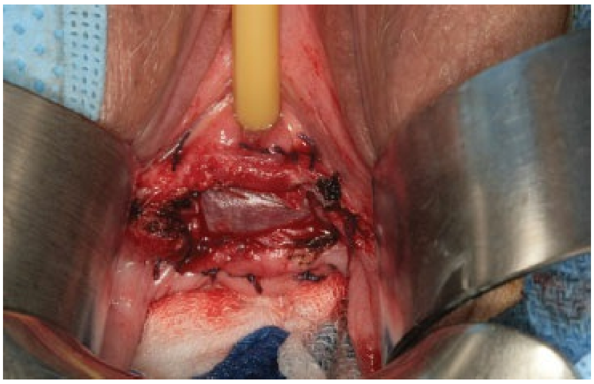

Figure 91.5 Surgisis Biodesign (Cook Medical, Bloomington, IN) used to replace vaginal epithelium after removal of eroded mesh.

Dyspareunia and Pelvic/Vaginal Pain

Dyspareunia and/or pain may develop after transvaginal mesh placement for POP. In a systematic review, the overall incidence of new-onset dyspareunia after vaginal mesh placement was 9.1% (with a range of 0%–67%) [23]. Pelvic muscle spasm/pelvic floor tension myalgia can present as chronic pelvic pain and may be confused with mesh-related pain. Though they may be difficult to distinguish from each other, both may improve with nonsurgical treatments such as pelvic floor physical therapy [31]. The authors recommend exhausting nonsurgical measures for the treatment of pelvic pain possibly related to mesh placement since patients undergoing surgical excision often have persistent pain [32]. Of all mesh-related complications, pain remains the symptom most resistant to medical and surgical treatment. It is often improved after mesh excision but may never disappear completely [33]. Thus, counseling patients prior to surgery about risks associated with mesh removal is paramount. These include bleeding, infection, injury to adjacent organs, new/persistent pain, and recurrent prolapse.

El-Nashar and Trabuco [32] performed an early excision of vaginal mesh, 11 days after implantation. This was performed for severe vaginal pain and urinary urgency/frequency, which began immediately after vaginal mesh placement. Complete excision, including mesh arms, was performed and the patient had resolution of all symptoms. The implanting surgeon was not the referring provider in the case earlier, and this is consistent with findings by Blandon and colleagues. In their study, only 14% of patients with mesh-related complications were referred by the surgeon who placed the mesh; about half were referred by a different physician/health-care provider and the remainder were self-referred.

Visceral Injury

Albeit rare, injury to the bladder and bowel can occur during placement of vaginal mesh. Significant emphasis has been placed on the concept that mesh placement requires a deeper dissection plane, i.e., through the full thickness of the vaginal epithelium to avoid vaginal erosion. However, the surgeon must also go to great lengths to avoid an inadvertent proctotomy or cystotomy and to avoid placing the mesh too deep (i.e., in the wall of the bladder or rectum).

If a bladder or bowel injury were to occur during dissection of the vaginal epithelium, the authors would recommend aborting mesh placement and proceeding with a native tissue suture repair. When performing a trocar-based mesh procedure, rectal exam and cystoscopy should routinely be performed with the trocars in place (prior to passage of arms) to assure no visceral penetration had occurred. In the rare situation where mesh is found postoperatively in the bladder or rectum, usually a major surgical procedure will be required to remove the mesh. If mesh is found in the rectum, a diverting colostomy may be necessary prior to attempting mesh removal.

CONCLUSION

Complications and untoward sequelae from reconstructive pelvic surgery occur with both native tissue and graft-augmented surgeries. Gauging the true incidence of these complications is difficult, because there is no good source for how many total procedures are being done and the frequency with which mesh augmentation is being used. As new procedures to correct pelvic floor disorders continue to evolve, open discussions among surgeons on how best to manage new and/or unforeseen complications are important.

92 Episiotomy and Perineal Repair

Ranee Thakar and Christine Kettle

INTRODUCTION

Perineal injury is inherent in childbirth, and various methods and materials have been used by accoucheurs in an attempt to restore perineal integrity. Surgical treatment in the form of a crossed or bootlace suture was first mentioned in Avicenna's famous Arabic book. However, the first recorded perineal suture was by Guillemeau in 1610 [1].

Perineal trauma resulting from childbirth remains a common problem [2] that causes a significant increase in maternal morbidity and may also have devastating effects on family life and sexual relationships. More than 85% of women sustain perineal trauma after childbirth [3], and up to two-thirds need suturing [2]. Perineal pain and discomfort affect up to 42% of women at 10 days postpartum, and in 10% of women, these problems persist at 18 months following childbirth [4]. Moreover, up to 58% of women experience superficial dyspareunia at 3 months postpartum [5].

This chapter covers the management and repair of episiotomy and first- and second-degree tears. Preventive measures are also discussed.

APPLIED ANATOMY

Anatomy of the Perineum

The perineum corresponds to the outlet of the pelvis and is somewhat lozenge-shaped. The perineum can be divided into two triangular parts by drawing a line transversely between the ischial tuberosities. The anterior triangle, which contains the urogenital organs, is known as the *urogenital triangle*, and the posterior triangle, which contains the termination of the anal canal, is known as the *anal triangle*.

Urogenital Triangle

The muscles are classified into a superficial and a deep group relative to the perineal membrane. The bulbospongiosus, superficial transverse perineal, and the ischiocavernosus muscles lie in the superficial compartment (Figure 92.1). The bulbospongiosus muscle encircles the vagina and inserts anteriorly into the corpora cavernosa clitoridis. Posteriorly, some of its fibers may merge with those of the superficial transverse perineal muscle and also with the external anal sphincter. Beneath the bulbospongiosus muscles lie the vestibular bulbs anteriorly and the Bartholin's glands posteriorly. The Bartholin's gland is a pea-shaped structure and its duct opens at the introitus just distal to the hymen at the junction of the upper two-thirds and the lower one-third of the labia minora. The deep transverse perineal muscle lies below the perineal membrane. It is thin and difficult to delineate and hence some authors deny the existence of this muscle [6].

Anal Triangle

This area includes the anal sphincters and ischioanal fossae. The external anal sphincter is subdivided into three parts—subcutaneous, superficial, and deep—and is inseparable from the puborectalis muscle posteriorly (Figure 92.2). The internal anal sphincter is a thickened continuation of the circular smooth muscle of the bowel. It is separated from the external anal sphincter (striated muscle) by the conjoint longitudinal muscle, which is a continuation of the longitudinal smooth muscle of the bowel but may receive contributions from the puborectalis muscle and the deep external sphincter [7] (see Chapter 92).

Perineal Body

The perineal body is the central point between the urogenital and the anal triangles of the perineum. Its 3D form has been likened to that of the cone of the red pine, with each "petal" representing an interlocking structure such as an insertion site of fascia or a muscle of the perineum [8]. Within the perineal body, there is interlacing of muscle fibers from the bulbospongiosus, superficial transverse perineal, and external anal sphincter muscles. Above this level, there is a contribution from the longitudinal rectal muscle and the medial fibers of the puborectalis muscle.

DEFINITION OF PERINEAL TRAUMA

Perineal trauma may occur spontaneously during vaginal birth or when a surgical incision (episiotomy) is intentionally made to facilitate delivery. It is possible to have an episiotomy and a spontaneous tear (e.g., extension of an episiotomy). Anterior perineal trauma is defined as injury to the labia, anterior vaginal wall, urethra, or clitoris; posterior perineal trauma is defined as any injury to the posterior vaginal wall or perineal muscles and may include disruption of the anal sphincters.

Structures Involved

First-degree perineal trauma is very superficial and may involve the skin and subcutaneous tissue of the anterior and posterior perineum, the vaginal mucosa, or a combination of these. Second-degree tears or mediolateral episiotomy involves the superficial perineal muscles (bulbocavernosus, transverse perineal) or the perineal body if a midline episiotomy incision is made. Rarely, more complex trauma can occur, whereby the tear extends in a circular direction, behind the hymeneal remnants, bilaterally upward toward the clitoris, causing the lower third of the vagina to detach from the underlying structures [6].

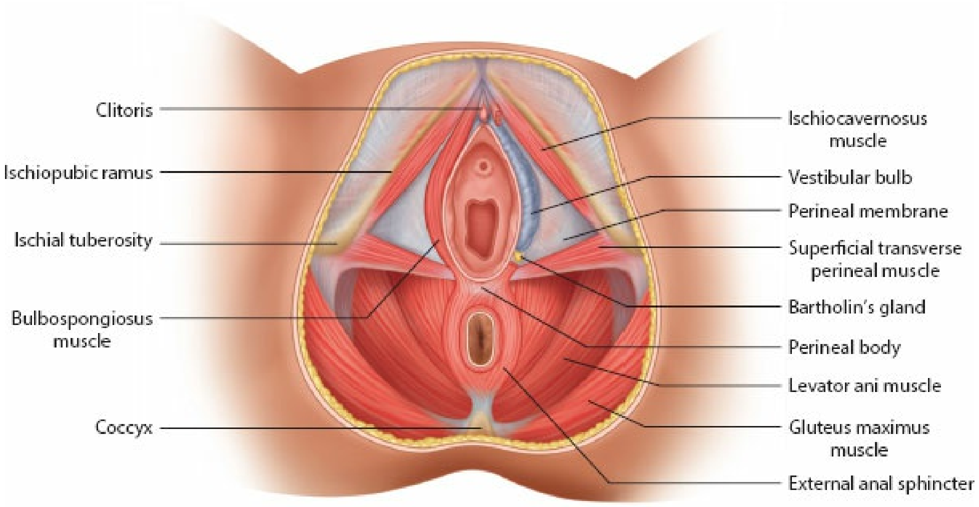

Figure 92.1 The superficial muscles of the perineum.

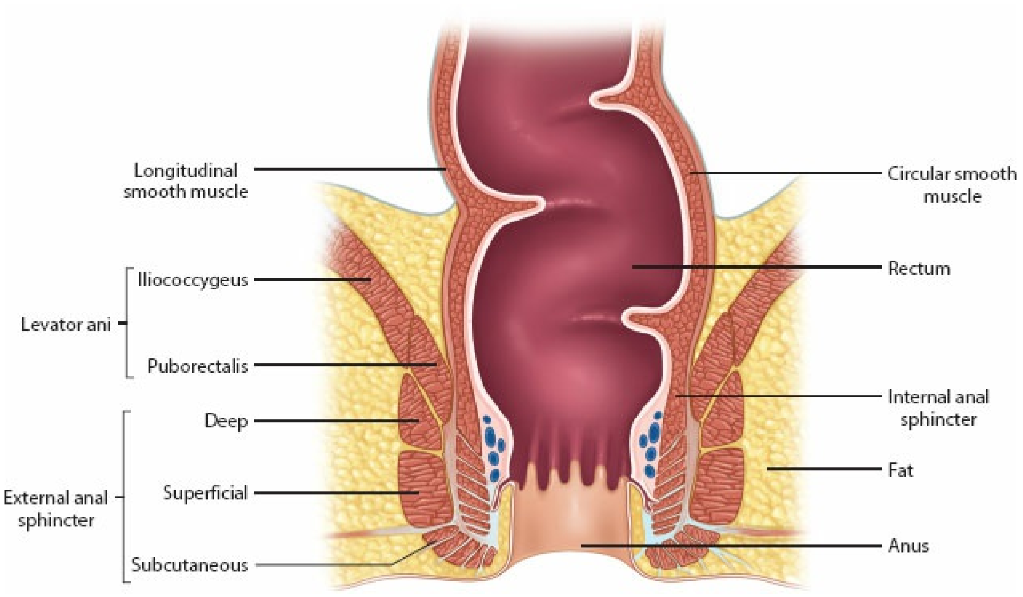

Figure 92.2 The anal sphincter.

EPISIOTOMY

Episiotomy is a surgical incision made with scissors or a scalpel into the perineum in order to increase the diameter of the vulval outlet and facilitate delivery [9]. The two main types of episiotomy incision are midline and mediolateral [10] although other types have been described [11]. When a midline episiotomy is undertaken, the incision is made from the central point of the posterior introitus and is directed vertically toward the anus; with a mediolateral episiotomy, the incision begins in the midline but is directed directly away from the anal sphincter and rectum. It is claimed that the midline incision is easier to repair and that it is associated with less blood loss, better healing, less pain, and earlier resumption of sexual intercourse. However, there is no reliable evidence to support these claims [4]. Limited evidence from one quasi-randomized trial suggested that the midline incision may increase the risk of third- and fourth-degree tears compared with the mediolateral incision [12]. However, these data should be interpreted with caution as there may be an increased risk of selection bias due to quasi-random treatment allocation and the analysis was not by intention to treat.

There is evidence accumulating that episiotomies angled too close to the midline are at a higher risk of causing obstetrical anal sphincter injuries (OASIS) [13–15]. This risk reduces by 50% for every 6° the episiotomy is angled away from the midline [14]. However, if the episiotomy angle becomes nearly horizontal (90°), the pressure on the perineum is not relieved and OASIS incidence increases ninefold [15]. The current recommendation is to cut an episiotomy at 45°–60° from the midline [16]. It is important to note that the angle of a mediolateral episiotomy will reduce significantly after the baby is born, i.e., a 40° episiotomy incision results in a suture angle of 22° from the midline [17]. If an episiotomy is performed at a 60° angle, when the perineum is distended, this will result in a suture angle of 45°, which is associated with a lower incidence of anal sphincter tears, anal incontinence, and perineal pain [18].

Incidence

There is a wide variation in the incidence of episiotomies performed in different countries. Clinicians' experiences, practices, and preferences of intrapartum interventions may influence the rate and severity of perineal trauma. Moreover, episiotomy rates may vary considerably according to individual practices and policies of staff and institutions. In the United Kingdom, it is estimated that over 85% of women who give birth will sustain some degree of perineal trauma and, of these, 60%–70% will require suturing [19]. However, episiotomy rates have decreased in English-speaking countries and Europe over the last 20 years, probably due to the accumulation of evidence supporting restrictive use of the procedure.

Episiotomy is a common obstetrical procedure, yet statistics relating to prevalence are not always easily located. Figure 92.3 presents data graphically to illustrate the considerable variation in the use of episiotomy [20]. Episiotomy rates that include both primiparous and multiparous women range from as low as 9.7% (Sweden) to 100% (Taiwan); rates for primiparous women range from 63.3% (South Africa) to 100% (Guatemala) [20].

Indications for Episiotomy

Episiotomy is still performed routinely in many parts of the world in the belief that it protects the pelvic floor. However, evidence from randomized controlled trials suggests that routine episiotomy does not prevent severe posterior perineal tears. A systematic review of randomized clinical trials using the Cochrane Collaboration methodology to determine the possible benefits and risks of restrictive episiotomy versus routine episiotomy included eight studies [4]. This revealed that, compared with routine use, restrictive use of episiotomy resulted in less severe perineal trauma, less suturing, and fewer healing complications. There were no significant differences in severe vaginal/perineal trauma, dyspareunia, urinary incontinence, or severe pain measures. The only disadvantage shown in restrictive use of episiotomy was an increased risk of anterior perineal trauma. The systematic review concluded that there is evidence to support the restrictive use of episiotomy compared to routine episiotomy (irrespective of the type of episiotomy performed) [4].

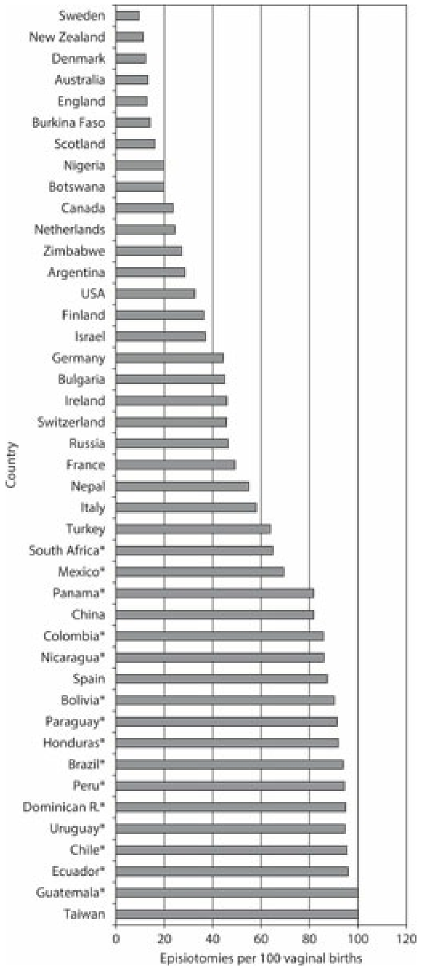

Figure 92.3 Graphical presentation of the considerable variation in the use of episiotomy: rates by country, 1995–2003. * indicates primiparous data only. (Reproduced from Graham ID and Davies C, Episiotomy: The unkindest cut that persists, in: Henderson C and Bick D, eds., *Perineal Care: An International Issue*, Quay Books, Salisbury, U.K., 2004, pp. 58–86. With permission.)

There is currently the absence of clear, evidence-based clinical indications for the use of episiotomy. However, it is reasonable to suggest that an episiotomy should be performed to accelerate vaginal delivery in cases of fetal distress, to facilitate safe delivery if shoulder dystocia occurs, to prevent severe perineal trauma during an instrumental delivery (forceps), and to aid vaginal delivery in cases where the perineal tissue is thick or rigid causing serious delay and in cases in which prolonged "bearing down" may be harmful for the mother (e.g., severe hypertensive or cardiac disease). However, these indications are not absolute and clinical discretion should always be used.

Episiotomy Rate

Although there is clear evidence to recommend restrictive use of episiotomy, there appears to be no consensus regarding the ideal episiotomy rate. Henriksen et al. [21] performed an observational study involving 2188 pregnant women and found that those allocated to the group of midwives with the lowest rate of episiotomies were more likely to have an intact perineum and more spontaneous perineal tears, but no increased risk of having an anal sphincter tear. In a further publication [22], the authors reported a relative decrease of 18% in episiotomy rates after distributing awareness profiles to the midwives, but the rate of anal sphincter tears did not change. There was a tendency toward an increased risk of tears if the midwives tried to reduce episiotomy rates below 20%. This supports the view that the overall ideal episiotomy rate should be between 20% and 30% but fails to indicate the ideal rate for nulliparae versus multiparae. The World Health Organization recommends that an episiotomy rate of 10% for spontaneous vaginal deliveries would be "a good goal to pursue" [23]; however, there is no robust evidence to support this recommendation.

MANAGEMENT OF PERINEAL TRAUMA

For many centuries, there has been a long-standing debate relating to suturing of perineal trauma following childbirth. Some accoucheurs believe that it is much better to leave perineal trauma unsutured to facilitate "ensuing" deliveries, while others argue that the outcome for women and their partners is considerably improved if the trauma is sutured.

Nonsuturing of Perineal Skin

Two trials included in a recent updated Cochrane review compared a two-stage repair technique where the skin was left unsutured but apposed (the vagina and perineal muscles were sutured) to the traditional three-stage approach where all three layers (vagina, perineal muscles, and skin) were sutured. The two large randomized controlled trials were carried out in Ipswich, United Kingdom (single center—n = 1780 women), and the other in Nigeria (multicenter—n = 1077 women) [24,25]. The pooled results suggested that the two-stage repair technique was associated with fewer women experiencing perineal pain up to 14 days; however, the difference between groups did not reach statistical significance at 2 days postnatal. There was a significant increase in wound gaping (more that 0.5 cm) in the two-stage repair group up to 10 days postpartum, but there was no clear evidence of any difference in long-term pain. Women undergoing two-stage repairs were less likely to report dyspareunia up to 3 months after delivery [26].

Nonsuturing of Perineal Trauma

It is unclear whether first- and second-degree tears need suturing. A recent Cochrane review included two RCT's comparing suturing versus nonsuturing (natural healing) of first- and second-degree tears (n = 154 women) [27,28]. These two studies found no difference in pain and discomfort up to 8 weeks postpartum, but one of the studies suggests that wound healing may be faster after suturing. However, the rate of breast feeding in this group was lower. In the other study, the use of analgesics was still high at 8 weeks in the sutured group, while no analgesics were used in the nonsutured group. Long-term effects of the two techniques have not been described, and there is a need for further research in this area. Until such evidence is available, women should be offered informed choice, and information provided should include the lack of available data on the long-term outcomes [29].

Suture Material

A Cochrane systematic review of 18 randomized controlled trials [30] involving 10,171 women carried out to assess the effects of different suture materials on short- and long-term morbidity following perineal repair. The pooled results from nine of the included studies showed that absorbable synthetic material (polyglycolic acid and polyglactin 910), when compared with catgut suture material, was associated with less pain up to 3 days after delivery and less analgesia up to 10 days postpartum. More women with catgut sutures required resuturing compared with synthetic sutures, while more women with standard synthetic sutures required the removal of unabsorbed suture material. Currently, the use of catgut has been largely superseded in developed countries by absorbable suture material.

Standard polyglactin 910 is not totally absorbed from the wound until 60–90 days. However, a more rapidly absorbable form of material is now available. This material has the same chemical composition as polyglactin 910 but is sterilized by gamma irradiation, which causes loss in tensile strength at 10–14 days and is completely absorbed from the tissue by 42 days [31]. Five RCTs included in the Cochrane review compared standard synthetic with rapidly absorbing synthetic suture material. The pooled results showed that short- and long-term pain were similar in both standard and rapidly absorbing synthetic suture group [30]. However, more women in the standard synthetic suture group required suture removal.

Method of Repair

Perineal trauma has traditionally been repaired using a continuous "locking" stitch to close the vaginal trauma, three or four interrupted sutures to reapproximate the deep and superficial muscles and continuous or interrupted transcutaneous stitches to close the perineal skin. For many years, researchers have been suggesting that continuous nonlocking suture techniques for repair of the vagina, perineal muscles, and skin are far better than "traditional" interrupted methods in terms of reduced postpartum pain.

The reason for the reduction in pain is probably due to the fact that the skin sutures are placed in the subcutaneous tissue, thus avoiding the profusion of nerve endings in the superficial skin surface. The rationale behind using the continuous technique is that stitch tension due to reactionary edema is transferred throughout the whole length of the single knotless suture in comparison with interrupted sutures that are placed transversely across the wound. Another advantage of the continuous suturing technique is that only one piece of suture material is required to complete the perineal repair as compared to two to three pieces for the interrupted method, thus reducing the overall expenditure.

A recent Cochrane systematic review [26] of 16 studies involving 8184 women showed that continuous suture techniques compared with interrupted sutures for perineal closure (all layers or perineal skin only) was associated with less pain up to 10 days postpartum. Furthermore, there was a greater reduction in pain when the continuous suturing technique was used for all layers. There was an overall reduction in analgesia use associated with the continuous subcutaneous technique versus interrupted stitches for repair of perineal skin. Subgroup analysis showed some evidence of reduction in dyspareunia experienced by participants in the groups that had continuous suturing of all layers. There was also a reduction in suture removal in the continuous suturing groups versus those with interrupted sutures, but no significant differences were seen in the need for resuturing of wounds or long-term pain. The authors concluded that the continuous suturing techniques for perineal closure, compared to interrupted methods, are associated with less short-term pain. If the continuous technique is used for all layers (vagina, perineal muscles, and skin) compared to perineal skin only, the reduction in pain is even greater.

Based on the evidence earlier, it can be concluded that perineal trauma should be repaired using the continuous nonlocking suturing technique to reapproximate all layers (vagina, perineal muscles, and skin) with rapid-absorption polyglactin 910.

Procedure for Perineal Repair

Assessment of Perineal Trauma [32]

The person responsible for the woman's care must inspect the perineum thoroughly as soon as possible following the birth, using good lighting. Prior to commencing suturing, it is important that the health professional explains the procedure to the woman and her partner and obtains consent. The woman is placed in a comfortable position so that the trauma is easily visualized. It is not necessary to use lithotomy poles to support the woman's legs during the procedure unless she has a working epidural or spinal anesthetic. After confirming effective pain relief, a vaginal examination should be carried out to assess the extent of perineal trauma including identification of the apex of the vaginal wound and the structures involved. In addition, a rectal examination should be carried out to assess whether there is any damage to the anal sphincter muscles. If the external anal sphincter is torn, the separated ends of the torn muscles will be observed to retract backward toward either side of the ischioanal fossa. If the woman has an effective epidural, she will not be able to contract her external anal sphincter muscle. The woman should be referred to a more experienced health-care professional if any uncertainty exists as to the nature or extent of the trauma sustained. This systematic assessment and its results should be fully documented. It is useful to include a diagram to illustrate the extent of the trauma.

Suturing Technique [32] (Figure 92.4)

Repair of the perineum should be undertaken as soon as possible to minimize the risk of infection and blood loss. It should only be undertaken after ensuring effective analgesia. This can be established by infiltrating the trauma with up to 20 mL of local anesthetic (lignocaine 1%), topping up the epidural, or performing spinal anesthesia if necessary.

The following steps should be followed:

1. *Suturing the vagina*: The first stitch is inserted above the apex of the vaginal trauma to secure any bleeding points that might not be visible. Close the vaginal trauma with a loose, continuous, nonlocking technique, making sure that each stitch is inserted not too widely to avoid narrowing the vagina. Continue to suture down to the hymenal remnants and insert the needle through the skin at the posterior fourchette to emerge in the center of the perineal wound.
2. *Suturing the muscle layer*: Check the depth of the trauma and close the perineal muscle (deep and superficial) with continuous nonlocking stitches. If the trauma is deep, the perineal muscles can be closed using two layers of continuous stitches. Realign the muscle so that the skin edges can be reapproximated without tension, ensuring that the stitches are not inserted through the rectum or anal canal.
3. *Suturing the perineal skin*: At the inferior end of the wound, bring the needle out just under the skin surface reversing the stitching direction. The skin sutures are placed below the skin surface in the subcutaneous tissue thus avoiding the profusion of nerve endings. Continue to take bites of tissue from each side of the wound edges until the hymenal remnants are reached. Secure the finished repair with a loop or an Aberdeen knot placed, if possible, in the vagina behind the hymenal remnants.

The equipment should be checked and swabs and needles counted before and after the procedure. Good anatomical alignment of the wound should be achieved and consideration given to cosmetic results. A rectal examination should be carried out after completing the repair to ensure that the suture material has not been accidentally inserted through the rectal mucosa. A detailed account should be documented covering the extent of the trauma, the method of repair, and the materials used. Rectal or oral, nonsteroidal anti-inflammatory drugs should be offered routinely after repair, provided these drugs are not contraindicated. Information should be given to the mother regarding the extent of the trauma, pain relief, diet, hygiene, and the importance of pelvic floor exercises [16].

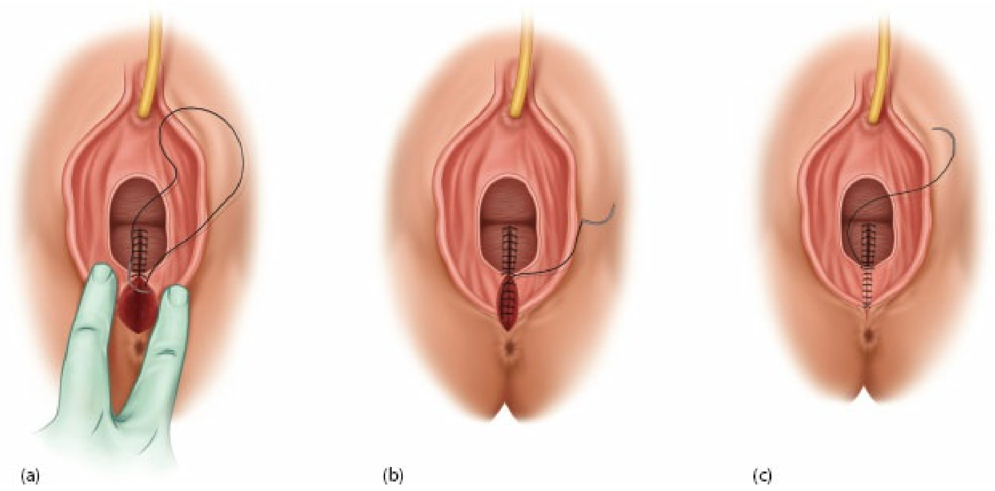

Figure 92.4 The continuous suturing technique. (a) Vaginal trauma is repaired using a loose, continuous nonlocking stitch to the vagina; (b) perineal muscle is repaired using a loose, continuous nonlocking stitch; and (c) skin is closed using a loose subcutaneous stitch. (Reproduced from Kettle C and Fenner D, Repair of episiotomy, first and second degree tears, in: Sultan AH et al., eds., *Perineal and Anal Sphincter Trauma*, Springer, London, U.K., 2007, pp. 20–32. With permission.)

Prevention of Perineal Trauma

Although the case for prevention of perineal trauma is compelling, how to accomplish this is less clear. Certain antenatal risk factors such as maternal nutritional status, body mass index, ethnicity, infant birth weight [33], race, and age [34] cannot be altered at the time of delivery but awareness of them might prompt modifications in the care pathway.

Episiotomy should only be performed when indicated and a mediolateral episiotomy preferable to a midline episiotomy [4]. Fewer women with vacuum delivery have anal sphincter trauma compared to forceps delivery [35]. Antenatal perineal massage reduces the likelihood of perineal trauma (mainly episiotomies) and the reporting of ongoing perineal pain, and it is generally well accepted by women. As such, women should be made aware of the likely benefit of perineal massage and provided with information on how to carry out perineal massage [36]. Other interventions such as water birth, position during labor and birth, delayed pushing with an epidural, second-stage pushing advice, perineal stretching, massage during the second stage, and perineal support at delivery have not been shown to reduce the risk of perineal trauma in randomized studies. Increased perineal trauma with epidural analgesia is due to the increased associated risk of an instrumental delivery [37].

TRAINING

Throughout the centuries, midwives have received very little formal training in the art of perineal suturing. In June 1967, midwives working in the United Kingdom were permitted by the Central Midwives Board (CMB) to perform episiotomies, but they were not allowed to suture perineal trauma [38,39]. In June 1970, the chairman of the CMB issued a statement that midwives who were working in “remote areas overseas” may be authorized by the doctor concerned to repair episiotomies, provided they have been taught the technique and were judged to be competent, but the final responsibility lay with the doctor. However, it was not until 1983 that perineal repair was included in the midwifery curriculum in the United Kingdom when the European Community Midwives Directives came into force and the CMB issued the following statement: “Midwives may undertake repair of the perineum provided they have received instruction and are competent in this procedure.”

However, there has not been enough emphasis on training. In 1995, Sultan et al. [40] carried out a survey in London to assess junior doctors’ and qualified midwives’ knowledge relating to perineal trauma and anatomy and to establish if they were satisfied with their training. Only 20% of junior doctors and 48% of midwives considered their training to be of a good standard when allowed to perform their first unsupervised perineal repair. Furthermore, many of the answers relating to anatomy and classification of tears were incorrect. To improve training, we have recently introduced a course using video presentations and specially designed models to demonstrate anatomy and techniques of repair (www.perineum.net) (Thakar, Kettle and Sultan, personal communication).

In a questionnaire survey of 208 health professionals attending this course, 64% were dissatisfied with their training prior to performing their first unsupervised perineal repair. Evaluation of the course carried out by administration of questionnaires 8 weeks following the course showed a significant increase in the participant’s ability to classify the degree of perineal trauma accurately. Participants changed their practice to evidence-based care after the course with significantly more performing the continuous suturing technique for repair of second-degree tears and episiotomy [41].

It has also been demonstrated that practitioners require more focused training relating to performing mediolateral episiotomies. Andrews et al. [13] carried out a prospective study over a 12-month period of women having their first vaginal delivery to assess positioning of mediolateral episiotomies. The depth, length, and distance from the midline, the shortest distance from the midpoint of the anal canal, and the angle subtended from the sagittal or parasagittal plane were measured following suturing of the episiotomy. Results of the study demonstrated that no midwives and only 13 (22%) doctors performed a truly mediolateral episiotomy and that the majority of the incisions were in fact directed closer to the midline [13].

A recent, pragmatic matched-pair cluster randomized controlled trial (PEARLS RCT) that enrolled women (n = 3681) sustaining a second-degree perineal tear in 1 of 22 UK maternity units (clusters) showed that implementation of the PEARLS-QI intervention was associated with a significant improvement in adherence to evidence-based repair practice and some of the women's reported outcomes. However, the study reported that regular training updates were essential to sustain the same level of improvement. An e-learning version of the PEARLS-QI intervention is now available for online access through StratOG (the Royal College of Obstetricians and Gynaecologists e-learning resource) and the Royal College of Midwives' e-learning suite [42].

The current recommendation is that all relevant health-care professionals should attend mandatory, multidisciplinary training in perineal/genital assessment and repair and ensure that they maintain these skills [43].

CONCLUSION

Obstetric perineal trauma can have a devastating effect on a woman's social life with associated psychological sequelae. Consequently, every attempt should be made to prevent such trauma, which may lead to short-term problems such as pain and dyspareunia or longer-term effects such as prolapse and incontinence. Practitioners must base their care on current research evidence and be aware of the potential maternal morbidity that may occur as a result of perineal injury following childbirth. Furthermore, there is a need for more structured training programs and national guidelines to ensure practitioners are appropriately skilled to identify, correctly classify, and repair perineal trauma in order to minimize morbidity and associated problems. Reducing the adverse sequelae of perineal trauma may make vaginal birth more desirable and could possibly decrease the escalating interest in cesarean section.

93 Primary Repair of Obstetric Anal Sphincter Injuries

Abdul H. Sultan

INTRODUCTION

Obstetric anal sphincter injuries (OASIS) are the major cause of anal incontinence and can have a devastating effect on women's quality of life. Until the advent of anal endosonography, the cause was attributed largely to pelvic neuropathy. However, despite identification and immediate repair of OASIS, the outcome is suboptimal as more than a third of women suffer from impaired continence. This chapter deals with issues related to acute OASIS and a description of the various repair techniques is given.

DEFINITION

The terms "primary" and "secondary" anal sphincter repair can lead to confusion and need clarification. Following OASIS, a repair of the anal sphincter in the immediate postpartum period is usually performed by an obstetrician as a primary procedure. If the diagnosis is not made immediately after delivery, but for various reasons only identified within the next few days, a delayed primary repair can be performed. However, when a repair of the anal sphincter is performed to treat fecal incontinence (usually months or years after childbirth), it is regarded as a secondary sphincter repair even though a direct primary repair may or may not have been attempted following delivery. There is now evidence to indicate that sonographic "occult OASIS" [1,2] largely represents undiagnosed [3] OASIS during childbirth and is a major etiological factor in the development of fecal incontinence [4]. In the United Kingdom, primary anal sphincter repair is conducted by obstetricians while secondary sphincter repairs are predominantly performed by colorectal surgeons.

CLASSIFICATION OF PERINEAL TEARS

There has been considerable inconsistency in the literature regarding the classification of perineal tears especially relating to third- and fourth-degree tears [5]. In order to standardize the description of anal sphincter injury, Sultan [6] modified the existing classification of perineal tears, and the new classification has been accepted by the Royal College of Obstetricians and Gynaecologists [7], The British National Institute for Health and Clinical Excellence [8], and the International Consultation on Incontinence [9]. This classification is divided into four degrees outlined as follows:

> *First degree*: Laceration of the vaginal or perineal skin only.
> *Second degree*: Involvement of the vaginal/perineal skin, perineal muscles, and fascia but not the anal sphincter.
> *Third degree*: Disruption of the vaginal/perineal skin, perineal body, and anal sphincter muscles. This should be subdivided into (Figure 93.1)
> 3a: Less than 50% of external sphincter thickness torn
> 3b: More than 50% of external sphincter thickness torn
> 3c: Both external and internal sphincter torn
> *Fourth degree*: A third degree tear with disruption of the anal epithelium.

Isolated tears of the rectal mucosa without involvement of the anal sphincter (Figure 93.2) is a rare event and should not be included in the earlier classification but referred to as "button hole" tears.

INCIDENCE OF OASIS AND OUTCOME OF REPAIR

The reported incidence of OASIS varies from one unit to the next and is dependent on obstetric practice but is especially related to the type of episiotomy practiced. OASIS are reported to occur between 0.5% in earlier studies [10,11] to 7.5% [12] of deliveries in centers where mediolateral episiotomy is practiced. It has been reported in 16% of instrumental deliveries [13] and 11% [14] (19% in primiparae [15]) in centers where midline episiotomy is practiced. Midline episiotomies have been favored in North American practice while mediolateral episiotomies are favored in Europe. Over a 25-year period between 1980 and 2005, 35 studies have evaluated outcome following OASIS with follow-up ranging from 1 to 36 months [16] (Table 93.1). The prevalence of anal incontinence (including flatus as a sole symptom) and fecal incontinence (liquids and solids with or without flatus) following end-to-end repair ranges between 15% and 61% (*n* = 35; mean = 39%) and 2% and 29% (*n* = 25; mean = 14%), respectively (Table 93.1). In addition, fecal urgency can affect a further 6% [10,46] to 28% [48] of women. Despite repair, persistent sonographic anal sphincter defects were identified in 34% [23] to 91% [46] of women. Anal incontinence during coitus occurs in about 17% of women following OASIS [44].

Anal resting and squeeze pressures are consistently lower in women who have previously sustained anal sphincter rupture [10,11,30,32,38,41,44], and the anal canal is shorter after repair [10,22]. The development of incontinence does not appear to be directly related to a pelvic neuropathy as demonstrated by EMG [25,33] and pudendal nerve motor latency conduction studies [4,10,30]. Tetzschner et al. [33] reported that 3-month pudendal latency measurements are longer in women with a risk of incontinence. However, these measurements were still within the normal range and no relationship was demonstrated between abnormal latency and incontinence. Although anal sphincter disruption and repair is invariably associated with some degree of denervation and atrophy, current available neurophysiological tests are neither sensitive nor specific enough to quantify pudendal neuropathy. There is, however, evidence to show that poor outcome following primary [10,25,30] and secondary [4] repair may be related more to persistent mechanical disruption as demonstrated by anal endosonography rather than *pudendal neuropathy*.

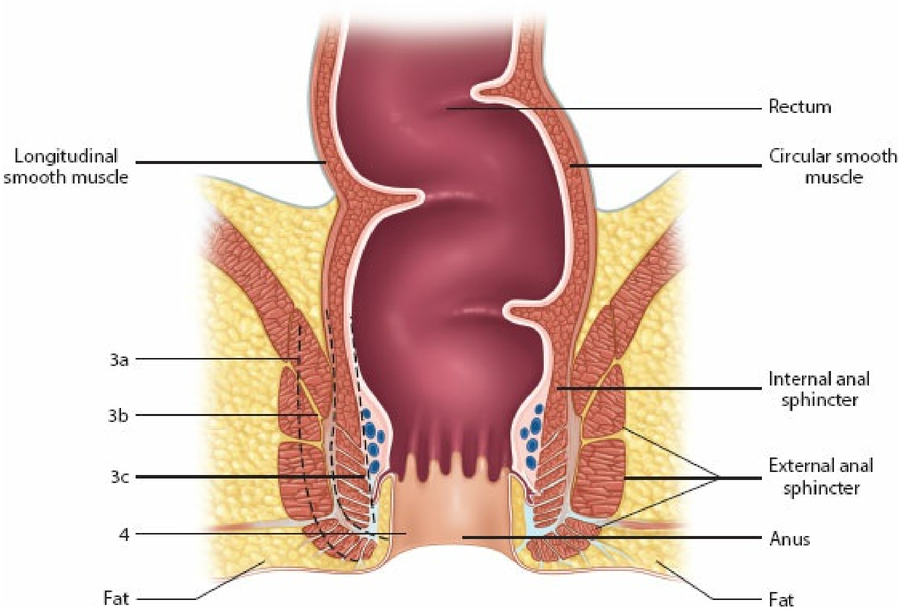

Figure 93.1 Schematic representation of the anal sphincter demonstrating the new classification of anal sphincter injury. (From Sultan AH, *Clin Risk*, 5(5), 193, 1999.)

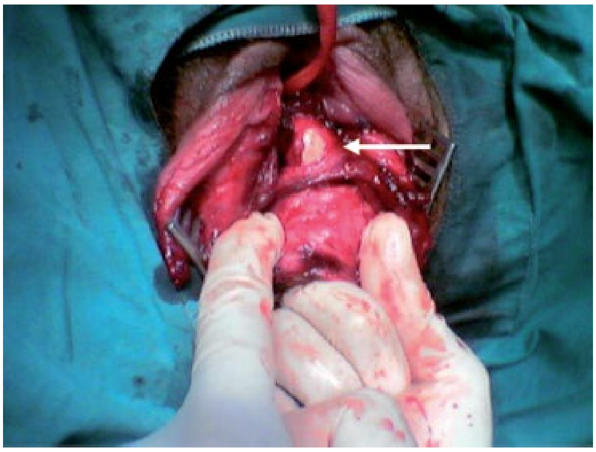

Figure 93.2 An isolated "button hole" tear of the rectal mucosa (arrow) inferior to which an intact anal sphincter can be seen.

Unsatisfactory outcome following primary sphincter repair may be attributed either to operator inexperience or repair techniques and subsequent management. Training and experience of clinicians performing perineal repair have been questioned [49,50] and hands-on training workshops have been shown to influence a change in clinical practice [51].

TECHNIQUE OF PRIMARY REPAIR

In 1930, Royston [52] described a commonly practiced technique of repair following OASIS where the ends of the torn sphincter were approximated by inserting a deep catgut suture through the inner third of the sphincter muscle and a second set (mattress or interrupted) through the outer third of the sphincter. Subsequently, Ingraham et al. [53] described a modification of the Royston technique [52], where the sutures were only inserted in the fascial sheath or capsule of the sphincter ani. Fulsher and Fearl [54] also described this technique but emphasized that no sutures should pass through the sphincter muscle. More specifically, Cunningham and Pilkington [55] inserted four interrupted sutures in the capsule of the external sphincter at the inferior, posterior, and superior points. In 1948, Kaltreider and Dixon [56] described the end-to-end repair technique that was used since 1935 in which one mattress or figure-of-eight suture was inserted to approximate the sphincter ends.

Obstetricians have used the end-to-end repair technique for decades either by single-interrupted sutures, "figure-of-eight" sutures, or mattress sutures [10] (Figure 93.3). However, as shown in Table 93.1, despite repair, anal incontinence still occur in 39% of women (range 15% [17] to 61% [48]). In addition, fecal urgency can affect a further 6% [10,46] to 28% [48]. Frank fecal incontinence affected 14% (range 2% [31] to 29% [45]). Persistent anal sphincter defects following repair has been reported in 34% [23] to 91% [46] of women (Figure 93.4).

Note:Fecal incontinence rates are shown in parentheses. "?" indicates that the figure for fecal incontinence has not been stated by the authors.

[a] Includes 2 with secondary sphincter repair.

By contrast, when fecal incontinence is due to sphincter disruption, colorectal surgeons favor the "overlap technique" for secondary sphincter repair as described by Parks and McPartlin [57]. Jorge and Wexner [58] reviewed the literature and reported on 21 studies using the overlap repair with good results ranging from 74% to 100%. Engel et al. [4] prospectively studied 55 patients with fecal incontinence undergoing an overlapping anterior anal sphincter repair and reported a good clinical outcome in 80%. A poor result was found to be associated with an external anal sphincter (EAS) defect while demonstration of an overlap by anal endosonography (Figure 93.5) correlated with a favorable outcome. It is now known that similar to other incontinence procedures, outcome can deteriorate with time and the follow-up study at 5-year follow-up reported 50% continence [59]. However, a number of women in this study had more than one attempt at sphincter repair [59]. Another prospective study reported success in 80% at a 7-year follow-up [60]. Sultan et al. [61] first evaluated the EAS overlap technique for acute OASIS and more importantly, advocated separate identification and repair (Figure 93.6) of the internal anal sphincter (IAS). Sultan et al. [61] evaluated the feasibility of this technique in 27 women and demonstrated that EAS overlap repair as well as identification and end-to-end repair of the IAS was possible following acute OASIS. They observed that compared to matched historical controls [10,61] who had an end-to-end repair, anal incontinence could be reduced from 41% to 8% using the overlap technique and separate repair of the internal sphincter. Based on this, they recommended a randomized trial between end-to-end and overlap repair.

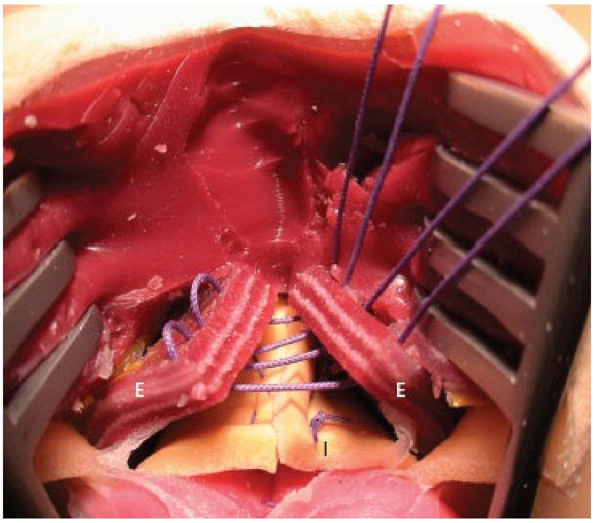

Figure 93.3 End-to-end approximation of the disrupted external sphincter (E) with two mattress sutures. The internal sphincter (I) has also been repaired by the end-to-end technique.

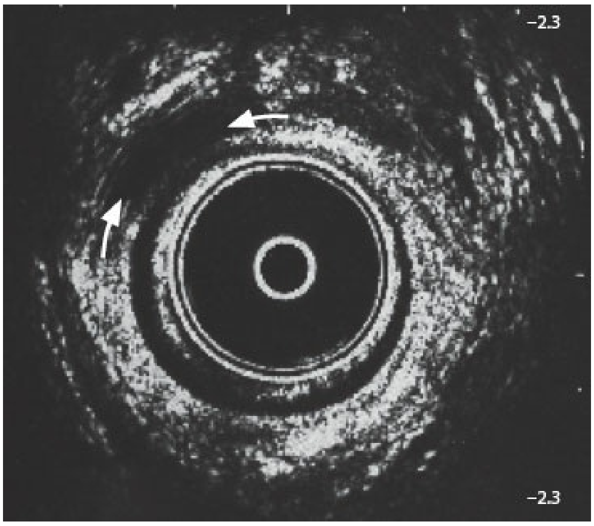

Figure 93.4 Anal endosonographic image demonstrating an external sphincter defect (between arrows) in a woman complaining of fecal incontinence following an end-to-end repair. The arrows overlie the two retracted ends of the muscle. (Reproduced from Sultan AH et al., *Br J Obstet Gynaecol*, 106, 318, 1999. With permission.)

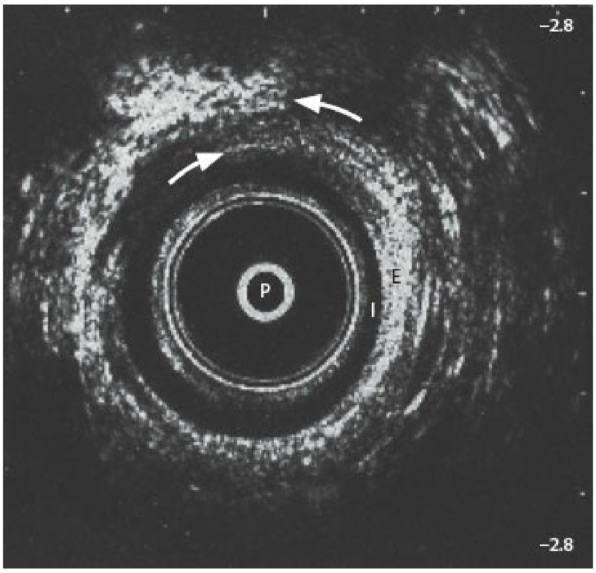

Figure 93.5 Anal endosonographic image demonstrating overlap of the two ends of the external sphincter. P = probe in anal canal with arrow showing its outer limit. Immediately adjacent to this is the anal epithelium. I, internal sphincter; E, external sphincter. The overlap can be seen between the open arrows. (Reproduced from Sultan AH et al., *Br J Obstet Gynaecol*, 106, 318, 1999. With permission.)

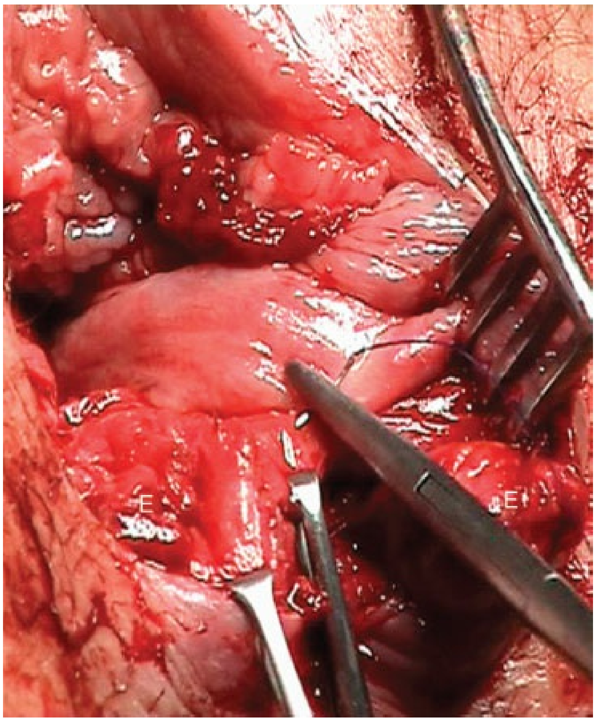

Figure 93.6 End-to-end approximation of the torn ends of the internal anal sphincter. The torn ends of the external sphincter (E) can also be seen.

The first published randomized trial by Fitzpatrick et al. [42] reported no significant difference between the two methods of repair at 3 months. In this study, they included partial EAS tears, and the torn IAS was not identified and repaired separately. They used a constipating agent for 3 days after the repair. However, a true overlap [10,57] is not possible if the sphincter ends are not completely torn, and attempts at overlapping would only place tension on the repair.

Garcia et al. [36] also performed a randomized trial of the two techniques, including only complete ruptures of the EAS (full-thickness 3b, 3c, and fourth-degree tears). Of the 23 women in the end-to-end group and 18 in the overlap group, only 15 and 11 women, respectively, returned for follow-up at 3 months. No significant difference was found between the groups in terms of symptoms of fecal incontinence or transperineal ultrasound findings. However, the authors acknowledged that the major limitations of their study were that randomization was inaccurate and that their study was underpowered.

Williams et al. [62] performed a factorial, randomized, controlled trial ($n = 112$) in which women were randomized into four groups: overlap with polyglactin (Vicryl; Ethicon, Edinburgh, United Kingdom), end-to-end repair with Vicryl, overlap repair with polydioxanone (PDS; Ethicon, Edinburgh, United Kingdom), and end-to-end repair with PDS. This trial was specifically designed to test the hypothesis regarding suture-related morbidity. At 6 weeks, there were no differences in terms of the need for suture removal due to pain, suture migration, or dyspareunia. The authors claim that there were no differences in outcome based on repair technique. Unfortunately, the majority of patients included in this trial were partial tears of the EAS (3a tears and as mentioned earlier), a true overlap cannot be performed if the EAS is only partially torn. Furthermore, their follow-up rate at 12 months was only 54%. These data need to be interpreted by caution.

Fernando et al. [63] performed an adequately powered randomized trial ($n = 64$) of end-to-end vs. overlap technique. At 12 months, they had an 81% follow-up rate and found that 24% in the end-to-end and none in the overlap group reported fecal incontinence ($p = 0.009$). Fecal urgency was reported by 32% in the end-to-end and 3.7% in the overlap group at 12 months ($p = 0.02$). There were no significant differences in dyspareunia and quality of life between the groups. After 12 months, 16% of women in the end-to-end group and no subjects in the overlap group reported deterioration of defecatory symptoms ($p = 0.01$).

Rygh and Korner [64] performed another randomized controlled trial ($n = 101$) with the primary outcome measure “of at least weekly solid stool incontinence.” They concluded that the overlap technique was not superior to the end-to-end repair. However, there were more women with symptoms of anal incontinence in the end-to-end repair group (34% vs. 20%).

Farrell et al. [65] performed a randomized controlled trial with a 6-month follow-up of an end-to-end ($n = 62$) vs. overlap ($n = 63$) EAS repair in primiparous women. They reported significantly higher rates of flatal but not fecal incontinence in the overlap group. However, there were more fourth-degree tears in the overlap group and therefore more IAS injury that could explain the increased flatal incontinence in this group [66]. At a 3-year follow-up however, there was no significant difference in anal incontinence between the groups, but the rate of fecal incontinence in the end-to-end group doubled while it remained static in the overlap group [67]. These support the findings of Fernando et al. [63], who demonstrated a significantly higher risk of deterioration in anal incontinence over time in the end-to-end group. This highlights the importance of longer term follow-up as one technique may prove to be more robust.

The Cochrane review [68] concluded that, compared with immediate primary end-to-end repair of OASIS, immediate primary overlap repair appears to be associated with a reduced risk for fecal urgency, anal incontinence score, and deterioration of anal incontinence symptoms at 12 months. At 36 months (based on only two small trials), there appeared to be no difference in flatus or fecal incontinence between the two techniques. They concluded that either an end-to-end or overlap repair of the EAS may be performed at the discretion of the clinician. It is important, however, to emphasize that the overlap technique has only been described for full-thickness EAS tears [61].

Kairaluoma et al. [69] presented results of 31 women who had sustained OASIS (3b and fourth degree) and had an EAS overlap repair immediately after delivery performed by two colorectal surgeons. In addition to an end-to-end repair of the IAS, they also performed a levatorplasty to approximate the levators in the midline with two sutures. At a median follow-up of 2 years, 23% complained of anal incontinence, 23% developed wound infection, 27% complained of dyspareunia, and one developed a rectovaginal fistula. Levatorplasty should be avoided during primary anal sphincter repair. By contrast, when primary repair with EAS overlap and separate repair of the IAS was performed by urogynecologists, none had fecal incontinence or any complications at 9 months [70].

PRINCIPLES AND TECHNIQUE OF REPAIR [16]

Ideally, primary repair should be conducted as soon as possible after delivery. However, a delay in repair may be justified in exceptional circumstances when an experienced obstetrician may not be available. In a recent randomized study, Nordenstam et al. [12] found no difference in anal incontinence 12 months after primary repair when women who had repair immediately after the tear were compared to others when repair was delayed for 8–12 hours. They concluded that there is no justification in delaying suturing except when a doctor competent in repair of OASIS is unavailable.

OASIS should only be repaired by a doctor who has been formally trained and is experienced in primary sphincter repair or by a trainee under supervision.

Ideally, the repair should be conducted in the operating theater where there is access to good lighting, appropriate equipment, and aseptic conditions. In our unit, we have a specially prepared instrument tray containing a Weitlander self-retaining retractor, four Allis tissue forceps, McIndoe/Metzenbaum scissors, tooth forceps, two artery/mosquito forceps, stitch scissors, and a needle holder (www.perineum.net).

General or regional (spinal, epidural, caudal) anesthesia is important as the inherent tone of the EAS can result in retraction of the torn muscle ends within its sheath. Muscle relaxation is necessary to retrieve the ends especially if the intention is to overlap the muscles without tension.

The full extent of the injury should be evaluated by a careful vaginal and rectal examination in lithotomy and graded according to the classification earlier (Figure 93.1). If there is any uncertainty about the grading of Grade 3a or 3b, it should always be given the higher grade.

On rare occasions, an isolated *button hole*–type tear (Figure 93.2) can occur in the rectum without disrupting the anal sphincter. This is best repaired transvaginally using interrupted Vicryl sutures. To minimize the risk of a persistent rectovaginal fistula, a second layer of tissue should be interposed between the rectum and vagina by approximating the rectovaginal fascia. A colostomy is rarely indicated for acute OASIS unless there is a large tear extending above the pelvic floor, or there is gross fecal contamination of the wound.

In the presence of a fourth-degree tear, the torn anorectal epithelium is repaired with a continuous nonlocking fine suture such as Vicryl 3-0. The technique of interrupted sutures with the knots tied in the anal lumen is recommended when catgut is used as catgut undergoes phagocytosis in tissues and increases the risk of infection. A subcuticular repair of the anal epithelium via the transvaginal approach has also been described [5] although there is some concern that the thin anorectal mucosa could tear with the passage of stool.

The sphincter muscles are repaired with 3-0 PDS dyed sutures (Figure 93.3). Compared to a braided suture, these monofilamentous sutures are believed to be less likely to precipitate infection. Nonabsorbable monofilament sutures such as nylon or Prolene (polypropylene) can cause stitch abscesses, and the sharp ends of the suture can cause discomfort, necessitating removal. Complete absorption of PDS takes longer than Vicryl, and therefore, to minimize the risk of suture migration, care should be taken to cut suture ends short and ensure that they are adequately buried by the overlying superficial perineal muscles. Alternatively, one randomized study has suggested that Vicryl 2-0 can also be used although the primary outcome was not the success of the repair but suture migration [62].

The IAS should be identified and, if torn, repaired separately from the EAS. The IAS lies between the EAS and the anal epithelium. It is thinner and paler than the striated EAS. The appearance of the IAS can be described as being analogous to the flesh of raw fish as opposed to the red meat appearance of the EAS. The ends of the torn muscle are grasped with Allis forceps and an end-to-end repair is performed with interrupted or mattress 3-0 PDS sutures. A torn IAS should be approximated with mattress sutures as overlapping can be technically difficult and will require unnecessary dissection. Mahony et al. [71] followed 500 women who sustained OASIS and found that a persistent IAS defect was independently associated with fecal incontinence. Nichols et al. [24] followed 56 women who sustained OASIS and found that, compared to an intact sphincter, combined defects of the IAS and EAS were associated with the highest risk of bowel symptoms. Roos et al. [72] performed a prospective study of 531 women who sustained OASIS and found that the outcome of primary repair of major (Grade 3c/fourth-degree) tears compared with that of minor (Grade 3a/3b) tears was less favorable. This suggests that tears involving the IAS are a poor prognostic factor. In women with major tears, defecatory symptoms were more prevalent and associated quality of life was worse. Furthermore, these women were more likely to have endosonographic isolated IAS or combined IAS and EAS defects and the maximum resting and squeeze pressures were lower. Women with endosonographic combined defects of the IAS and EAS were associated with a higher risk of loose fecal incontinence, lower maximum resting and squeeze pressures, lower incremental squeeze pressures, and a shorter anal canal length [72].

The torn ends of the EAS may retract and should be grasped and retrieved with Allis tissue forceps (Figure 93.7). In order to perform an overlapping repair, the muscle may need mobilization by dissection with a pair of McIndoe or Metzenbaum scissors, separating it from the ischioanal fat laterally. When performing an overlap repair, the EAS should be grasped with Allis forceps (Figure 93.8) and pulled across to overlap in a "double-breasted" fashion. The torn ends of the EAS can then be overlapped (Figure 93.9a and b) using PDS 3-0 (Ethicon) sutures. A proper overlap is only possible when the entire thickness is torn and the torn ends of the EAS in full length are free and mobile. Overlapping allows for a greater surface area of contact between muscles (Figure 93.9a and b). By contrast, an end-to-end repair can be performed without identifying the full length of the EAS giving rise to incomplete apposition [16]. Consequently, the woman may maintain continence in the short term but would be at risk of developing incontinence later in life. A shorter anal length has been reported following an end-to-end primary repair of the EAS [10,73]. It has also been shown that a shorter anal length is the best predictor of fecal incontinence following secondary sphincter repair [74]. Unlike end-to-end repair, if further retraction of the overlapped muscle ends were to occur, it is highly probable that muscle continuity would be maintained. However, if the operator is not familiar with the overlap technique or if the EAS is only partially torn (Grade 3a and some 3b), then an end-to-end repair should be performed. Two or three mattress sutures (Figure 93.3) should be inserted similar to that described for IAS repair. Hemostatic "figure-of-eight" sutures should not be used to repair the sphincters (or anorectal mucosa) as it could cause ischemia.

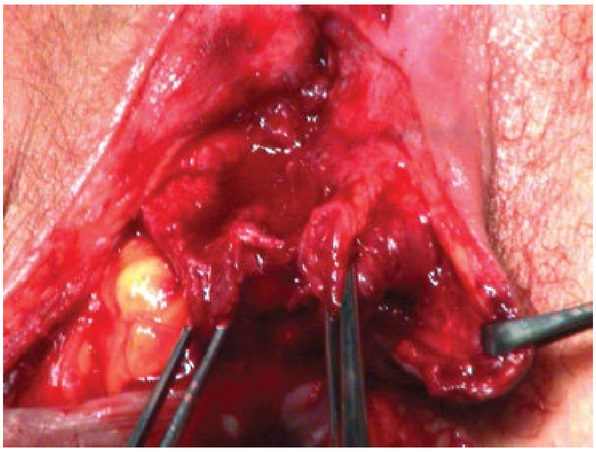

Figure 93.7 Torn ends of the external sphincter being elevated by two pairs of Allis forceps. Note the landmark yellow ischioanal fat lateral to the external sphincter.

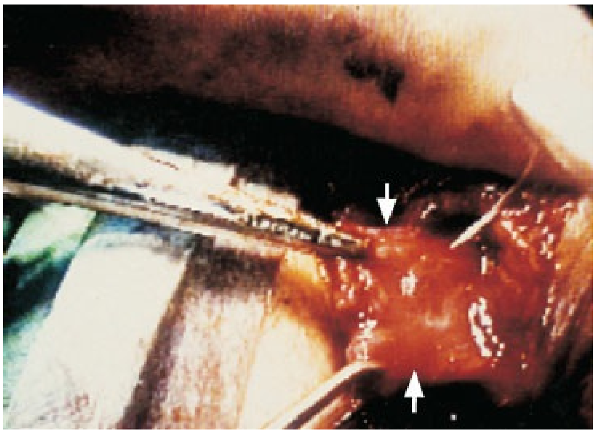

Figure 93.8 Full length of the external sphincter after mobilization. (Reproduced from Sultan AH et al., *Br J Obstet Gynaecol*, 106, 318, 1999. With permission.)

After repair of the sphincter, the perineal muscles should be sutured to reconstruct the perineal body. A short deficient perineum would make the anal sphincter more vulnerable to trauma during a subsequent vaginal delivery.

The vaginal skin is sutured and the perineal skin is approximated with a Vicryl 3-0 subcuticular suture.

A rectovaginal examination should be performed to confirm complete repair and ensure that all packs or swabs have been removed.

Intravenous broad-spectrum antibiotics such as cefuroxime 1.5 g and metronidazole 500 mg should be commenced intraoperatively, and we prefer to continue this orally for at least 3 days. In a prospective, randomized placebo-controlled study [75] of patients who had sustained OASIS (n = 147), it has been shown that patients who received a single dose of intravenous second-generation cephalosporin had a significantly lower risk of perineal complications (8% compared to 24%) compared to a placebo by 2 weeks after the repair.

Severe perineal discomfort, particularly following instrumental delivery, is a known cause of urinary retention, and following regional anesthesia, it can take up to 12 hours before bladder sensation returns. A Foley catheter should be inserted for 12–24 hours unless the midwifery staff can ensure that spontaneous voiding occurs at least every 3 hours.

Detailed notes should be made of the findings and repair. A pictorial representation of the tears proves very useful when notes are being reviewed following complications, audit, or litigation [16].

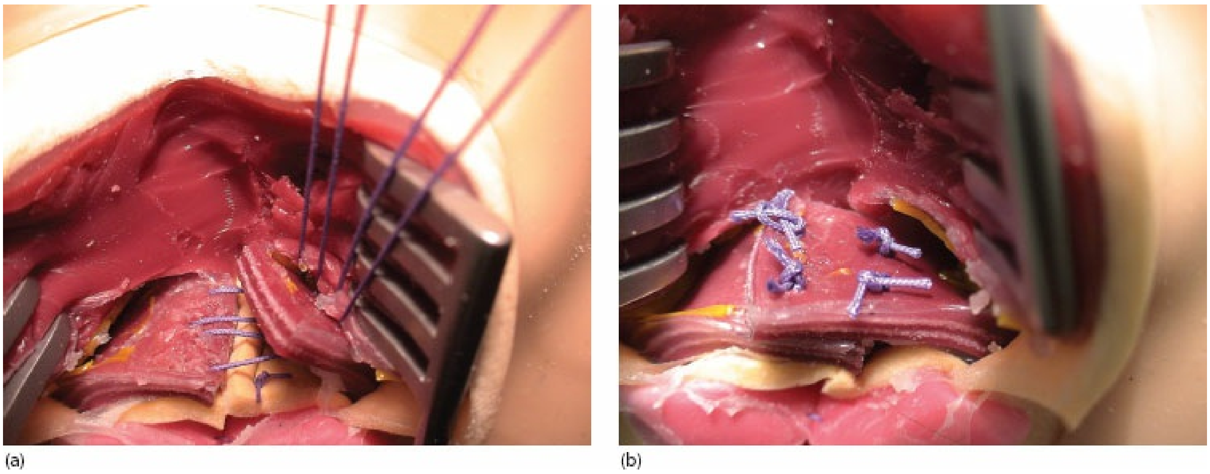

Figure 93.9 The technique of overlap repair of the external anal sphincter. (a) The first suture is inserted about 1.5 cm from the torn edge of the muscle and carried through to within 0.5 cm of the edge of the other arm of external sphincter. (b) A second row of sutures is inserted to attach the loose end of the overlapped muscle.

As passage of a large bolus of hard stool may disrupt the repair, a stool softener (lactulose 15 mL bd) is prescribed up to 10 days postoperatively. The dose can be titrated to ensure that stools are soft. A randomized trial (n = 105) of constipating versus laxative regimens found that the use of laxatives was associated with a significantly earlier and less painful first bowel motion as well as earlier discharge from hospital [76]. Compared to 5% in the laxative regimen group, 19% in the constipated regimen group experienced troublesome constipation (two required hospital admission for fecal impaction). There were no significant differences in continence scores, anal manometry, or endoanal scan findings. Bulking agents such as ispaghula husk (Fybogel) should be avoided as another randomized study [77] has indicated that incontinence occurred significantly more often (33% versus 18%) when lactulose and Fybogel were consumed compared to lactulose only.

It is important that the woman understands the implications of sustaining OASIS and should be informed how to seek help if symptoms of infection or incontinence develop.

Ideally, these women should be followed up in a dedicated perineal clinic by a team with a special interest in OASIS. All women should be given advice on pelvic floor exercises while others with weak or absent sphincter contractility may need electrical stimulation [78].

Management of Subsequent Pregnancy after OASIS

Women who sustain OASIS need careful counselling regarding their management in a subsequent pregnancy. It is known that the risk of recurrence of anal sphincter injury in centers that practice mediolateral episiotomy is 4.4% [79,80] to 7.1% [81,82].

All women who sustained OASIS should be assessed in a hospital by a senior obstetrician about 12 weeks after delivery. As there appears to be a rise in OASIS rates [13,83], there appears to be a need for dedicated multidisciplinary perineal or pelvic floor clinics. In a survey conducted in 2010 [83], 30% of hospitals in the United Kingdom had such a dedicated clinic. A structured bowel symptom questionnaire or scoring system should be used. A proper vaginal and rectal examination should be performed to check for complete healing, scar tenderness, and sphincter tone. Mild incontinence (fecal urgency, flatus incontinence, infrequent soiling) may be controlled with dietary advice, constipating agents such as loperamide, physiotherapy, and/or biofeedback. Women who have severe incontinence should, in addition, be assessed by a colorectal surgeon for a secondary sphincter repair or sacral nerve modulation.

There are no randomized studies to determine the most appropriate mode of subsequent delivery following OASIS. Women who have had a successful secondary sphincter repair for fecal incontinence should be delivered by cesarean section [84]. Some women with fecal incontinence may choose to complete their family prior to embarking on anal sphincter surgery. It would appear that these women may be allowed a vaginal delivery as the damage to the sphincter has already occurred and risk of further damage is minimal and probably insignificant in terms of outcome of surgery. The risk of worsening or de novo neuropathy has not been quantified and, in practice, does not appear to be clinically significant.

In order to counsel women with previous OASIS appropriately, Sultan and Thakar [16] advocate the use of a symptom questionnaire, anal ultrasound (Figures 93.4 and 93.5), and manometry results [9]. If vaginal delivery is contemplated then these tests should be performed during the current pregnancy unless performed previously and found to be normal. Therefore, asymptomatic women who have no evidence of compromised anal sphincter function (ideally, confirmed by anal ultrasound and manometry) should be counselled accordingly and encouraged to have a vaginal delivery [82]. Cesarean section is associated with increased morbidity and mortality [84]. Therefore, unless it is the explicit wish of the woman, it should be reserved for those who are symptomatic or women who had undergone a successful secondary anal sphincter repair for fecal incontinence. In a prospective study over a 5-year period, Scheer et al. [82] found that when women who had no evidence of significant anal sphincter compromise, based on anal endosonography and manometry, were allowed a vaginal delivery, there was no deterioration in symptoms, anorectal function, or quality of life.

94 Surgery for Fecal Incontinence

Julie Ann M. Van Koughnett and Steven D. Wexner

INTRODUCTION

Fecal incontinence (FI) is a common problem of varying severity, which may have a substantial negative impact on a person's life. Anal incontinence may range from mild leakage of gas causing social embarrassment to complete daily loss of control of feces and avoidance of all social activities. It is important to have an approach to quantifying the severity of FI when speaking with a patient, as this may impact their desire to undergo therapy and allow the physician to recommend the most appropriate treatment. There are many scoring systems and scales that have been developed to qualify the severity of FI; the Cleveland Clinic/Wexner Incontinence Score (CCIS) is the most commonly cited scoring system. The CCIS ranges from 0 to 20 and measures incontinence to gas, liquid, and solid stool, the need to wear a protective pad, and the impact of FI on daily activities [1]. Patients with a CCIS of greater than 10 have been shown to have significantly lower quality of life and are more likely to seek medical attention for their FI than individuals with scores less than 10 [2,3].

The exact prevalence of FI is unknown, though large population-based surveys estimate it to be up to 20%. A survey of 4000 American adults found the prevalence to be 8.3% [4]. However, in a more recent study of over 5800 women, called the Mature Women's Health Study, the prevalence of "accidental bowel leakage" was nearly 20% [5]. Interestingly, less than one-third of the women with accidental bowel leakage in the Mature Women's Health Study sought treatment, even though almost 40% of them had symptoms that were affecting their quality of life [3,6]. It is important to note that urinary incontinence and other pelvic floor dysfunction often occur in patients with FI, and so a thorough history must be obtained in every patient presenting with any of these symptoms [7]. Common factors associated with FI include obstetrical trauma causing internal sphincter injury or altered pelvic floor descent, age, obesity, diarrhea, frequent bowel movements, sedentary lifestyle, urinary incontinence, diabetes, neurological disorders, and a history of iatrogenic injury [4,5,8–13]. Once again, women with CCIS greater than 10 are more likely than women with scores less than 10 to seek medical attention [3].

The treatment of FI must be individualized to the patient, depending on the severity of symptoms and impact on quality of life. Options range from dietary modification to fecal diversion with a colostomy. In general, therapy may be categorized into nonsurgical treatment, sphincter repair, sphincter augmentation, sphincter replacement, nerve stimulation, and fecal diversion (Table 94.1). Each of these treatments has different risks, success rates, and degrees of invasiveness. A Cochrane review of the treatment of FI found that there is not enough comparative literature to adequately compare surgical options to each other, leaving much of the decision-making to the physician and patient [14]. A recent task force of the American Society of Colon and Rectal Surgeons reviewed newer treatment alternatives to offer guidance [15]. Not every treatment is appropriate for every patient; therefore, the physician must have a systematic approach to both FI and its potential treatment modalities.

NONSURGICAL THERAPY

Dietary Modification and Medical Treatment

In cases of mild FI, surgery may not be required to control symptoms and negate the impact on activities of daily living. Smoking cessation, weight loss, increased physical activity, and good diabetic control may all have a positive impact on FI [13]. A high-fat or low-fiber diet may cause loose stools leading to FI, either of which may be easily modified through nutritional counseling. Loose stools secondary to bile salt malabsorption after cholecystectomy may contribute to FI and can be improved with the use of bile acid sequestrants, again highlighting the importance of a full patient history during consultation [16]. The impact of dietary fiber must not be underestimated; in the treatment of incontinence, it provides stool bulk with little morbidity and has been shown to be very effective. A placebo-controlled randomized trial of patients in the community living with FI found that the addition of fiber supplements improved stool consistency and reduced FI [17]. These results can be extrapolated to the general population and should be considered in all patients with FI and specifically to individuals with loose stools. Other medications, such as loperamide (Imodium^{TM}), diphenoxylate with codeine (Lomotil^{TM}), codeine, and tincture of opium, may be considered in patients with FI exacerbated by loose stools. The most studied medication is loperamide, which improves stool consistency and may also improve anal resting tone [18,19]. It is also relatively cheap and does not require a prescription. A Cochrane review, which sought to compare the efficacy of medications for FI, found that there are no high-quality studies comparing medications, and therefore, none can be recommended above the others [19].

Biofeedback

Biofeedback is essentially physical therapy for the pelvic floor. It is a program led by a physical therapist aimed at retraining the pelvic muscles, improving sensory awareness, and individualizing treatment for problems such as FI or pelvic outlet dysfunction. While it does require a commitment on the part of the patient to undergo weeks of treatments, it is a nonsurgical option that may be quite helpful and is a definitive treatment for some patients with FI. The best patients to undergo biofeedback are those with mild or moderate incontinence who have failed or are not good candidates for medical treatment [20]. Though there are very few large studies of the efficacy of biofeedback, it has been shown to be beneficial to many patients without imposing morbidity [21,22]. Studies have found that around 70%–80% of patients with FI show improvement with biofeedback in nonrandomized trials [23–25]. However, one study found that less than half of all patients referred for biofeedback actually completed the treatment, largely due to the lack of convenient access to a treatment center [23]. It has been shown that the willingness to complete all recommended biofeedback sessions is the strongest independent predictor of success [26]. If available, it may be a safe and convenient solution to mild FI.

Table 94.1 Treatment Options for Fecal Incontinence (109)

Category	Treatments
Nonsurgical therapy	Fiber Medications Biofeedback
Sphincter repair	Overlapping anterior sphincteroplasty Postanal repair
Sphincter augmentation	Injectable materials Radio-frequency energy
Sphincter replacement	Artificial bowel sphincter Dynamic graciloplasty Magnetic anal sphincter
Stimulation	Sacral nerve stimulation Posterior tibial nerve stimulation
Fecal diversion	Antegrade continence enema Stoma

Biofeedback programs are led by physical therapists and are centered around pelvic floor exercises and retraining. One to several sessions per week are conducted for a number of weeks, though there is no single treatment regimen that is routinely followed. Pelvic floor exercises alone may improve symptoms of FI, when compared to additional therapies [27]. These exercises may be done at home or in the presence of the physical therapist. Other adjunctive treatments may be utilized, including digital feedback, manometric testing, ultrasound guidance, electrical stimulation, or anal balloons. Many studies have found that the addition of manometric monitoring, digital feedback, or electrical stimulation may improve the results of biofeedback [27–29]. Anal manometry may also be used to monitor the treatment effect, which has been shown to be durable at 1 year after finishing therapy [30,31]. The type of biofeedback offered is dependent on the individual physical therapist and the patient level of comfort with various treatment modalities. The main advantages of biofeedback are that it may avoid surgery in patients with mild FI and does not interfere with any future surgical treatment options.

SPHINCTER REPAIR

Overlapping Anterior Sphincteroplasty

Overlapping sphincteroplasty is done to restore the integrity of the sphincter complex and was historically the gold standard treatment for FI. Eligible candidates have a thin anovaginal septum or a palpable sphincter defect, confirmed with an anal ultrasound. However, it is important to note that not all sphincter injuries result in FI [32]. Nonetheless, the majority of overlapping sphincteroplasties are performed in women with a history of prior vaginal deliveries [33]. Other related risk factors for FI associated with a sphincter defects are third- or fourth-degree tears during delivery, forceps-assisted vaginal delivery, and multiple prior vaginal deliveries [34]. The suboptimal long-term durability of sphincteroplasty was the impetus for the development of the many new treatment options. Short-term results show that about 50% of patients have excellent function and over 70% of patients have good function [35]. However, long-term, durable success is seen in less than 50% of patients [36–42]. Even though FI scores may show worse function with time, patients often report durable improvements in quality of life for many years after overlapping anterior sphincteroplasty [36,39]. Additional treatments should thus be based on patient symptoms, rather than on follow-up physiological testing.

The most common form of delayed sphincteroplasty is the overlapping anterior sphincteroplasty. With the patient in the prone jackknife position under general anesthesia with a roll under the hip, a curvilinear incision is made over the perineum. With cephalad dissection, anterior scar will be encountered in place of the sphincter complex. Lateral dissection is then undertaken to identify the edges of the external anal sphincter. The scarred edges are grasped with an Allis clamp, after which the dissection continues laterally, following the course of the external sphincter, until the edges are mobile enough to be reapproximated. Care must be taken to not dissect too far laterally, to avoid injury to the pudendal nerves bilaterally. The levator muscles and internal anal sphincter are imbricated, after which the ends of the external sphincter are then overlapped for 1–2 cm and sutured together using a delayed absorbable suture. A finger in the anus is used to confirm that the new muscle bulk is snug but not too tight as to cause evacuatory outlet dysfunction. The incision is then closed in layers, with the medial portion left open for drainage. Patients must avoid straining and hard stools in the postoperative period, which may lead to early failure of the repair.

Postanal Repair

Although posterior anal sphincter repair is not commonly performed, it is occasionally utilized in conjunction with anterior sphincteroplasty or perineal rectosigmoidectomy. The reasons one may choose to perform a postanal repair alone or in conjunction with an anterior sphincteroplasty are iatrogenic posterior injury after an anorectal procedure or in the setting of multiple sphincter defects due to trauma. It may also be used for neurogenic incontinence or to avoid anteriorly located scar tissue in a patient who has previously undergone an anterior sphincteroplasty. Postanal repair does not improve on the durability of anterior sphincteroplasty and may in fact have inferior results compared to anterior sphincteroplasty [43,44]. The technique is similar to an anterior sphincteroplasty. A curvilinear incision is again made, but posterior to the anus. Overlap of the external sphincter edges is performed after lateral dissection is performed to attain adequate mobilization of the sphincter. While technically similar to anterior sphincteroplasty, postanal repair should be reserved only for patients with documented and specific posterior sphincter defects. Otherwise, overlapping anterior sphincteroplasty is the gold standard approach for sphincter repair.

AUGMENTATION

Injectable Materials

Injectable materials have been developed to add bulk to the anal sphincter complex. They are injected directly into the anal canal to help keep the anus “closed” at rest. Various materials have been used in animals and humans, including silicone, collagen, adipose tissue, and carbon-coated beads [45]. An injectable material is best used for patients with mild to moderate FI. The benefits are that the procedure can be performed in the office setting and does not require sedation. Though it may require a second treatment to achieve good results, there is little morbidity and the procedure is generally well tolerated. Currently, the injectable material of choice is dextranomer in hyaluronic acid gel (NASA/Dx) or Solesta$^{\mathrm{TM}}$. There is increasing literature on this injectable in particular in recent years. Numerous cohort studies have found that about 50% of patients who undergo NASA/Dx injection have a 50% reduction in FI episodes [46–48]. A randomized sham-controlled study of NASA/Dx reported an average reduction in CCIS from 16.8 to 12.8 [49]. While this is an improvement, it may still leave the patient with residual moderate FI. There are no randomized trials comparing NASA/Dx to other injectable materials. Complications from the injections are rare but bleeding, abscess, and pain have been reported [46–49]. Most studies report follow-up of less than 2 years, though longer-term outcomes are currently being studied.

As mentioned previously, NASA/Dx injection may be performed in the office without sedation. The patient is placed in the lithotomy or prone jackknife position. The material is injected in four quadrants, with 1 mL of NASA/Dx injected in each quadrant, about 5 mm proximal to the dentate line to avoid pain. The material is injected into the submucosa at a 30° angle. The needle is left in the submucosa for 30 seconds to ensure that it thickens slightly and would not leak out of the injection site. An anoscope is used to directly visualize the dentate line and injection site. The patient is monitored for a short period after the procedure is completed to rule out a reaction to the material or bleeding from the injection site. If there is poor response to the treatment at the time of follow-up, as assessed by the CCIS and/or quality-of-life scores, a repeat injection may be performed or alternate treatment modality considered. An injectable used in combination with a bulking agent, namely, fiber, may be most helpful for patients with incontinence secondary to leakage of liquid stool.

Radio-Frequency Energy

Radio-frequency energy application is another way to augment the anal canal without major surgery. The therapy, known as the SECCA® procedure, is used in the setting of mild or moderate FI that has not responded to medical management. The procedure was developed after a similar procedure was shown to be effected for the treatment of gastroesophageal reflux disease (GERD) at the gastroesophageal junction. The Stretta® procedure for GERD is effective and durable up to 10 years at reducing reflux scores and improving quality of life [50,51]. It may be helpful even in the presence of a sphincter defect in patients who are unwilling or not candidates for sphincter repair, though the defect should be less than 30°. In contrast to the injectables, the SECCA procedure induces collagen and muscle restructuring, thus producing a stronger and thicker sphincter complex to help control incontinent episodes. While the durability of radio frequency for FI is not yet known, the study with the longest follow-up found that the majority of patients in the cohort had a least 50% improvement in symptoms at 5 years [52]. Most other cohort studies have also demonstrated significant improvement in fecal incontinent episodes, and some found significant improvement in quality-of-life scores [53–55].

Radio-frequency energy delivery requires conscious sedation and so is performed in the endoscopy unit or the operating room. It is an outpatient procedure. The SECCA device includes a clear anoscope, which is marked with a ruler and contains four retractable curved needles. The device is deployed in each quadrant four times, starting at or slightly distal to the dentate line and moving 5 mm more proximal with each deployment. When the device is deployed, the four curved needles penetrate the rectal mucosa and into the internal anal sphincter. Radio-frequency energy is delivered through these needles for exactly 60 seconds per deployment. During activation, the device is attached to a monitor, which measures the tissue temperature and impedance to ensure that no unwanted damage is done to the mucosa or anal sphincter. Auditory and visual feedback from the monitor guides the operator through the procedure and provides feedback on the safety of the treatment. The entire procedure takes about 30 minutes and may be a good alternative for patients wishing to avoid, or who are not ideal candidates for, major surgery for their FI.

SPHINCTER REPLACEMENT

Artificial Bowel Sphincter

The artificial bowel sphincter is a good option for a select group of patients with severe FI. It is a plastic and metal device with three main components—the artificial sphincter, pump device that sits in the scrotum or labus majorum, and fluid reservoir. By filling and releasing fluid from the artificial sphincter, the patient is essentially able to recreate the relaxation of the sphincter complex to evacuate the rectum and have a continent bowel movement on demand. Thus, the patient must be mentally competent and dexterous to operate the device. Currently, the main indication for the artificial bowel sphincter is severe sphincter damage or malformation, whether traumatic, iatrogenic, or congenital. Other options are preferred due to the high rate of complications with the device. In those patients who retain the device, continence is significantly improved in over 75% [56]. Incontinence scores and quality-of-life scores can be vastly improved with the device [56–62]. The artificial bowel sphincter should not be used in the setting of perineal infection, Crohn's disease, irritable bowel syndrome associated with incontinence, or severe constipation [63]. Unfortunately, broader applications of the artificial bowel sphincter for incontinence have been limited by the device's complications. Device failure and infection are the most common complications, leading to device explantation in up to 50% of patients [64,65]. These complications continue to occur long term after many years [64]. Other complications include erosion of the device and constipation. Meticulous surgical technique by an experienced surgeon is essential to minimize the potential complications, though they unfortunately do still occur with the artificial bowel sphincter.

The patient is placed in the modified lithotomy position under general anesthesia. The hair is clipped from the perianal, perineal, and pubic bone areas. Meticulous sterile preparation and technique are employed throughout the procedure. If available, two surgical teams should be used to simultaneously prepare the perineal and Pfannenstiel's incisions. A curvilinear perineal incision is made anterior to the anus. Dissection down to the rectum is performed and then extended laterally and posteriorly. Blunt dissection is required to encircle the rectum, and this is then measured with the cuff sizer to choose the appropriate device size. Once the artificial sphincter, or cuff, is chosen, it is placed around the anal canal and closed. The clear tubing from the cuff is tunneled to the space of Retzius and a trial filling is undertaken. After equilibration, the reservoir is filled and left in the space of Retzius. The second (black) tubing is attached to the pump. A dilator is then used to create a tunnel and a pocket in the labus majorum or the scrotum. The pump is left in the newly created pocket. Care must be taken to ensure that all components of the device are as deep as possible, so as to avoid the risks of infection and device erosion. Once the pump is activated in the clinic after 6 weeks, the patient will begin using the artificial bowel sphincter. At baseline, the cuff is filled with liquid, thus providing the bulk of an anal sphincter and therefore continence. When the patient pumps the device, the fluid leaves the cuff and enters the reservoir. It then slowly refills over a period of about 2–3 minutes, during which time the patient is able to have a bowel movement with good control. This mimics normal sphincter relaxation to allow for rectal evacuation.

The manufacturer of the artificial bowel sphincter (American Medical Systems, Minnetonka, Minnesota) has recently discontinued distribution and support of this device; thus, it is no longer available for implantation.

Dynamic Graciloplasty

Muscle transposition was developed to replace the anal sphincter complex with autologous muscle bulk. Gluteoplasty with bilateral tongues of the gluteus maximus has been described but never gained popularity [66]. The more popular muscle is the gracilis muscle from the leg, which is considered the gold standard for muscle transfer. The gracilis is a useful muscle due to its long length, substantial bulk, and single proximal neurovascular pedicle in most patients. Small series of less than 10 patients were published showing that a neosphincter wrap of gracilis muscle had near perfect success in treating FI [67,68]. In attempts to reproduce this success in larger trials, nerve stimulation, or dynamic graciloplasty, was introduced. Long-term success of dynamic graciloplasty is reported to be between 60% and 75% [68–74]. A multicenter North American trial of dynamic graciloplasty found that function continued to improve and be sustained up to 24 months, and that continence was slower to improve in patients who originally had a stoma at the time of the graciloplasty procedure [74]. Stimulation of the gracilis occurs either with direct stimulation by an implanted lead or temporary stimulation with an external stimulator to retrain the gracilis. Dynamic graciloplasty is not without problems, including infection, pain, and erosion of the stimulator lead [73,75]. Currently, the procedure is not approved for use in North America but continues to be offered to specific patients in Europe and elsewhere.

Graciloplasty is performed with the patient under general anesthesia, but without muscle paralysis. Muscle harvest is done in the modified lithotomy position. The location and course of the gracilis muscle is palpated and marked along the medial aspect of the thigh. Two or three longitudinal incisions are made proximally and distally over the muscle. The insertion tendon is divided near the knee and the muscle is then divided from its deep perforating blood supply. At the medial aspect of the gracilis, meticulous care must be taken to preserve the neurovascular bundle. Confirmation of the identification of the nerve is done through direct nerve stimulation. The muscle is then tunneled medially. Left and right circumanal incisions are made as deeply as possible and the gracilis is delivered into the perineal incision and circumferentially wrapped around the distal rectum to re-create the anal sphincter complex. It is sutured in place to either the ipsilateral or contralateral ischial tuberosity. An electrode is placed in the gracilis muscle and stimulation is achieved with an implantable stimulator, similar to that of sacral nerve stimulation (SNS), which is discussed later in this chapter. Postoperatively, the patient is placed on bed rest in an adduction splint for 72 hours to prevent early failure of the muscle wrap.

Magnetic Anal Sphincter

A newer device has been developed to simplify the concept of sphincter replacement. The magnetic anal sphincter provides anal pressure and baseline tone at rest, which is overcome during pushing to open the anal canal and allow for defecation. It is currently undergoing clinical trials and is not approved for use in North America. The results from a multicenter prospective feasibility trial showed significant improvements in the CCIS from 17 to 8 and better quality-of-life scores [76]. Another study comparing the magnetic anal sphincter to the artificial bowel sphincter found equivalent improvements in incontinence and similar complication rates, but shorter hospital stay and operative time in the magnetic anal sphincter group [77]. While long-term results are not yet available, it appears that about two-thirds of patients are satisfied with the results of the procedure at about 2 years [78]. Complications of the procedure include bleeding, infection, pain, obstructed defecation, device failure, and device erosion [76]. The need for device explantation appears to be lower than that of the artificial bowel sphincter, but the data are sparse in these small trials.

The magnetic anal sphincter is implanted under general anesthesia as an inpatient surgery. An anterior curvilinear incision is made on the perineum. Much like graciloplasty and artificial bowel sphincter procedures, a circumferential tunnel is created around the anal canal with sharp and blunt dissection. The magnetic sphincter is then fit to size by removing or adding magnetic beads to the chain. The chain of magnetic beads is then wrapped around the rectum and secured in place. The tightness of the device is tested using an anal dilator or finger. The device must be snug enough to provide resting tone and continence, but loose enough that the magnets will be overcome by Valsalva maneuver during defecation and not cause outlet obstruction–type constipation. The incision is then closed and the patient is treated with antibiotics in the postoperative period to reduce the risk of device infection. This is a promising procedure that may provide a less complicated alternative to the artificial bowel sphincter and dynamic graciloplasty in the near future.

STIMULATION

Sacral Nerve Stimulation

SNS has markedly changed the treatment of both fecal and urinary incontinence. It has provided an effective alternative for moderate to severe FI without having to access the perineum or anal sphincter complex itself, which is desirable given the infectious complications of some of the treatments discussed earlier. The stimulator is implanted only after a test phase of stimulation is completed. Improvement in FI during the test phase positively predicts overall success of SNS [79]. Patients with prior sphincter repair, current sphincter defects, or known pudendal nerve injuries have all had good success with SNS [80–82]. The mechanism of action of SNS is not clear and appears to be multifactorial. Not only is there direct stimulation of S3 on the anal sphincters, but it also improves the sensation of rectal filling, alters colonic transit, and increases central nervous activity at the level of the cerebral cortex [83–86]. Significant improvements in FI scores have been universally reported in the short and long term, and the majority of studies also show sustained improvements in quality-of-life scores [87–93]. A report by the SNS Study Group found that almost 90% of patients had long-term reduction in incontinent episodes and over one-third had complete continence at 5 years or longer [87]. Infection, pain, and device migration are the most common complications of the procedure, which occur in about 10% of patients [91,94,95]. The SNS Study Group found that about one-third of patients need some sort of device manipulation or removal over long-term follow-up [87]. SNS is one of the few treatments for FI that has been robustly examined for cost-effectiveness and has been shown to be cost-effective in multiple reports [96,97].

SNS is done in two stages—a test phase and implantation procedure. The device consists of a tined quadripolar electrode lead and implantable pulse generator. During the first phase of the procedure, that patient is placed in the prone position in the operating room under light sedation. Using mostly local anesthesia for pain control, the tined lead is introduced into the medial aspect of the S3 foramen via a posterior approach. Fluoroscopic guidance is used to plan the insertion point and assess the depth of the lead. By stimulating the guide wire and then the lead, confirmation of good placement is achieved in three ways: by looking for plantar flexion of the great toe, visualizing anal bellows (inward retraction of the anus), and asking the patient to report stimulation in the perineal area. Once a good response is confirmed, the lead is deployed in position and attached to a temporary external stimulator. The test phase is conducted over 1–2 weeks while the patient keeps a bowel diary. If the patient experiences a 50% reduction in incontinent episodes, the second stage of the procedure is completed. Alternatively, a temporary lead may be placed in the office setting with local anesthesia using bony landmarks to guide placement. If a good response is attained, this temporary lead is again attached to an external stimulator for 3–5 days.

During the second stage, the implantable pulse generator, similar to a cardiac pacemaker, is inserted deep in the gluteal fat, just above the gluteal fascia. If an office-based test phase with a temporary lead had been performed, the permanent tined quadripolar electrode lead is also placed during the second stage of the procedure. The patient controls the intensity of the stimulation and can also adjust which of the four electrodes is being stimulated using the control device. The device needs to be exchanged every 4–5 years to replace the battery.

Posterior Tibial Nerve Stimulation

This novel approach to the treatment of FI is borrowed from the treatment of overactive bladder syndrome and urinary incontinence. It can be thought of as a bridge between biofeedback and SNS, as it is a noninvasive attempt to retrain the anal complex through stimulation of the sacral nerve complex. Patients undergo percutaneous or transcutaneous tibial nerve stimulation in an outpatient setting for 30 minutes at a time for about 12 weeks. A systematic review recently found that both percutaneous and transcutaneous stimulation are effective modalities [98]. The cortical effect of posterior tibial nerve stimulation (PTNS) appears to be durable with time, even after the treatment sessions have ceased. At least, a 50% reduction in fecal incontinent episodes is seen in over two-thirds of patients [98–101]. Long-term follow-up beyond 2 years is not yet known, though it is clear that patients need to undergo monthly treatment to maintain the durability of the response, similar to biofeedback. The fact that this treatment combines the similar multimodal benefits of SNS with the minimally invasive appeal of biofeedback may make PTNS a potentially desirable treatment for moderate FI for many patients who are willing to undergo a full course of treatment.

Currently, PTNS is done in the presence of a physical therapist in an outpatient facility. A surface electrode or needle electrode is placed just posterior and caudal to the medial malleolus of one elevated leg with the patient awake in the lying or sitting position. If a needle electrode is used, the goal is to place it near, but not directly into, the posterior tibial nerve. A ground pad is placed and the stimulator is activated for 30 minutes. Pulse stimulation is performed and correct placement of the electrode is confirmed by visualizing flexion or fanning of the toes and plantar flexion of the foot. Sensory stimulation may also be reported by the patient on the plantar aspect of the foot. The patient typically undergoes 1 or more sessions per week over a course of 12 weeks. Changes in the number of FI may not be noticed immediately and typically occur after multiple sessions. PTNS is not approved for treatment of FI in the United States, but is being used for this indication elsewhere in the world.

FECAL DIVERSION

Antegrade Continence Enema

The antegrade continence enema (ACE), also known as the Malone procedure, is the most commonly described in the pediatric population. It can be helpful in both children and adults, especially in those with colonic dysmotility resulting in overflow FI. This most commonly occurs in institutionalized patients or those with neurogenic bowels due to spina bifida. In this population, the ACE procedure is done in combination with surgical treatment for neurogenic bladder and overflow incontinence [101,102]. It allows for the patient to effectively flush out the colon daily in a controlled setting to avoid the problem of overflow incontinence. There are very few studies that describe long-term outcomes of the ACE in adults with FI. It is also important to note that many patients do not continue to perform antegrade enemas in the long term [103]. In those that do use the ACE, 75% of patients report significant reduction in FI and most have improved quality-of-life scores [104–106]. Problems with the procedure include infection and leakage or stenosis of the access site that may require a revision. Thus, it is a procedure worth considering in a very select adult patient population.

There are many variations of the ACE procedure. In essence, an access point to the bowel is brought to the skin. The distal ileum, appendix, cecum, and even left colon have been used as access points. The appendix is the most commonly used, as it can be inverted at the level of the skin to act as a channel for the irrigation catheter. The procedure should be laparoscopically performed, if feasible, to enhance recovery. After the access point is left fixed to the skin, a catheter is left in place for a few weeks to allow for the site to mature. The patient or caregiver is educated on how to perform intermittent catheterization of the access point. Then, large volumes of water or a bowel cleansing solution are used to flush the colon every 1 to few days. Both water and cleansing solutions are effective and the choice largely depends on patient preference and effectiveness. By evacuating the colon in a timed and controlled setting at home, the patient is able to perform daily and social activities without the fear and inconvenience of overflow FI. While this may seem to be a burdensome procedure, it can afford selected children and adults better hygiene and social independence throughout the day.

Stoma

The only way to completely eliminate the risk of FI is to create a stoma. Patients are often worried about the social stigma and embarrassment of a colostomy or ileostomy and so are often hesitant to proceed, unless the symptoms are severe. It should be considered, though, to be a very well-tolerated option for those with severe incontinence. Unless the patient has impaired colonic transit, a colostomy is preferred over ileostomy due to thicker and more formed stools from a colostomy, which are easier to manage. In the current era of minimally invasive surgery, a diverting colostomy can be laparoscopically created to minimize the morbidities of surgery, including bleeding, infection, incisional hernia, and cardiac or respiratory complications. Anecdotally, many patients with severe FI are very happy once they proceed to colostomy and find it to give them much more freedom in their daily lives. In fact, a study of patients with FI found that patients with a colostomy had significantly higher general quality of life and FI-related quality-of-life scores, compared to those with FI [107]. Others have found that 80% of patients who underwent colostomy for FI are satisfied and state they would choose the procedure again [108]. Therefore, in the event that other treatment modalities have failed, we must not forget to offer this treatment option to patients with severe FI.

95 Rectal Prolapse and Other Causes of Fecal Obstruction

Susanne D. Otto, Kaven Baessler and Jörn Gröne

DEFINITION AND CLASSIFICATION

Rectal prolapse is a circular invagination of all layers of the rectal wall in a longitudinal direction [1,2]. The prolapsed segments are situated in the aboral intestinal lumen and may protrude outside the anus.

A distinction is made between internal and external rectal prolapse [3–5]. Internal rectal prolapse is also designated as intussusception, a condition in which the intestinal wall folds into itself like a telescope. The prolapsed rectal segments are situated in the ampulla or anal canal and do not protrude externally (Figure 95.1a). Depending on the level, a distinction is made between rectorectal and rectoanal intussusception. External rectal prolapse is the true form of rectal prolapse in the strictest sense. Here, the prolapsed parts emerge through the anus either spontaneously or while straining and are visible outside the body (Figure 95.1b).

Rectal prolapse is often clinically classified into Grades 1–3. Grade 1 corresponds to internal prolapse or intussusception. Grade 2 refers to protrusion through the anal canal while straining. Grade 3 denotes a prolapse externally visible even at rest (Table 95.1). Another classification, the Oxford rectal prolapse score, focuses on internal prolapse and thus on x-ray defecography findings (see Table 95.2) [6,7].

Special forms of prolapse are partial rectal prolapse and mucosal prolapse. Partial prolapse does not involve circular protrusion; only part of the wall slides out—usually the anterior wall. Mucosal prolapse does not involve all wall layers; only the mucosa protrudes, and here too the affected area is usually the anterior rectal wall.

EPIDEMIOLOGY

Rectal prolapse can basically occur at any age. Its annual incidence is approximately 2.5 per 100,000 people [8]. There are two incidence peaks. The first one is seen among children during the first 2 years of life. The incidence among adults gradually increases with age and reaches a second peak in women during the seventh decade of life. Affected men are somewhat younger than women on the average. The incidence is markedly higher in women than men with a female-to-male ratio of approximately 9:1 [8].

ETIOLOGY AND PATHOPHYSIOLOGY

The etiology of rectal prolapse is multifactorial. Risk factors include chronic constipation, obesity, connective tissue or muscle weakness, and in women vaginal delivery and multiparity. The pathogenesis of the disease has not been fully clarified. A number of possible explanations have been proposed. In 1912, the Hungarian surgeon, Alexis Victor Moschcowitz, developed the sliding hernia theory [9]: the hernial orifice is situated in the anal canal at the pelvic floor; the hernial sac is the anterior rectal wall. The theory is supported by typical concomitant features such as an elongated sigmoid colon, a mobile mesorectum, lax lateral ligaments, and pelvic floor weakness. Today, the hernia is considered to be the consequence rather than the cause of the disease. Rectorectal invagination is thus considered to mark the onset of the disease, the earliest phase in the development of complete rectal prolapse. The emergence of cineradiography first enabled Broden and Snellman to radiographically substantiate this theory in the 1960s [10]. This is in keeping with the conical high-pressure zone radiographically detected by Shafik et al. at the rectosigmoid junction [11]. This zone resembling a bottleneck may be regarded as the starting point of invagination. In addition, various neurological changes have also been linked with rectal prolapse [12,13].

The prolapsing tissue narrows the intestinal lumen. In contrast to stenosis, this is a dynamic effect that is augmented by straining during defecation and thus leads to functional stenosis. This typically causes severe defecation disorders that may also be designated as obstructed defecation. Due to secondary pelvic floor and sphincter damage, incontinence usually becomes a predominant problem later in the course of the disease.

SYMPTOMS

Rectal prolapse is associated with a variety of symptoms (Table 95.1). Grade 1 is often completely asymptomatic and in that case has no disease status. However, functional stenosis during defecation can cause abdominal complaints, defecation disorders, a sensation of bulging in the rectum, and thus a feeling of incomplete evacuation. Those affected may have frequent or prolonged defecation times or require digital support during defecation. In Grade 2, many patients additionally experience soiling and mild incontinence symptoms. Patients can touch the prolapsed intestine during defecation and push it back in place. Grade 3 is usually characterized mainly by gross incontinence. Ulceration and bleeding may occur in the prolapsed mucosa. Patients are at risk for incarceration and gangrene [2,14,15].

Patients often have a considerably reduced quality of life and markedly restricted social life [8]. Evacuation is painful and is perceived to be psychologically degrading. Fecal incontinence leads to fear of embarrassing situations in everyday life and thus results in social isolation.

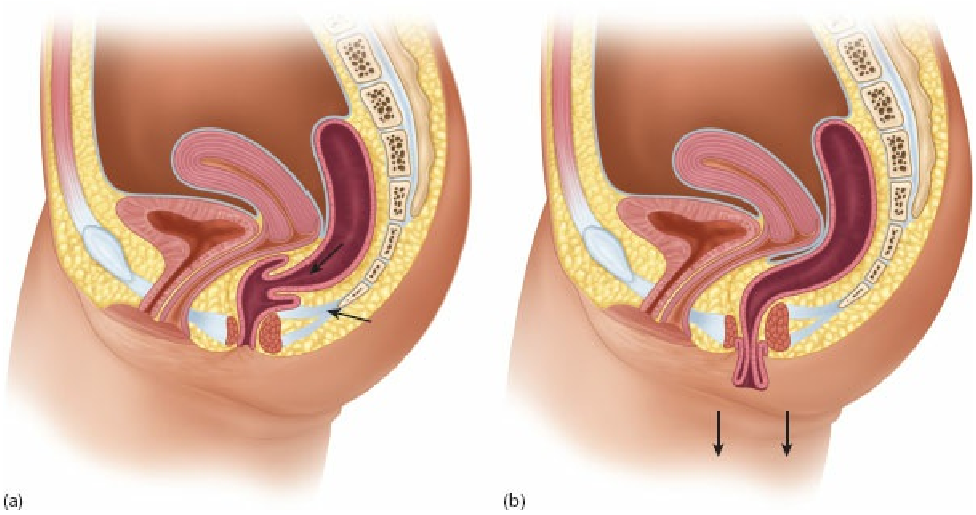

Figure 95.1 (a) Internal rectal prolapse (intussusception) and (b) external rectal prolapse.

Table 95.1 Clinical Classification of Rectal Prolapse

Grade	Definition	Typical Symptoms
1	Internal prolapse (intussusception)	Asymptomatic or impaired evacuation
2	External prolapse during straining	Impaired evacuation, incontinence
3	External prolapse at rest	Incontinence, bleeding, ulcerations, gangrene

Table 95.2 Oxford Rectal Prolapse Score

Grade	Definition
1	High rectorectal intussusception
2	Deep rectorectal intussusception
3	High rectoanal intussusception
4	Deep rectoanal intussusception
5	External rectal prolapse

DIAGNOSIS

Clinical Assessment

Grade 2 and 3 rectal prolapse show the typical clinical picture with circular mucosal folds (Figure 95.2) and can thus be clearly differentiated from anal prolapse with its radial mucosal folds. Prolapse is classified as Grade 3 if present at rest and as Grade 2 if the rectum protrudes only during straining maneuvers [14]. It can usually be pushed out most easily in a squatting or sitting position. Digital rectal examination often reveals reduced resting and squeeze pressure.

Rectoscopy, Manometry, Endosonography

Rectoscopy, manometry, endosonography, and coloscopy are used as complementary measures. They can indicate the extent of prolapse and possibly exclude concomitant diseases [2,16]. Rectoscopic signs may include mechanical irritation of the mucosa and ulcerations (ulcus simplex, typically on the anterior rectal wall). Manometry documents the frequently reduced resting and squeeze pressure. Endosonography can demonstrate alterations or injuries in the anal sphincter, and coloscopy can exclude important differential diagnoses like cancer.

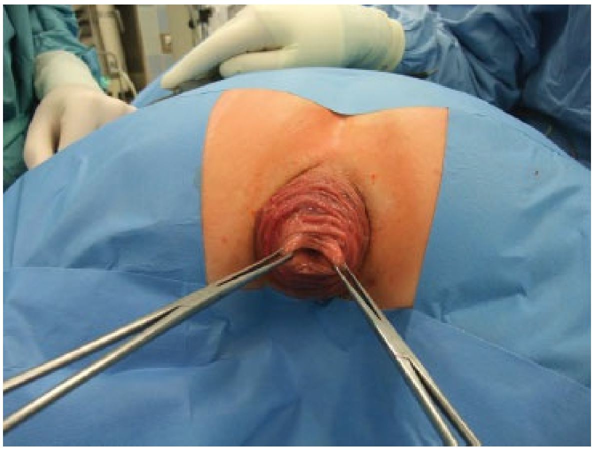

Figure 95.2 External rectal prolapse.

Diagnostic Imaging

Cinedefecography is performed to detect Grade 1 rectal prolapse (intussusception) [2,16]. This dynamic examination during defecation can demonstrate a functional obstruction that only becomes manifest in the defecation process (Figure 95.3a and b). Defecography also enables reliable differentiation from rectocele.

CONSERVATIVE TREATMENT

Depending on the clinical findings, conservative management is possible in Grades 1 and 2. It consists of dietary measures to promote bowel regularity (high-fiber food, plenty of fluids), laxatives, stool softeners, pelvic floor exercises, and biofeedback [14].

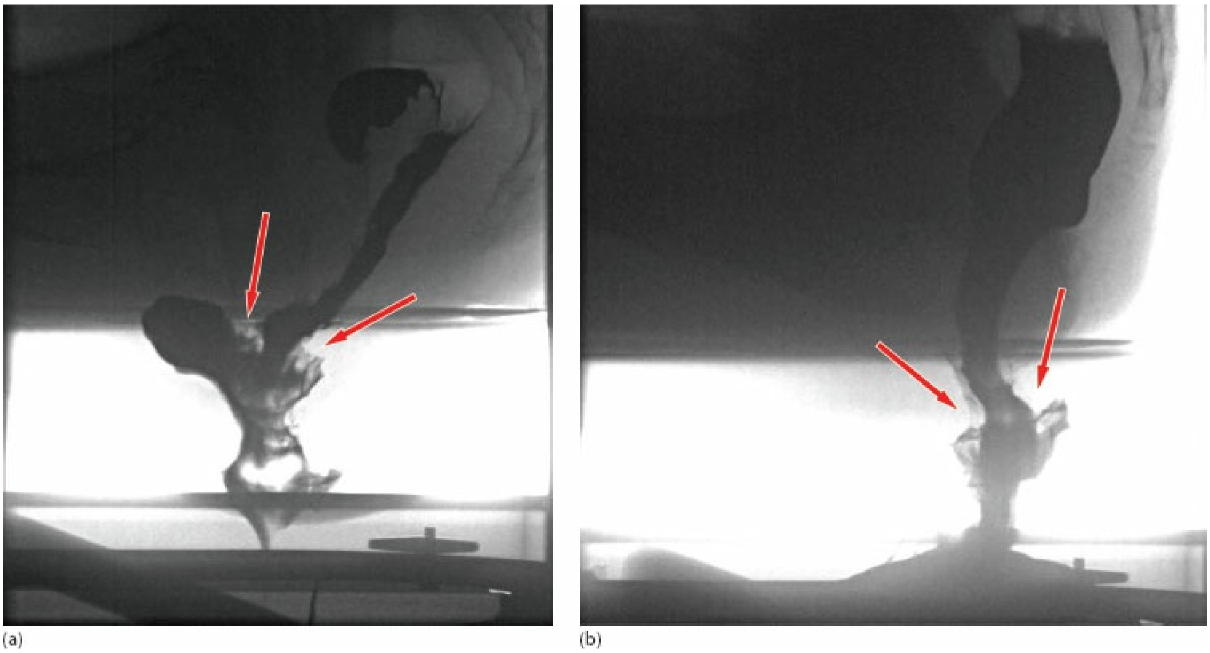

Figure 95.3 (a, b) Two cases with radiographic intussusception (arrow).

SURGICAL TREATMENT

Surgical Indication

The only potentially curative treatment for rectal prolapse is surgery [1]. It does not regress spontaneously or with conservative treatment in adults. Nevertheless, the indication is always dependent on the clinical symptoms and the success of conservative therapy. The general operability of the mostly older patients has to be considered. Intussusception (Grade 1 rectal prolapse) without clinical symptoms may be an incidental imaging finding and is not an indication for therapy [17]. Grade 3 rectal prolapse, on the other hand, is always an indication for surgery, since complications such as ischemia and bleeding may occur if left untreated.

Surgical Methods

There are many different surgical methods for treating rectal prolapse. The aim of all procedures is anatomical correction to improve bowel function and reduce prolapse-related symptoms. However, there are basic differences in the technical implementation of this principle: the surgical approach can be either abdominal or perineal. The abdominal procedure can be performed by either open or laparoscopic surgery [18]. According to the surgical technique, a distinction is also made between bowel fixation (rectopexy), bowel resection (sigmoidectomy), and a combination of the two (resection rectopexy) [1].

There is no gold standard or clear evidence-based recommendation as to which method is most suitable [1]. Relapse rates reported in the literature are mostly lower for abdominal than for perineal interventions. This procedure is therefore recommended particularly for younger and otherwise healthy patients [3,4,19,20]. On the other hand, perineal procedures are associated with lower morbidity and mortality. Thus, they are generally recommended for older and multimorbid patients [4,19]. Some authors have achieved favorable results with laparoscopic abdominal surgery in older people and therefore recommend this type of surgery for these patients [21–23]. Current surgical procedures will be presented in this chapter.

Abdominal Procedures: Rectal Resection and Rectopexy

Abdominal procedures can be performed by open or laparoscopic surgery. Various studies have demonstrated less stress and a faster recovery for patients undergoing laparoscopic interventions. However, these studies have a low evidence level [1].

Sudeck published one of the first studies on rectopexy in 1922. The mobilized rectum was fixed to the presacral fascia with sutures. This method was further developed and modified in various ways. The Wells procedure supplements fixation by placement of synthetic mesh in the presacral space [24]. The Ripstein procedure entails wrapping synthetic mesh around the anterior rectal wall and fixing it to the sacrum on both sides [25]. A newer approach is the Orr-Loygue laparoscopic ventral rectopexy [26]. It is a nerve-sparing procedure, since rectal mobilization and fixation with sutures or synthetic mesh is only performed anteriorly. Though very good results have been published for this method, randomized controlled trials are lacking [27,28].

A procedure that combines rectopexy with resection is the resection rectopexy as described by Frykmann und Goldberg. Very good results have also been published for this frequently applied surgical method [28]. It involves complete circular mobilization of the rectum up to the pelvic floor musculature and resection of the rectosigmoid colon. The rectum is then fixed to the promontory with sutures or by placing synthetic mesh anterior to the sacrum. A lower rate of postoperative constipation had been reported for resection rectopexy than for -pexy without resection [1,19]. However, resection also harbors the risk of anastomotic leak and is thus associated with an increased complication rate.

The material used for rectal fixation also varies widely and includes meshes made from synthetics such as polypropylene, although fixation can also be performed with simple sutures or laparoscopic staples. No clear evidence-based recommendations have been made as to what material is most suitable [1].

Perineal Procedures: Rehn–Delorme, Altemeier, STARR

The Rehn–Delorme procedure involves circular resection of the mucosa of the prolapsed rectum approximately 1 cm above the dentate line. The corresponding muscle layer is unfolded and fixed above the sphincter with single button sutures (Figure 95.4) [1,29]. This procedure can be used for prolapse up to 10 cm long.

The Altemeier procedure entails transanal full-thickness resection of the prolapsed segment. The distal rectal wall is resected approximately 1 cm above the dentate line. The rectum should be proximally mobilized beyond the prolapse. The anastomosis is hand-sutured or mechanically created with a circular stapler [1].

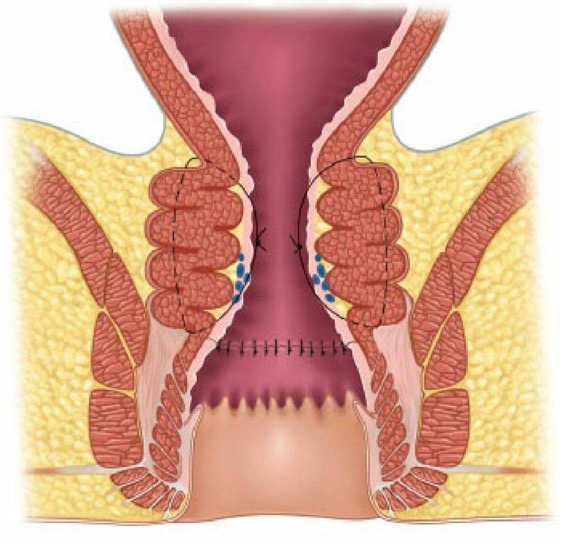

Figure 95.4 Principle of Rehn–Delorme procedure: after isolated circular resection of the mucosa with preservation of the lamina muscularis propria, the corresponding muscle layer is unfolded and fixed above the sphincter with single button sutures.

The STARR operation (stapled transanal rectal resection) is a relatively simple procedure that can be performed for small prolapses with a maximum length of 5 cm. Full-thickness rectal resection is performed here too. The anastomosis is approximately 2 cm above the dentate line. It is important to avoid entrapping any part of the vagina in the staple line, since this may result in necrosis and sepsis [30].

Treatment of Pediatric Rectal Prolapse

Rectal prolapse is usually treated conservatively in small children, since it tends to regress spontaneously by the time they reach the age of 3 [31,32]. Therapy consists of dietary measures to promote bowel regularity and enemas if necessary. Open or laparoscopic suture rectopexy may be performed in rare cases where spontaneous regression does not occur. The rectum is mobilized and fixed to the periosteum of the sacral promontory [33].

COMPLICATIONS AND PROGNOSIS

If left untreated, external rectal prolapse can lead to ulcerations and bleeding. Particularly in Grade 3, patients are at risk for incarceration, gangrene, and sepsis [1]. However, even surgery carries no guarantee of success. Data on complications and relapses vary widely. A complication rate of about 10% and a relapse rate of approximately 6%–15% are reported in the literature [20,21].

The initial complaints—impaired evacuation and incontinence—persist in some patients even after surgery. The literature reports a 30%–40% persistence rate with a higher rate for perineal than for abdominal interventions [20]. Previously masked incontinence may only become manifest after surgical correction of rectal prolapse for impaired evacuation. This means that patients should be informed in detail that their functional problems may not improve even by surgery [4,20].

OTHER CAUSES OF OBSTRUCTED DEFECATION

Obstructed defecation is defined as difficulty in evacuating the rectum despite the urge to defecate [34]. This leads to incomplete evacuation, frequent and prolonged defecation, digital support during defecation, and rectal pain. The most frequent cause is internal rectal prolapse (intussusception), as described previously [34]. Other causes are enterocele, or rectocele. Rectocele involves bulging of the rectal wall, usually anteriorly, due to expansion of the rectovaginal septum. This is often asymptomatic. Symptomatic cases primarily receive conservative treatment as described for conservative management of rectal prolapse. Surgical correction is only performed if relevant symptoms persist despite conservative therapy [35]. Other possible causes of obstructed defecation are neurological disorders such as multiple sclerosis or spinal cord injuries. Treatment is difficult. If possible, the underlying disease is treated, and the patient also receives conservative therapy as described earlier [36,37].

SYNOPSIS

Obstructed defecation is defined as difficulty in evacuating the rectum despite the urge to defecate. The most common cause is rectal prolapse. A distinction is made between internal rectal prolapse (intussusception), where impaired evacuation is the predominant symptom, and external rectal prolapse, which leads to fecal incontinence. The only definitive treatment is surgery. The approach can be either perineal or abdominal. While perineal procedures have a lower complication rate, the relapse rate is lower after abdominal procedures. However, both procedures often fail to improve the initial complaints. Thus, it is necessary to carefully select patients for surgery and provide patients with detailed informed consent. Other causes of obstructed defecation are enterocele, rectocele, neurological disorders, and spinal cord injuries.

Laparoscopy and Robotics

96 Section Introduction: The Role of Laparoscopic Surgery in Urogynecology

Anthony R.B. Smith

INTRODUCTION

The role of laparoscopic surgery in urogynecology is still unclear. This is partly due to a lack of robust evidence supporting the use of the laparoscopic approach to urogynecological procedures and partly due to a lack of training opportunities for both young and older surgeons. The lack of robust evidence of added value for the laparoscopic approach enables those who are resistant to change to maintain their position.

This area has become more complicated by the increased accessibility to robotic surgery, meaning that some surgeons have been able to avoid the difficulties of learning standard laparoscopic surgical techniques by moving straight to robotic surgery.

The chapters in this section provide a comprehensive review of the different laparoscopic urogynecological surgical procedures that have been reported. The term “minimally invasive surgery” has been used for laparoscopic surgery but is misleading because it suggests that the risk of complications is minimized. The potential risks and reported complications of this type of surgery are reviewed and the management discussed.

The role of robotic surgery is reviewed, and the health economics of both laparoscopic and robotic surgery are evaluated.

The vesicoscopic approach to surgery involving the bladder is also covered by a team who have developed the skills to approach such difficult surgery by an alternative route. It is important that such surgery is fully evaluated by teams who have the necessary experience and skills before adoption by others is considered.

97 Pelvic Anatomy through the Laparoscope

Fiona Reid

INTRODUCTION

Knowledge of anatomy is required to perform safe and effective surgery. However, anatomy is usually presented in a format that is not directly relevant to surgeons.

Performing surgery also alters the anatomy as it is traditionally described. There is sometimes a degree of variation in anatomy that is not emphasized in anatomical texts but that can be of significance to surgeons.

The aim of this chapter is to present anatomy in a format that is directly relevant to laparoscopic surgery.

LAPAROSCOPIC ENTRY

The most obvious difference between open and laparoscopic surgery is the method used to access the surgical field.

Insertion of Veress

If pneumoperitoneum is created using a Veress needle, it is commonly introduced at the umbilicus. In theory, it is more effective to introduce the Veress through the base of the umbilicus rather than the inferior margin because the amount of tissue traversed is less at the base, even in obese patients (Figure 97.1).

Adhesions

Brill et al. [1] demonstrated that previous surgery increases the incidence of adhesions of the omentum or the bowel to the anterior vaginal wall. Following a previous Pfannenstiel incision, 27% of patients had adhesions and 55% had adhesions following a previous midline incision below the umbilicus. Therefore, insertion of the Veress at the umbilicus when there is a previous midline incisions could be associated with increased injury to the bowel or omentum. This risk can be reduced by insertion of the Veress needle at Palmer’s point.

Palmer’s point is located in the left hypochondrium within 3 cm of the ribs in the lower margin in the midclavicular line (Figure 97.2). It is important to exclude splenomegaly by palpation. There is no rectus sheath at Palmer’s point so only a single click is felt with the insertion of the Veress through the peritoneum.

Alternative points of insertion of the Veress include midline insertion approximately halfway between the umbilicus and the symphysis pubis. This has the advantage of avoiding potential injury to the great vessels, but the abdominal wall may be very thick in obese patients.

Another alternative is to use the Hasson open laparoscopic entry technique. This may reduce vascular but not bowel injury. This is discussed in more detail in Chapter 102.

Insertion of Ports

The safe insertion of laparoscopic ports requires knowledge of the vasculature of the anterior abdominal wall and the great vessels.

The Great Vessels

Nezhat et al. [2] demonstrated that the cephalocaudal relationship between the umbilicus and the aortic bifurcation varies widely, regardless of body mass index. The position of the aortic bifurcation can range from 5 cm cephalad to 3 cm caudal to the umbilicus. The bifurcation was more likely to be caudal to the umbilicus if the patient is in the Trendelenburg position rather than horizontal. Therefore, most surgeons prefer to insert the primary umbilical port with the patient in the horizontal position.

The aorta bifurcates into the common iliac vessels. The inferior vena cava lies to the right of the aorta and is formed by the joining of the common iliac veins below the level of the aortic bifurcation.

It is this relationship that accounts for injuries to both the right common iliac artery and the left common iliac vein during insertion of a single trocar (Figure 97.3).

Usually, the bifurcation of the aorta is at the level of the fourth lumbar vertebrae; however, it can be between L3 and L5. The vena cava almost always bifurcates below the level of the aortic bifurcation at L5; however, this can also vary from L4 to S1.

These variations are significant to insertion of the primary trocar and dissection of the peritoneum sacral promontory during a sacrocolpopexy.

Insertion of Secondary Ports

The most important structures to identify prior to insertion of lateral secondary ports are the inferior epigastric vessels. The origin of the inferior epigastric artery is from the external iliac artery just before it passes under the inguinal ligament. The origin is approximately midway along the length of the inguinal ligament, and from there, its path is toward the umbilicus. Transillumination will not reliably identify the inferior epigastric vessel. It should be directly visualized; however, in the obese, this can be difficult. The inferior epigastric vessels are found approximately 1 cm lateral to the obliterated umbilical artery (Figure 97.4).

The inferior epigastric vessels lie medial to the deep inguinal ring, which can be identified by following the round ligament to its insertion into the inguinal canal.

The inferior epigastric is a branch of the external iliac artery (Figure 97.5).

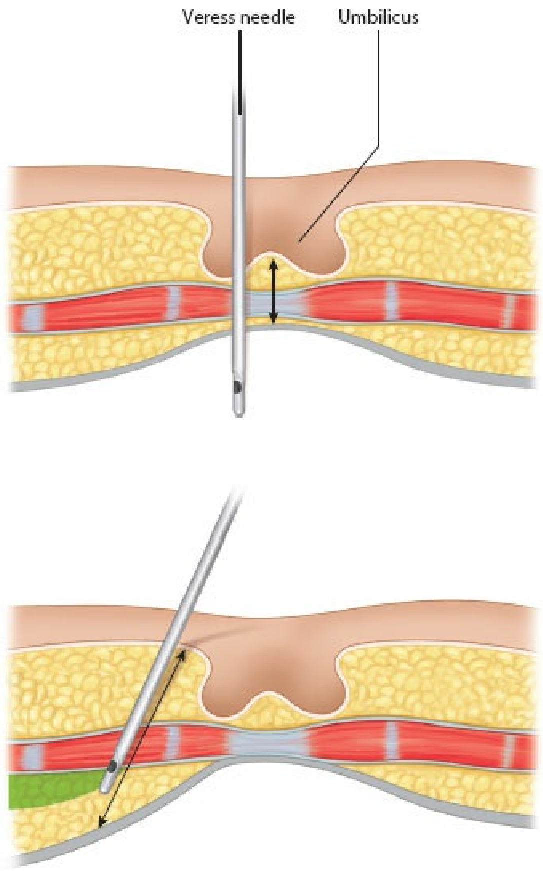

Figure 97.1 Insertion of the Veress needle through the umbilicus.

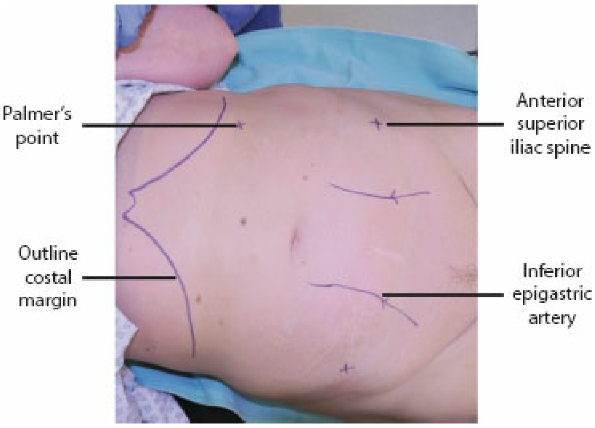

Figure 97.2 Surface anatomy.

Figure 97.2 demonstrates that the flow of blood in the inferior epigastric artery is caudal to cephalad. Hence, if it is injured during secondary port insertion, suturing should be performed caudal to the injury.

The first lumbar nerve divides into the iliohypogastric nerve and the ilioinguinal nerve that traverse the anterior abdominal wall as shown in Figure 97.6. Laparoscopic surgery, by avoiding large abdominal wall incisions, may prevent transection of the iliohypogastric and ilioinguinal nerves, which can lead to cutaneous anesthesia of the pubic region, the inside of the thighs and labia majora, as well as weakness of the muscles of the anterior abdominal wall predisposing to hernia formation.

However, secondary ports placed close to the anterior superior iliac spine may lead to nerve injury during placement or postoperative pain due to nerve entrapment during closure of the port site.

PRESACRAL SPACE

The presacral space begins at the aortic bifurcation and descends to the pelvic floor. It may be entered by pulling the rectosigmoid colon to the left side of the pelvis and incising the peritoneum vertically to the right of the attachment of the sigmoid peritoneum to the posterior pelvis. The dissection begins caudal to the bifurcation of the aorta and proceeds toward the hollow of the sacrum.

Obese patient may have increased fat over the sacral promontory that can make the promontory more difficult to visualize.

In such cases, it may be necessary to use an instrument to feel the edge of the promontory.

The anterior and upper margin of the first sacral vertebrae bulges forward and is known as the sacral promontory (Figure 97.7). Surgeons commonly describe attaching polypropylene mesh to the sacral promontory; however, the attachment is usually cranial to the promontory at the level of the fifth lumbar vertebrae, not the sacrum.

When opening the presacral space, at this level, there is a potential to injure the left common iliac vein that crosses the fifth lumbar vertebrae from left to right to join with the right common iliac to form the inferior vena cava (Figure 97.7).

During laparoscopy, the raised intra-abdominal pressure created by the CO_2 gas can cause compression of the left common iliac vein. This could lead to injury of the vessel during attachment of polypropylene mesh to the spine. To prevent this, surgeons should be aware of the “pillow sign.” When the spine is felt with an instrument, there is a slight softness and a rebound—similar to pressing a pillow (Figure 97.8).

The middle sacral vessels could also potentially be injured during the attachment of the mesh to the anterior longitudinal ligament of the spine as they emerge from under the common iliac vein and descend toward the sacral hollow. Wieslander et al. [3] studied the variation in vascular anatomy of the presacral space in 52 unembalmed females and concluded that although it was possible to identify an avascular area in each cadaver, it was not possible to define a general “safe” avascular zone.

The sympathetic nerve supply to the abdomen comprises two ganglionic trunks and a network of nerves covering the surface of the aorta. The lumbar splanchnic nerves from the left and right trunks unite below the bifurcation of the aorta to form the superior hypogastric plexus. These nerves carry the sympathetic nerve supply to the pelvis. Some nerve fibers pass over the anterior surface of the fifth lumbar vertebrae and may be damaged during the attachment of the mesh to the anterior longitudinal ligament of the spine.

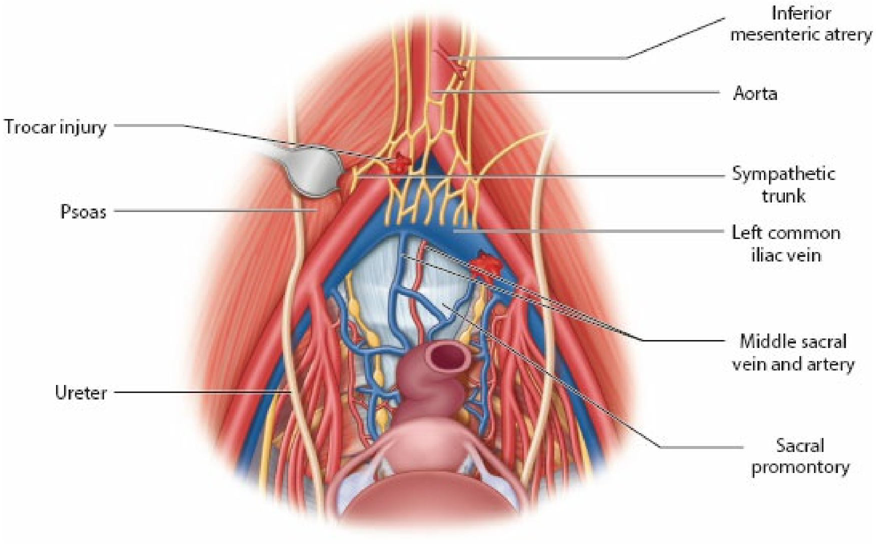

Figure 97.3 Trocar injury to the right common iliac artery and the left common iliac vein.

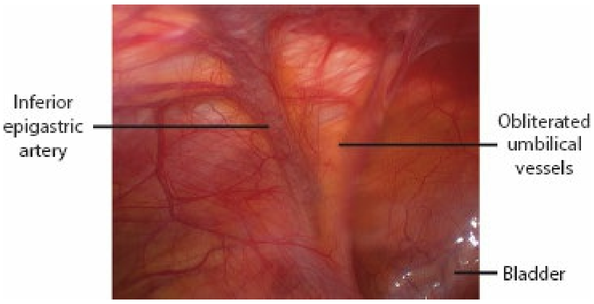

Figure 97.4 Left inferior epigastric vessels.

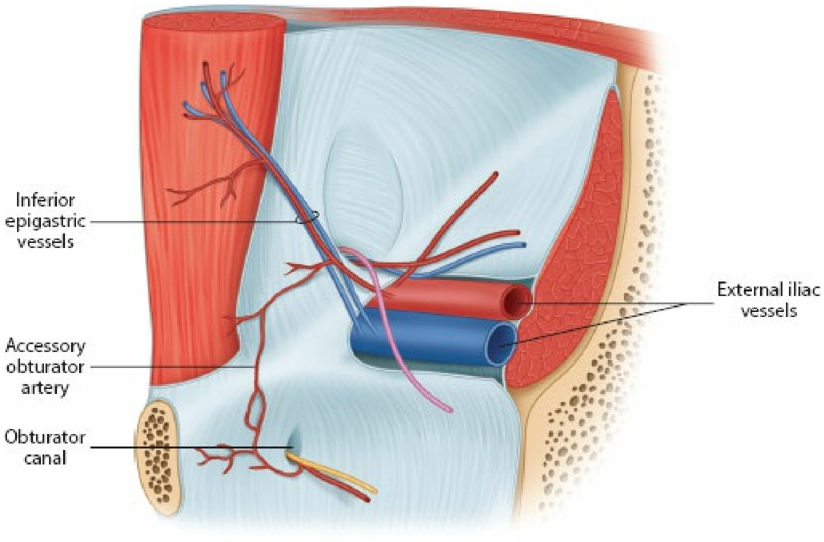

Figure 97.5 Origin of the inferior epigastric vessels

The presacral space is opened during a sacrocolpopexy to attach polypropylene mesh to the spine, and then the dissection is continued caudally to reach the vaginal vault. To the right and lateral to the dissection, the right ureter crosses over the bifurcation of the common iliac vessels and descends along the pelvic sidewall (Figure 97.9).

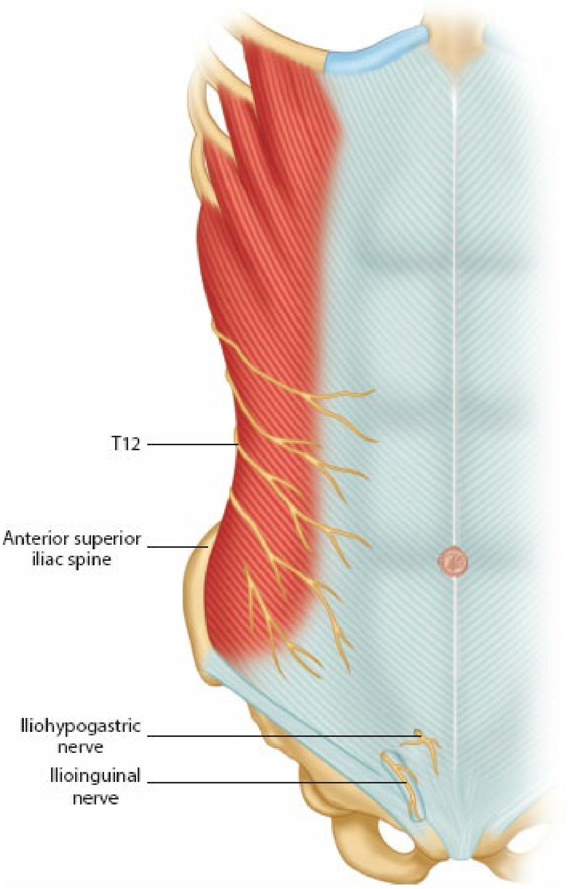

Figure 97.6 Nerves crossing the anterior abdominal wall.

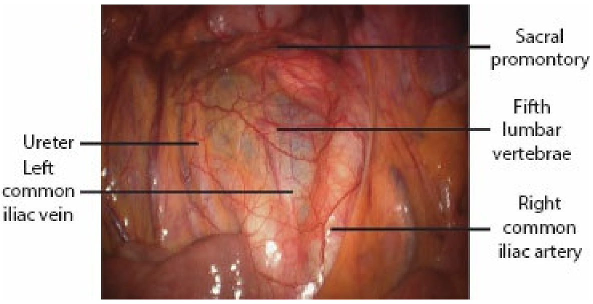

Figure 97.7 Course of the left common iliac vein.

The ureter then passes toward the origin of the uterosacral ligaments. It normally lies only 1–3 cm from the ligament, and this relationship can be altered by endometriosis or previous surgery.

One of the major advantages of the laparoscopic approach is the degree of magnification provided. This is demonstrated in Figure 97.10, showing the peritoneum being opened over the sacral hollow.

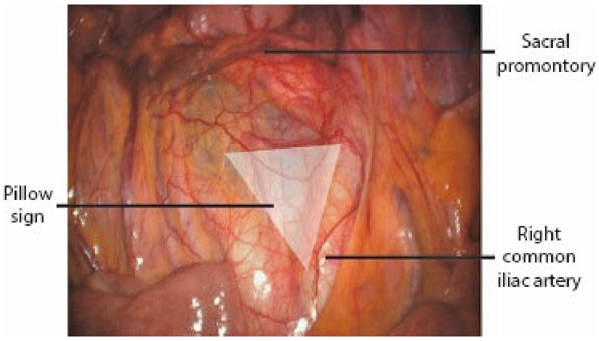

Figure 97.8 Area of pillow sign.

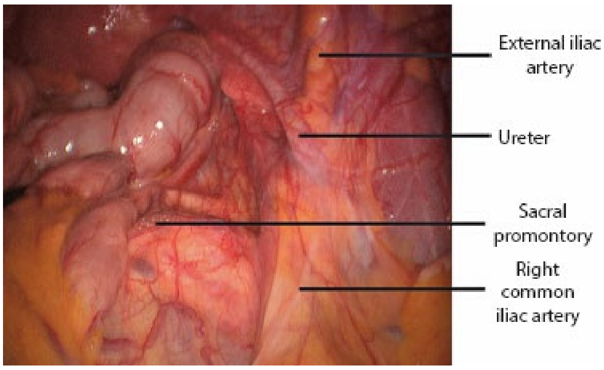

Figure 97.9 Sacral promontory.

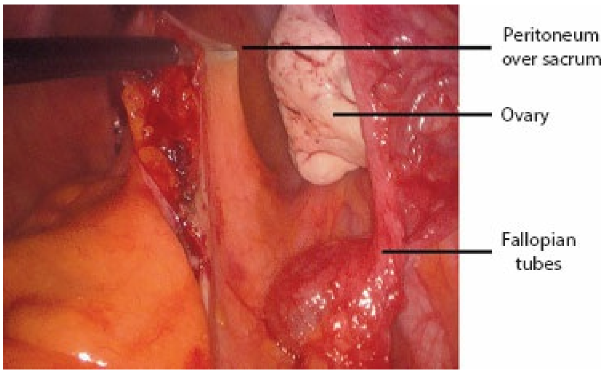

Figure 97.10 Magnification of structures.

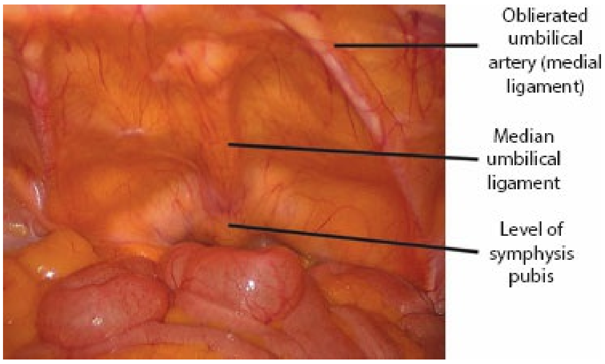
RETROPUBIC SPACE: CAVE OF RETZIUS

The retropubic space (cave of Retzius) is a potential space that lies behind the symphysis pubis and in front of the bladder. It is opened to perform both Burch colposuspensions and paravaginal repairs. The sidewalls are composed of the pubic bone and obturator internus muscle. It normally only contains a venous plexus covered with lose adipose tissue (Figure 97.11).



Oblierated umbilical artery (medial ligament)
Median umbilical ligament
Level of symphysis pubis

Figure 97.11 Umbilical ligaments.

The obliterated umbilical arteries are remnants of the fetal circulation. Occasionally, they will remain patent even in adults. They are branches of the internal iliac arteries. The obliterated umbilical arteries can be used as lateral markers for entry into the cave of Retzius; however, if they are not adequately diathermied prior to cutting, they may retract and bleed extensively (Figure 97.11).

There are inconsistencies in textbooks about alternative names for the obliterated umbilical arteries. Some refer to them as the medial umbilical ligaments [4] and others as the lateral umbilical ligaments [5]. The most logical nomenclature would seem to be that lateral umbilical ligaments are the condensation of peritoneum over the inferior epigastric vessels, while the medial umbilical ligaments are equivalent to the obliterated umbilical arteries.

The median umbilical ligament is another remnant of a fetal structure, the urachus. It runs from the dome of the bladder to the umbilicus. It can occasionally remain patent causing a urachal fistula to the umbilicus. All the umbilical ligaments can bleed when surgically divided.

The retropubic space can be opened 2–4 cm above the dome of the bladder. Sometimes, it is helpful to fill the bladder with 200–300 mL saline or methylene blue to enable its margins to be seen. In the midline, anterior to the bladder at the level of the pelvic floor are the urethra and dorsal vein of the clitoris that should be avoided. The space is bound laterally by the obturator canal and the arcus tendineus fasciae pelvis (white line) (Figure 97.12).

The obturator artery is a branch of the internal iliac that runs on the lateral wall of the pelvis to the obturator canal. In about 25% of the population, an aberrant obturator artery arises from the inferior epigastric or external iliac artery. In some cases, both a normal and an aberrant obturator artery are present; the aberrant artery is then called an accessory obturator artery (Figure 97.5).

The superior boundary is the symphysis pubis and the pectineal ligament (Cooper's ligament) (Figure 97.13).

The obturator nerve (Figure 97.12) arises from the lumbar plexus (L2–L4). It enters the true pelvis through the greater sciatic foramen and then runs in the extraperitoneal fat along the lateral wall to reach the obturator canal. It then divides into an anterior and posterior branch to supply the medial thigh muscles.

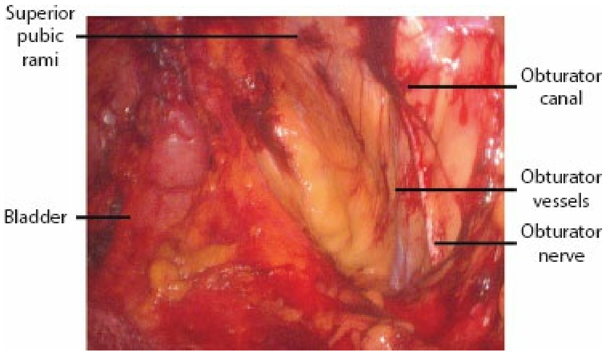


Figure 97.12 Right lateral wall of the retropubic space.

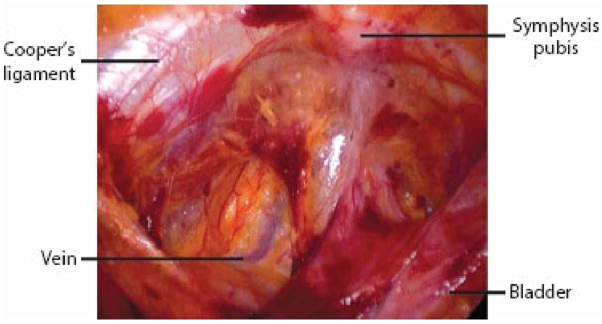

Figure 97.13 Superior boundaries of the retropubic space.

The arcus tendineus fasciae pelvis (white line) is a tendinous arch that originates at the back of the symphysis pubis and runs along the posterior aspect of obturator internus muscle to the ischial spine.

Cooper's ligament (the pectineal ligament) is a strong aponeurotic lateral continuation of the lacunar ligament along the iliopectineal line of the pubis.

ACKNOWLEDGMENT

I am grateful to Harry Heyes of the Medical Illustrations Department of Central Manchester Foundation Trust for producing the illustrations used in this chapter.

98 Training and Accreditation in Laparoscopic and Robotic Pelvic Floor Surgery

Karl Jallad, Marie Fidela R. Paraiso, and Alfred Cutner

DECREASED SURGICAL EXPERIENCE

There is a growing concern that the surgical training of doctors is not sufficient to meet the needs of new graduates [1]. With the advancement of science, newer medical therapies have replaced traditional surgical approaches. Residents and fellows in the United States are now bound to work a maximum of 80 hours per week, reducing the time spent in operating rooms and getting sufficient surgical training. In the United Kingdom, the situation is even more extreme with the European 48 hour week working time directive. Newer technologies are constantly emerging making it difficult for surgeons to become proficient and for hospitals to control credentialing. These are important if patients are to be offered new procedures in a safe operating environment.

All trainees are now expected to be skilled in laparoscopic surgery. Robotic surgery is a requirement in some urological procedures in the United Kingdom and for both gynecology and urology in the United States. Alongside developing new skills, the trainee is also required to attain skills in traditional surgery. Thus, despite reduced hours, the trainees are required to learn a greater variety of skills than in the past. In addition, the length of training has remained unchanged. This has led to the emergence of young graduating surgeons who are not confident enough or ready to operate independently.

In addition, due to medicolegal implications, the concern for OR time, and patient awareness of the medical system, it is now less acceptable to practice on patients [2].

The trend is now shifting toward increased training outside of the operating room by using simulators. The hope is to provide more uniform training and use objective data to grade and certify surgeons. Simulators are accessible to all levels of training, including medical students, residents, fellows, and attending surgeons [3]. They can be used for initial training, and also for evaluation, testing, or recertification purposes.

LAPAROSCOPIC SIMULATION

There are three types of simulators available on the market: box trainers, virtual reality simulators, and augmented reality trainers.

The box trainers are usually plastic boxes built to simulate an abdominal cavity into which real instruments can be inserted [2]. They are relatively inexpensive, provide realistic haptic feedback, and can be coupled with animal or cadaveric material to provide realistic anatomy. However, they require mentors for accurate scoring and do not provide objective performance metrics. There are various models available on the market: the Fundamentals of Laparoscopic Surgery (FLS); Society of American Gastrointestinal and Endoscopic Surgeons, Los Angeles, CA; and eoSim (eoSurgical, Edinburgh, Scotland, United Kingdom). Multiple studies have demonstrated the educational value of the FLS simulator training in surgical residency curricula [4]. At present certification in the FLS is required by the American Board of Surgery for graduating residents though the American Board of Obstetrics and Gynecology has not implemented this requirement. However, a number of institutions require the FLS certification prior to privileging staff in laparoscopic surgery.

In the United Kingdom, all trainees attend a basic surgical skills course, which includes some basic simulator training in laparoscopic surgery, but there is very limited requirement for sign-off. Surgically, the most advanced absolute requirement for all gynecologists is the ability to manage an ectopic pregnancy laparoscopically.

The virtual reality simulators provide a computer-generated environment mimicking real-life scenarios. They facilitate objective scoring without the presence of a mentor and allow for a large number of varied scenarios. However, they are very expensive, require frequent maintenance, and do not exactly replicate haptic feedback of real surgery [2]. Available models on the market are the LapSim® (Surgical Science, Gothenburg, Sweden), LAP Mentor™ (Simbionix™, Cleveland, OH) [5], and MIST VR (Mentice Medical Simulation, Gothenburg, Sweden).

The earliest virtual reality simulators provided no feeling of resistance. Given that surgery relies heavily on the sense of touch and haptics, the virtual reality simulators could not reproduce the more realistic feel provided by the box trainer. With a virtual simulator, one cannot test different suture materials or check the integrity of a knot. However, with improved technology, newer models now mimic real-life scenarios. Despite being more expensive initially, virtual reality simulators do not require a constant change of equipment and supply of suture material. More importantly, virtual simulators eliminate the need to have a supervisor to assess, time, and grade the performance. This is of particular importance in residency programs and surgical training centers where transparency and objective scoring are mandatory.

Newer models on the market now combine both technologies. The augmented reality trainers provide a realistic haptic feedback and objective metric recording; however, they are expensive and are prone to vision tracking system malfunction. Available products on the market are ProMIS™ (Haptica, Dublin, Ireland, and the United Kingdom) and TrEndo (Delft University of Technology, Delft, the Netherlands). With improvement in technology and the advent of new companies, the field of virtual simulators and box trainers is growing exponentially and will undoubtedly play an even more important role in training the surgeons of the future.

A recent Cochrane review to assess the benefits and harm of supplementary virtual reality training of surgeons, with limited laparoscopic experience, revealed that virtual reality training appears to decrease the operating time and improve the operative performance of surgeons with limited laparoscopic experience when compared with no training or with box trainer exposure [6]. However, the authors further discussed the need to perform well-designed trials to assess the impact of virtual reality training on clinical outcomes and the need to control for inherent risk of bias in those studies.

SIMULATOR FOR THE DA VINCI® SURGICAL SYSTEM

The Intuitive Surgical® Skills Simulator that is offered for the *da Vinci Si* Surgical System is based on Mimic's proprietary simulation technology, MSim™. With the growing concern for safety and importance of rigorously preparing the next generation of surgeons, initial training outside of the operating room has become the norm. The dv-Trainer provides an extensive array of various scenarios with a gradual increase in level of complexity. Surgeons performing the tasks are timed and objectively graded with scores compared to experienced surgeons. Simulators provide the residents, fellows, and surgeons flexibility of access to training and more importantly offer a safe environment away from the patients. Multiple studies were performed and demonstrated face, content, and construct validity that is clinically relevant [7,8]. The dv-Trainer is a great introduction to robotic surgery and an invaluable tool to be used for training.

LAPAROSCOPIC SUTURING

Once a surgeon decides to use a simulator, he or she should pick the one that best fits his or her needs. As described earlier, this will depend on the area of deficiency, cost, and location of training. Invariably, one should set goals and objectives and gradually progress from minor skills to complex tasks. It is imperative to train regularly and keep track of progress. One can use a simple notebook and keep track of the time, repetitions, and completed tasks. The more sophisticated virtual simulators have complex computing systems that allow the surgeons and mentors to assess individual or group progress and store valuable information.

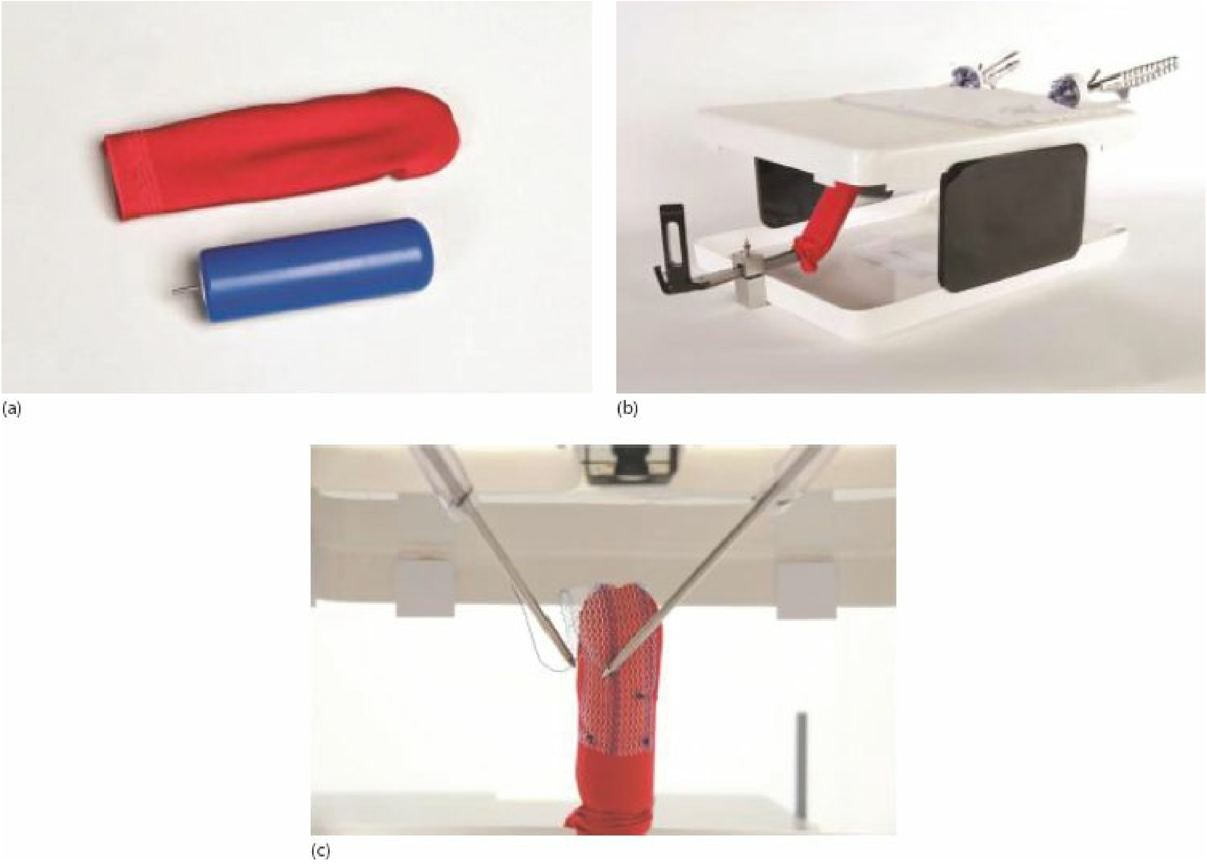
In order to perform a complex task like suturing, the apprentice first starts by appreciating depth perception, followed by exploring different instruments and then grasping and touching specific objects. The next step focuses on grasping the needle and learning how to correct its orientation until it is perpendicular to the tip of the instrument. This is a crucial step that the novice surgeon should master perfectly well before attempting more complex tasks. The next step involves grasping the tissue or sample with the nondominant hand and using the dominant hand to drive the needle in. It is imperative to accurately pronate the wrist and enter the tissue at a 90° angle and then gradually advance the needle and supinate the wrist. Once the needle emerges from the tissue, the surgeon should grasp the needle tip with the nondominant hand and gradually release tension off the dominant hand and complete the task. The needle is then transferred back to the dominant hand in the proper orientation ready for another tissue pass. The most difficult task that trainees have to acquire is the ability to operate with both hands working together. This skill is required for all areas of advanced laparoscopic surgery.

ADVANCED LAPAROSCOPIC SKILLS IN MINIMALLY ACCESS SURGERY AND UROGYNECOLOGY

The three main procedures that require advanced laparoscopic skills in urogynecology are sacrocolpopexy, sacrohysteropexy, and colposuspension. The first is a requirement of most modern practicing urogynecologists, whereas the places of the last two have yet to find their definitive place.

Performing these advanced procedures requires advanced surgical skills. These include a knowledge of hemostatic devices, retroperitoneal dissection, and suturing. One has to incorporate fine dissection technique, master extensive intracorporeal and extracorporeal suturing, and have a thorough understanding of pelvic anatomy. Despite the required advanced surgical skills, there is no specific mandatory laparoscopic training for fellows specializing in urogynecology. In the United Kingdom, the subspecialty-training program enables attainment of skills for sacrocolpopexy either open or laparoscopic. However, a more detailed training in laparoscopic urogynecology has yet to be established. This is in marked contrast to other areas or advanced minimal access surgery. It is interesting that there is no political drive to develop training programs despite the recent U.S. Food and Drug Administration [9] and UK Medicines and Healthcare Products Regulatory Agency [10] guidance relating to the establishment of vaginal mesh surgery outside structured training.

Recently, Tunitsky-Bitton et al. [11] developed a model to simulate laparoscopic sacrocolpopexy (Figure 98.1). They measured construct validity by comparing observed masked performances on the model between experienced female pelvic medicine and reconstructive surgeons and upper-level trainees. Experts performed significantly better than trainees in the total score and in every domain of the Global Operative Assessment of Laparoscopic Skills scale. More importantly, the majority of the subjects “agreed” or “strongly agreed” that the model was authentic to the live procedure and a useful training tool [11]. The use of such model could be used in fellowship programs to gradually initiate the trainees and hopefully improve safety, efficiency, and OR time. Given that this is a new and emerging approach to training, further randomized controlled studies will be needed to better assess the potential clinical impact of such models.



(a)
(b)
(c)

Figure 98.1 (a–c) Simulated laparoscopic sacrocolpopexy.

Simulators can also be used when one has to master the steps to perform a rare procedure. Ureteral anastomosis is a complicated procedure, and even in the busiest centers, fellows will not have enough exposure to become proficient at the end of their training. Tunitsky et al. [12] proposed an authentic and useful simulation model and were able to demonstrate evidence of construct validity. Fellows can now train outside of the OR and perfect their skills in preparation to real-life scenario.

Despite the fact that it is widely accepted that the initial learning and practice of laparoscopic surgical technique should occur in a simulated environment, there is still no available standardized curriculum established by the obstetrics and gynecology, minimally invasive surgery, or urogynecology societies. At present, laparoscopic training still varies widely among our institutions. The American Board of Surgery requires graduates to be FLS certified that greatly helps in standardizing laparoscopic surgical training. At the Cleveland Clinic Foundation in Ohio, fellows in Female Pelvic Medicine and Reconstructive Surgery are expected to train in a dry lab prior to performing a specific procedure on patients. In addition, prior to participating in laparoscopic procedures, all fellows must successfully complete the FLS training program. In order to pass the the FLS training program, the trainee must demonstrate proficiency in performing five laparoscopic skills: peg transfer, precision cutting, ligating loop, and suturing with extracorporeal and intracorporeal knot-tying. To pass the FLS training program, the trainee must demonstrate proficiency in performing five laparoscopic skills: peg transfer, precision cutting, ligating loop, and suturing with extracorporeal knot and intracorporeal knot.

In the United Kingdom, currently, there is no accredited training program, sign-off, or reaccreditation in laparoscopic urogynecology. Anyone who states that they have the ability can perform these procedures. A recent Coroner's verdict in Australia, following an inquest into two deaths following laparoscopic sacrocolpopexy, was critical of the lack of formal accreditation in laparoscopic surgery in some countries. The report from the coroner stated:

> It surprised the Court that elective surgery of the complexity involved in (these cases) carrying as it does a risk of harmful injury however small, can be carried out by medical practitioners whose qualifications and expertise to perform this surgery are in large part based upon self teaching, word of mouth and

reputation but not upon objective assessment of the practitioner's skill as might be evidenced by formal training, examination and certification by a professional institution.

CREDENTIALING

The process of credentialing varies depending on the institution. It is in place to verify that the surgeon can safely complete a procedure as intended and recognize potential complications. It is based on initial training, board certification, and ongoing experience. With the emergence of novel surgical modalities, credentialing now plays an even more crucial role. During their training, residents and fellows in the United States are required to maintain a detailed log of the number of cases they perform. In order for the residents to graduate in obstetrics and gynecology, they need to perform at least 60 laparoscopic cases of which 20 are hysterectomies.

The surgeon seeking privileges to perform laparoscopic surgeries must submit a case list including his or her role (resident, fellow, primary surgeon, etc.) with a brief description of procedures and complications. The surgeon must include a letter from the program director or chair stating whether the candidate can independently and competently perform a specific procedure. The requirement to maintain privileges is usually determined by the chief of a department and its governing body. Depending on the performance, the surgeon might be recertified, monitored, or even requested to undergo additional training and proctoring. The American Association of Gynecologic Laparoscopists (AAGL) recently published guidelines for institutions granting privileges for gynecologic surgery using laparoscopic techniques. The ultimate goal is to provide the highest quality of care and standardize the training and accreditation process.

Robotic surgery has emerged in recent years. While some residency and fellowship programs provide adequate robotic training, most physicians have had minimal exposure. In this situation, initial certification depends on the completion of online training module, completion of at least 2 hours of bedside training for docking and 1 hour of hands-on training with inanimate training aids, demonstration of competency on a robotic simulator, and participation in a live pig lab.

To maintain privileges, a surgeon must perform a minimum of 20 robotic procedures each calendar year. If the surgeon fails to meet the minimum number, he or she would require a proctor on the next case or must achieve a score of at least 85% on robotic simulator.

The situation described relates to the United States and is not currently applicable in the United Kingdom despite a recognized advanced special skills module in urogynecology and a well-established subspecialty-training program.

Minimally invasive surgery is a growing field and is constantly evolving. The use of simulators provides an alternative and safer modality for training. They are now being used for evaluation, testing, and recertification purposes. The ultimate goal is to improve the patient safety, do no harm, and provide the best possible care. A robust system of training, certification, and monitoring should reassure patients that their surgery will be performed by surgeons who have the appropriate skills to complete their surgery to the highest standard.

There is no set learning curve and indeed skill with other laparoscopic operations, and general dexterity skills will have an impact on the numbers required to be competent at these procedures. The trainee who has developed advanced skills such as suturing in the training laboratory will translate these in the operating theater environment. Each trainee will thus have a different learning curve, and perhaps initial credentialing is better being competency based rather than numbers based.

It would appear in line with other, often less complex, operation, that the surgeon carrying out laparoscopic urogynecology should perform a minimum of 20 operations involving retroperitoneal dissection and suturing per year.

99 Laparoscopic Colposuspension and Paravaginal Repair

Arvind Vashisht and Alfred Cutner

INTRODUCTION

Damage to the urethral sphincter and/or to mechanisms pertaining to its function is believed to be determinants in the pathogenesis of urinary stress incontinence. Undoubtedly, genetic and lifestyle factors that determine connective tissue strength and function are relevant in the etiology of stress incontinence. Pregnancy, childbirth, and in particular vaginal delivery are causative risk factors [1,2], and the condition may often present for the first time during pregnancy or postpartum.

Treatment options will need to take into account the patients' age, comorbidities, and medical and surgical history. Conservative treatment may suffice. The role of a multidisciplinary approach is important. If symptoms are refractory and the woman wishes surgical treatment, there is a range of possible surgical options.

Surgical techniques evolve over time. Maintaining treatment efficacy and reducing morbidity remains key in the evaluation and uptake of such procedures. In many units, the previous gold standard, open colposuspension procedure, has been superseded by midurethral tape surgery, with a drive toward quicker patient recovery. The numbers of colposuspensions performed and surgeons undertaking such procedures have diminished over the past 20 years [3,4]. Laparoscopic colposuspension, the modern-day colposuspension, has persistently had a place in urinary stress incontinence surgery, with those trained in the procedure advocating its use for women who are young, those with significant urethral mobility and anterior compartment prolapse, those requiring other concomitant abdominal surgery to the pelvis, or those with previous failed midurethral tape surgery.

Currently, there is renewed interest in laparoscopic colposuspension. This is due to concerns over midurethral tape surgery and an increasing number of procedures to treat tape-related complications [3]. This resurgence is driven by its efficacy, safety, and patient choice. This chapter will provide a revision of the surgical technique and indications. It will provide an update on the efficacy and morbidity for laparoscopic colposuspension and compare it to other surgical methods.

COLPOSUSPENSION

Although the Burch colposuspension was first described in 1961 [5], the Tanagho modification is now considered the standard method by which a colposuspension should be performed [6]. However, colposuspension is taken to be synonymous with Burch colposuspension, which is neither in the case semantically nor in the reporting of the literature. Colposuspension merely refers to elevating the vagina, or "colpos."

The first report in the literature of a laparoscopic colposuspension was by Vancaille and Schuessler in 1991 [7]. This was not in fact a Burch but rather a modification of the Marshall–Marchetti–Kranz procedure [8]. The authors suspended the vagina with two nonabsorbable 2-0 sutures on either side of the bladder neck to the pubic symphysis as they were unable to clearly visualize Cooper's ligaments. The first actual report of a laparoscopic-modified Burch colposuspension was in 1993 by Liu and Paek [9]. They used two absorbable sutures to elevate the vaginal tissue to Cooper's ligaments.

Variations in Procedure

The various methods of colposuspension described in the literature are shown in Table 99.1. To carry out a modified laparoscopic Burch colposuspension, there are two different methods of entry into the cave of Retzius, either trans- or extraperitoneal. We will later describe in detail the method of transperitoneal laparoscopic Burch colposuspension as carried out in our unit.

The extraperitoneal approach involves accessing the preperitoneal space and dissecting into the cave of Retzius. Either a Veress needle can be placed in a suprapubic site or a cutdown technique with dissecting balloons can be used. In addition, a gasless laparoscopic colposuspension procedure using extraperitoneal balloon dissection followed by a mechanical abdominal wall retractor has been described [12]. Once a pneumo-Retzius has been obtained, the additional ports are inserted. Typically, two operative 11 mm trocars are used just above the pubic hairline and close to either side of the midline, but the procedure can be performed with one suprapubic operating 5 mm port and a 5 mm port for the laparoscope. The colposuspension is then carried out in the same manner.

The advantage of the extraperitoneal approach is reduced risk of injury to intra-abdominal organs and quicker dissection time. In particular, the incidence of bladder injury is reduced. However, it is not possible to inspect the abdominal contents or to carry out additional intraperitoneal procedures at the same time. In addition, the reduced access of this approach and the close port placement makes suturing more difficult. Thus, some authors adopting this approach changed to using mesh and tacks rather than sutures to carry out this type of colposuspension [13].

Apart from the approach to the cave of Retzius, the other variations in the literature relate to the type, number and size of ports, methods used for dissection, type and number of sutures, and whether mesh is used. In addition, there are variations in the type of knots used to elevate the vagina, but these are rarely expanded upon as it is assumed that they are all similar. However, it has been demonstrated in in vitro studies that different methods of knot tying result in different strengths [14,15]. There are also reports of bone anchors, staples, and clips being used to attach the suture to Cooper’s ligaments or the pubic ramus [16–18].

Table 99.1 Different Methods Used to Suspend the Vagina

Author	Year	Method
Vancaille and Schuessler [7]	1991	Nonabsorbable sutures to pubic symphysis
Ou et al. [19]	1993	Hernia mesh and surgical staples
Liu and Paek [9]	1993	Absorbable sutures to Cooper’s ligaments
Carter [22]	1996	Laparoscopic Stamey
Birken and Leggett [20]	1997	Mesh and staples
Breda et al. [21]	1996	Handheld needle
Das [18]	1998	Bone anchors
Kiilholma et al. [10]	1995	Glue
Shoemaker and Wilkinson [11]	1998	Telescopy
el Toukhy and Davies [51]	2001	Tacks
Zullo et al. [48]	2001	Staples
Ross et al. [23]	2002	Bipolar electrochemical energy
Ankardal et al. [50]	2004	Transperitoneal mesh and staples

As well as the standard Burch colposuspension, other methods have also been employed. A technique using mesh to suspend the vagina to Cooper’s ligaments has been described by several authors [19,20]. One or two pieces of Prolene mesh are inserted along the paravaginal fascia longitudinally, 2 cm lateral to the bladder neck on either side, and are fixed to Cooper’s ligaments with staples or tacks. A combined laparoscopic and vaginal approach using a handheld needle has been described [21]. This involves using one suprapubic port to create a pneumocavity in the space of Retzius. Two small suprapubic incisions are made on either side and a suture mounted on a specially designed handheld needle is passed through Cooper’s ligaments and through the lateral fornix of the vagina. The needle is then withdrawn after taking a second bite of the vagina and the vagina is fixed to Cooper’s ligaments with an extracorporeal knot. Carter described another variation, which was described as a laparoscopic Stamey procedure in 1996 [22]. Ross et al. [23] describe a technique using bipolar electrochemical energy to induce shrinkage of the paravaginal tissue causing bladder neck elevation in 94 women. They found that this resulted in 30% shrinkage of the tissue. None of these techniques have been studied in robust, randomized trials and should therefore be regarded as experimental.

Transperitoneal Burch Colposuspension Technique

We will detail the technique that we employ in our unit. Most of the steps are a result of copies and adaptations from the open technique and are subsequently refined over years of experience, many of which remain as yet without a solid evidence base, and some are likely to undergo ongoing evolution.

Preoperative counseling includes a full explanation of the risks of the procedure and the advantages and disadvantages compared to the open procedure. The risks include those of laparoscopic entry and laparoscopic surgery and those of the procedure itself. All women are consented for the possibility of requiring a concomitant elevation of apical support at the time of colposuspension. Preoperative bowel preparation is sometimes advised as it improves visualization of the operative field and reduces contamination in the event of a bowel injury [24]. In certain patient groups, and in particular the elderly or those with relevant medical comorbidities, one should be mindful of using laxative agents due to the risks of exacerbating pre- and perioperative dehydration, with knock on adverse renal function. Most commonly now, we suggest a preoperative bowel enema on the morning of surgery, which is generally equally satisfactory in achieving an empty and compliant rectum for easy mobilization during surgery.

A single intravenous dose of a prophylactic broad-spectrum antibiotic is given (we always use gentamicin providing no contraindications). The patient is prepared for surgery, cleaned, and draped. She is initially placed supine without any table tilt. The legs are placed in a lithotomy position at an angle of 30° at the hips. A size 14 Foley catheter with 10 mL of water in the catheter balloon is placed in the bladder and left on free drainage. We believe this size of catheter to be a sensible compromise allowing relative patient comfort postoperatively and of being of sufficient gauge to ensure free drainage of urine following the inevitable intraoperative manipulation of the bladder and urethra.

Our entry technique follows recommendations as set out in the Royal College of Obstetricians and Gynaecologists Green-top Guideline published in 2008 [25]. We normally use a Veress needle to obtain a pneumoperitoneum. An incision is made in the umbilical region, as it is at this point that the layers of the rectus sheath and peritoneum are fused. The patient is placed supine with no tilt and the needle is first directed toward the sacral promontory, and when the characteristic clicks of passing through the layers are felt, the needle is then directed toward the pelvis. A water test is used to confirm entry into the correct space and the abdomen is insufflated. Insufflation ceases when the preset pressure of 20 mmHg is achieved. The main 11 mm trocar is then placed through the umbilical region. The intra-abdominal pressure is then reduced to 15 mmHg. Where the patient is at high risk of bowel adhesions near the umbilicus from previous abdominal surgery, other sites for first port entry are considered. We use Palmer's point in high-risk cases (the left subcostal area in the midclavicular line) [26,27] (Figure 99.1). Palpation to identify the spleen is carried out prior to insertion of the Veress needle, and a nasogastric tube is inserted to reduce the chance of perforating an inflated stomach [28] (Figure 99.2). Where the patient is very thin, a Hasson entry technique is used to reduce the risk of vascular injury [29]. Some surgeons employ optical ports for first port entry.

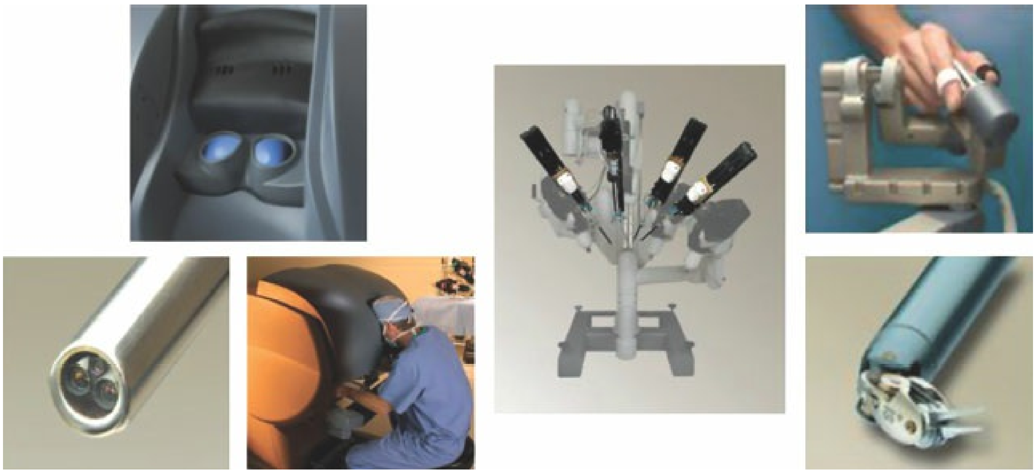

Figure 99.1 Veress needle entry at Palmer's point.

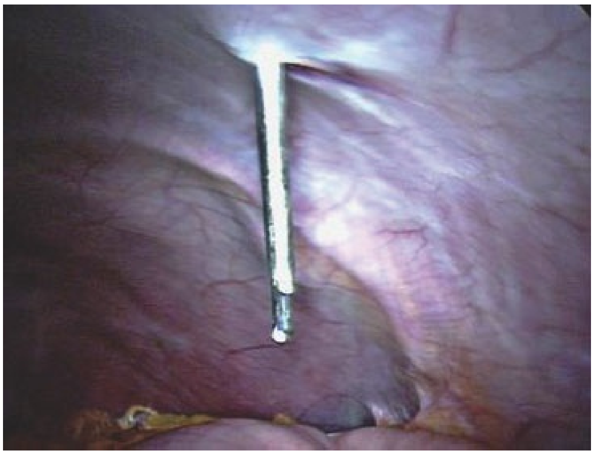

Figure 99.2 Dilated stomach visible in the left subcostal region. To prevent injury to the stomach when inserting the Veress needle subcostally, a nasogastric tube is inserted to deflate the stomach.

Once the laparoscope is inserted, the abdominal contents are examined and the patient placed in a head-down tilt. The placement of additional ports is important. All additional ports must be placed under direct vision to avoid injury to viscera or vessels. Ports should be placed either very lateral or medial to avoid the inferior epigastric vessels [30,31]. They should be placed so that adequate dexterity can be achieved during the operation. For laparoscopic colposuspension, we place two lateral 5 mm ports and one suprapubic 11 mm port. We use 11 mm ports with a variable top for ease of passing sutures into the abdominal cavity. This latter port is often inserted after the dissection into the cave of Retzius only to facilitate suturing: the surgeon can normally comfortably and ergonomically access the surgical space using instruments inserted into the two lateral ports. The lateral ports are placed at least 8 cm from the midline at the level of the umbilicus and inserted perpendicular to the skin to lessen the risk of epigastric vessel injury. We believe this to be the most ergonomically easy for operating in the pelvis. We do not use large ports laterally as these need to be formally closed to reduce the incidence of incisional hernias [32,33]. This closure can increase postoperative discomfort. Due to the size of the suprapubic incision routinely used, we do ensure that the rectus sheath is sutured closed beneath this port site. However, in our experience, this does not cause as much discomfort as deep lateral port closure.

Prior to the colposuspension, the abdominal cavity is assessed. If any additional surgery is required (such as hysterectomy or removal of adnexa), this is carried out prior to the colposuspension. However, the final step of some additional procedures, such as sacral promontory fixation in vault elevation surgery, is carried out after the colposuspension. Elevation prior to the colposuspension makes the latter more difficult to perform chiefly because of the ensuing reduced vaginal mobility on the (now well-supported) vaginal apex and proximal vaginal walls.

The bladder is initially filled with 300 mL of saline (this can be mixed with methylene blue) to aid identification of the superior edge of the bladder dome. The obliterated median umbilical ligaments are used as markers for entry to the cave of Retzius. They are incised 2–4 cm cephalad to the bladder dome (Figures 99.3 and 99.4). The cave of Retzius is dissected toward Cooper's ligaments. The bladder is then drained to enable better access to the paravaginal tissues (Figure 99.5). Dissection is performed with monopolar scissors on 60 W coagulation, or using an ultrasonic scalpel. Both types of energy source enable bleed-free tissue dissection. The dissection should avoid the urethra and the dorsal vein to the clitoris in the midline and the obturator neurovascular bundle laterally. This dissection will expose the pubic symphysis and bladder neck in the midline and Cooper's ligaments and the arcus tendineus fasciae pelvis laterally.

The bladder is retracted medially to allow the colposuspension to be performed. A pledget on a grasper with a marker thread (or a disposable pledget on a stick) is used for blunt dissection (Figure 99.6). Nonabsorbable No. 0 Ethibond® sutures are used for the colposuspension, as it is a permanent suture that has been traditionally used for the procedure. Other surgeons may use a slowly absorbable suture such as polyglycolic acid, with the reasoning that the medium- and long-term success of the procedure depends not on the strength of the sutures per se but the fibrosis they cause. In particular with a permanent suture material, one needs to be mindful of avoiding sutures being placed in the vagina or bladder. One suture is placed on either side at the level of the bladder neck. A second suture is then placed on each side in a slightly more cephalad position (Figures 99.7 and 99.8). A double bite of the vagina is taken with each suture to ensure a good amount of paravaginal fascial tissue is taken and the suture is then placed through the ipsilateral Cooper's ligament. Each suture is tied after insertion on limited tension using an extracorporeal surgical knot. The suture is tied to leave an approximate distance of around 1.5 cm between the ligament and paravaginal fascia. This is thought to give sufficient elevation of the bladder neck and yet still allow satisfactory postoperative voiding. If required, a surgical drain is left in the cave of Retzius. As with most surgery, the decision for leaving a drain will depend on surgeon's preference: we would use a drain if there had been above average blood loss noted during dissection. A cystoscopy is performed with a 120° scope to identify any sutures inadvertently placed in the bladder and to confirm that the ureters are patent by visualizing urine jets. In the unlikely event that sutures are seen in the bladder, these require immediate removal and replacement. We would suggest that visualization of ureteric jets is a good clinical practice and provides surgical reassurance of ureteric function, particularly if a concomitant procedure has also been performed. We have not come across ureteric obstruction during colposuspension, and indeed if ureters are stented during the procedure (for a separate indication such as a concomitant hysterectomy with the need for stent to aid visualization higher in the pelvis), it is apparent that the ureteric path would usually be well away from correctly placed sutures.

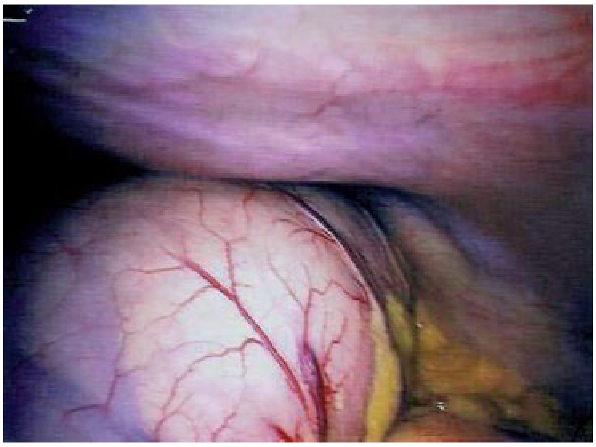

Figure 99.3 The median umbilical ligament is grasped cephalad to the bladder dome after filling the bladder with 300 mL of saline.

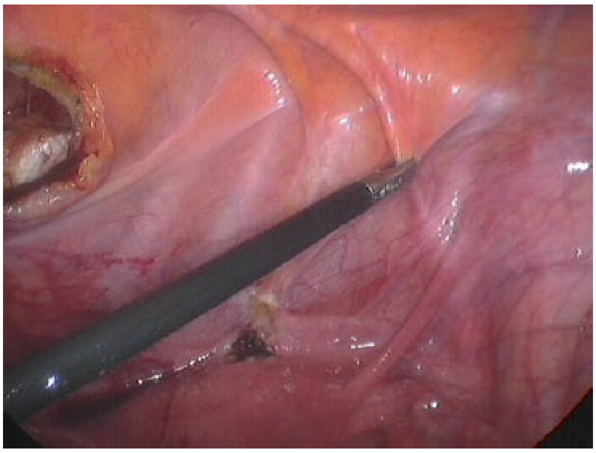

Figure 99.4 An incision is made in the median umbilical ligaments cephalad to the bladder dome to gain access to the cave of Retzius.

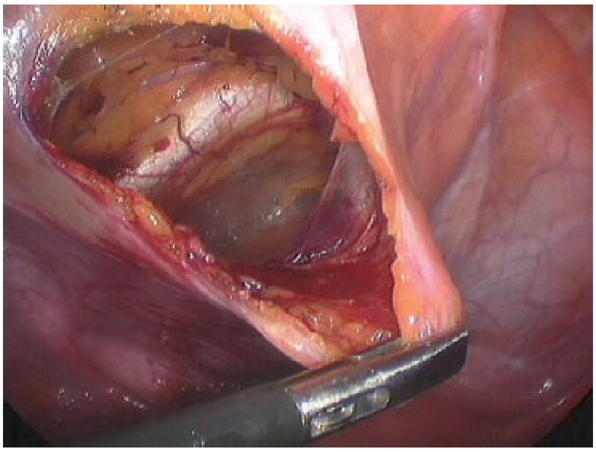

Figure 99.5 The cave of Retzius is dissected, clearly demonstrating the pubic symphysis and Cooper's ligaments.

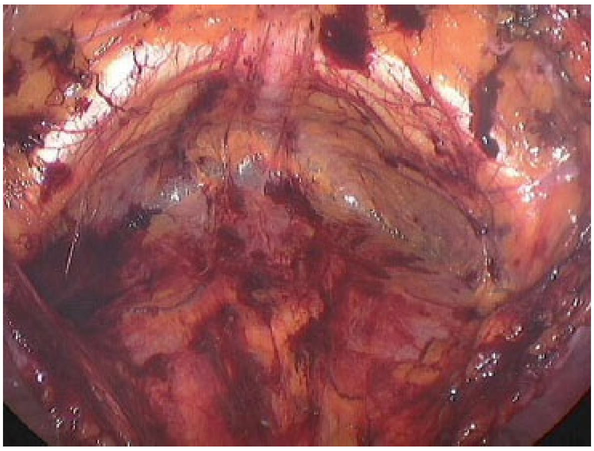

Figure 99.6 A pledget is used to dissect the bladder medially to allow suture placement.

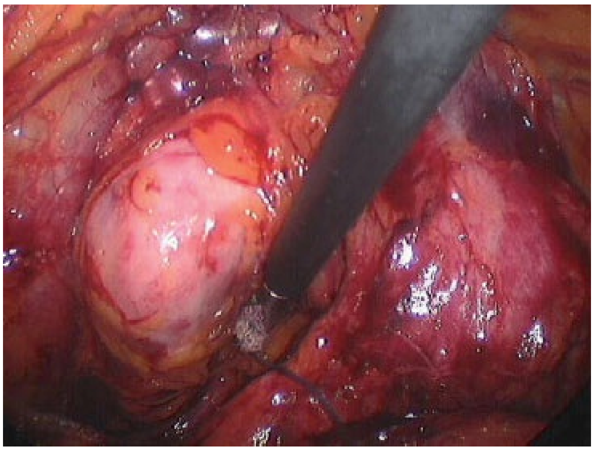

Figure 99.7 The first suture is placed at the level of the bladder neck.

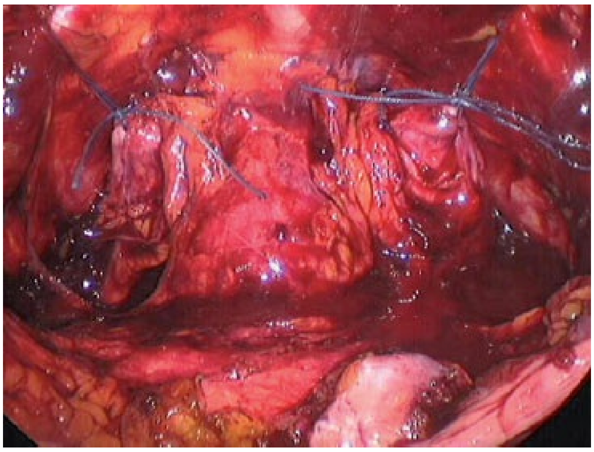

Figure 99.8 The second suture is placed cephalad to the previously placed suture.

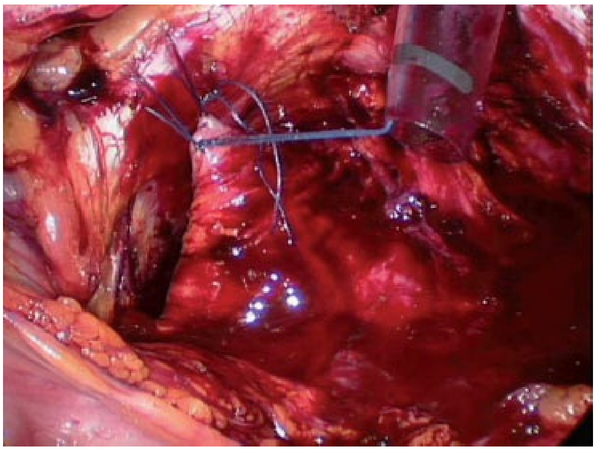

Figure 99.9 The ureter is dissected lateral to the uterosacral ligaments.

If preoperatively there is known to be significant uterine prolapse, then a concomitant laparoscopic hysterectomy and vault suspension or hysteropexy using mesh [34] or a suture is performed [35]. For some women, a hysterectomy may be the most appropriate and requested, but for others, a uterine conservation technique will be employed with a possible lowered morbidity. If it is clear preoperatively that a uterine or vault elevation procedure will be necessary, for ease of surgical access, preparation of the sacral promontory and uterosacral ligaments (or dissection of uterovesical and rectovaginal spaces in the case of a mesh hysteropexy) may be performed prior to the colposuspension (Figures 99.9 and 99.10). The rest of the hysteropexy is then performed following completion of the colposuspension.

At the end of surgery, an indwelling urethral catheter is usually left for 2 days in our unit, although the duration in other units may vary from overnight to 10 days. After the catheter is removed, a trial of void protocol is instituted. The postvoid residual is measured with a bladder scanner after the second void, the results of which determine the need for recatheterization. If the residual is high, the patient is discharged home with an indwelling catheter. An outpatient trial of void is carried out 1 week later. We no longer use suprapubic catheters. The use of bladder scanners and outpatient follow-up has removed the need of clamping and unclamping suprapubic catheters. This has resulted in less discomfort and earlier ambulation. In addition, the suprapubic catheter site can leave an unsightly scar.

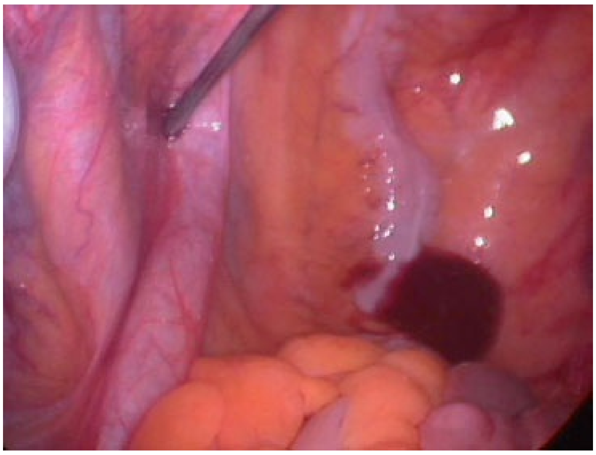

Figure 99.10 Both uterosacral ligaments have been shortened and plicated together in the midline.

Evaluation of the Role of Laparoscopic Colposuspension

In order to appropriately assess the role of laparoscopic colposuspension, a couple of questions need to be addressed: Colposuspension or not? And laparoscopic or not? Within these two questions, several factors need to be taken into consideration.

Open retropubic colposuspension has stood the test of time as a surgical procedure, both in the short and long term [36–38]. It has been shown to be similarly efficacious to traditional suburethral sling procedures [39] and minimally invasive sling procedures [40]. The indications will depend on patient and surgical preference. Due to the obvious increased recovery time and morbidity, particularly associated with the open procedure, the indications for colposuspension have narrowed. It is certainly useful as an option for those women who have significant anterior vaginal wall or bladder neck mobility, for those women undergoing other concomitant abdominal surgery, and for those women with previous failed midurethral tape surgery. Indeed, De Cuyper et al. reported the successful outcomes for laparoscopic colposuspension following failed midurethral tape surgery. In this retrospective study, subjective cure rates of 93% were reported at a median follow-up of 2 years [41]. In addition to this, we believe that there will be an inevitable rise in demand for effective alternatives to midurethral tape placement due to concerns arising from recent media and regulatory body alerts regarding synthetic slings [42].

The debates about laparoscopic surgery have raged since its inception as a surgical technique. We believe that laparoscopic surgery should be considered the same as open surgery but carried out through smaller incisions with longer instruments. The advantages of the laparoscopic approach are better visualization of the anatomy, less postoperative pain, and an earlier return to normal activities [43]. Although there is increased exposure and magnification deep in the pelvis, this is at the expense of less tactile feedback. As with any new procedure, however, there has been healthy skepticism of its merits and careful consideration of its risks. The problems cited have previously centered around efficacy, morbidity, cost, and operative duration. These problems in the early phase of laparoscopic surgery were, in part, explained by the limitations in the optics and the instruments available. Advances in these areas have enabled the surgeon to operate in a more dexterous manner. SynOptics launched the tube camera in 1978 and William Chang invented the first solid-state medical video camera in 1981. The first three-chip camera to be produced giving better clarity of vision arrived in 1989. The S-Video signal was developed in 1992 and the first digital zoom and digital enhancement capabilities were developed in 1999. There have been ongoing steps forward in image clarity with the advent of high definition and 3D technology. The next phase of ultrahigh definition (4K) is on the horizon. Alongside this, instrumentation has advanced to be ergonomically more suitable, further aiding surgical movements. Operating rooms have also been modified, with integrated theaters being developed, allowing the operating surgeon to modify the theater and equipment controls to their own desired settings. This theater environment potentially reduces stress and, hence, may result in enhanced surgical safety [44]. The development of robotic surgery may result in further advances [45] (Figure 99.11). However, as yet, there are no data to suggest any advantages in robotic urogynecology over the laparoscopic approach.

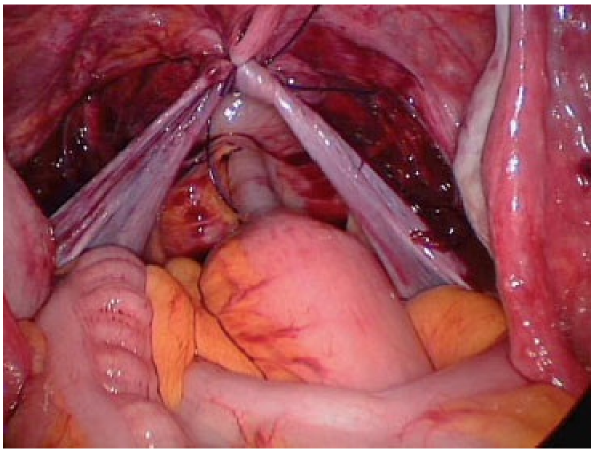

Figure 99.11 The “da Vinci” robotic surgical system.

Many studies have compared open colposuspension to laparoscopic colposuspension with variable success rates reported. Any discussion on laparoscopic colposuspension should be very similar to that of the open counterpart. The reported effectiveness of any of the procedures is reliant on the definitions of subjective and objective improvement and cure rates. Other compounding factors include surgical technique and experience. The requirement to learn new surgical skills for the different operative environment results in a learning curve, which has led some surgeons to develop “shortcut” surgery, and hence, new operations have been devised [46]. These are often given the same name as the traditional counterpart but must be assessed in their own right and should not be considered the same. Most alterations to the traditional approach are due to the difficulty that surgeons have had in learning suturing techniques.

When evaluating operative outcomes, careful consideration should be given to who performs the surgery as well as carefully deliberating which patients are appropriate for surgery. In a review on urinary incontinence, the National Institute for Health and Clinical Excellence (NICE) specified that surgery for urinary incontinence “should be undertaken only by surgeons who have received appropriate training or who work within a multidisciplinary team with this training, and who regularly carry out surgery for urinary incontinence in women” [47]. Despite observing no significant difference in outcome between open and laparoscopic approaches (level 1), the reviewers suggested that laparoscopic colposuspension is not recommended as a routine procedure for the treatment of stress urinary incontinence. Perhaps this was because of the fact that they found level four evidence that the procedure consumes more resources and that there is a longer learning curve for skill acquisition compared to other procedures. The authors reiterated their advice that laparoscopic colposuspension should only be performed by those with experience in performing the procedure, although presumably this advice still holds true for all surgical procedures.

Having established that there is an indication for evaluating laparoscopic colposuspension and having established some ground rules by which it should be assessed, to further evaluate its role, it is necessary to evaluate both the success rate, complication rate, the cost of the laparoscopic approach, and how it compares to other surgical techniques.

Success Rates of Nonsuture Colposuspension

Table 99.1 demonstrated the different methods that have been used to carry out a colposuspension laparoscopically. Apart from the traditional suture method, the main method variation adopted has been the use of mesh and tacks to carry out the suspension.

One randomized trial of 60 women compared suturing and nonsuturing laparoscopic methods. The authors demonstrated a higher objective failure rate at 1 year of 26.9% with the mesh technique compared to 11.1% with sutures [48]. Ankardal et al. [49] similarly demonstrated a statistically significant difference in cure rate using sutures as opposed to that achieved with mesh and staples. There are further studies in the literature that compare the laparoscopic route using mesh to the open procedure using sutures [50,51]. Both studies reported a lower success rate with the laparoscopic approach. However, these studies are in fact comparing two entirely different operative procedures and the results cannot therefore be interpreted as outcome data for all laparoscopic colposuspension procedures.

Success Rates of Laparoscopic Colposuspension

Table 99.2 shows the reported success rates for laparoscopic colposuspension in the literature where sutures were used to elevate the vagina. A variety of different techniques are likely to have been employed, and while most studies report objective cure rates, even within this, there are differences in the objective criteria used. Prezioso et al. using an extraperitoneal approach [52] used patient satisfaction questionnaires and urodynamics to assess outcome. They found a patient satisfaction rate of 90% and a cure rate of 72% at 6 months. The number of sutures placed at the time of the procedure is not clear from the methodology described. A similar cure rate, defined as a negative cough test with a comfortably full bladder, after a mean of 52 months was seen by Hong et al. [53], who also performed surgery by the extraperitoneal approach, placing two sutures 2 cm laterally on each side of the urethra and 2 cm distal to the bladder neck. As is seen with the open technique [37], a diminishing cure rate was seen over time. This is echoed on other studies with long-term follow-up. Barr et al. [69] showed a subjective cure rate of 52% 10 years after laparoscopic colposuspension. McDougall [16] reported only a 30% success rate at 45 months for laparoscopic colposuspension with a nonabsorbable suture compared with 35% for needle suspension. However, it is noteworthy that the suture was attached to Cooper’s ligaments by an absorbable clip in this latter study, perhaps explaining this particularly low long-term success rate.

The most marked difference for technique using sutures is the number of sutures used to elevate the vagina. Persson and Wolner-Hanssen randomized 161 women undergoing laparoscopic colposuspension and showed a higher objective success with two single-bite sutures on each side (83%) compared with one double-bite suture (58%) [70].

Table 99.2 Reported Cure Rates for Laparoscopic Colposuspension with Sutures

Author	No. of patients	Length of follow-up (Months)	Cure rate (%)
Langebrekke et al. [52]	8	3	88

Complications

Major complications reported following laparoscopic colposuspension include urinary tract injury, bowel injury, major vascular injury requiring transfusion, and abscess in the space of Retzius. In the longer term, failures of the procedure requiring repeat surgery, de novo detrusor overactivity, voiding difficulty, pain, urethral obstruction, fistula, or posterior compartment prolapse may occur as for the open procedure.

Buller and Cundiff [71], in their review of 1867 patients, report an overall complication rate of 10.3%. The bladder dome was the most commonly injured site and was repaired laparoscopically in the majority of cases. The lower urinary tract is injured in 2%–3% of cases of laparoscopic colposuspension and paravaginal repairs [24,72]. This reported rate is lower than the 10% reported with the open procedure [73]. Intraoperative diagnosis of urinary tract injury is the main factor associated with decreased morbidity [74]. Small bladder injuries can be managed by catheterization, but if greater than 0.5 cm, they should be closed laparoscopically in one or two layers with an absorbable suture.

Where mesh has been substituted for sutures, different additional complications can occur. Kenton et al. have reported two cases of women who presented with complications following laparoscopic colposuspension with Prolene mesh and tacks. Both women had tacks removed retropubically from the bladder and retropubic space and no tacks were seen in Cooper’s ligaments in either patient [75]. In both cases, postoperative cystoscopy was not performed at the time of the colposuspension.

Disadvantages

The main disadvantage of the laparoscopic approach is that the surgeon must possess adequate minimal access skills to perform the procedure competently. It would appear that the modifications introduced in order to overcome the difficulty of suturing in the cave of Retzius, result in lower success rates. To quote the NICE, laparoscopic colposuspension “should be undertaken only by surgeons who have received appropriate training.” This very truism has blighted the uptake of laparoscopic colposuspension, hampered, in part, by inadequate training facilities and archaic theaters. There is a steep learning curve in laparoscopic surgery and this has resulted in fewer laparoscopic colposuspensions being performed. This is likely to be corrected by the stepwise improvements in training opportunities, particularly with plans for the development of laparoscopic urogynecology teaching modules to become incorporated as part of subspecialist training, and the ever evolving developments in theater setup and design.

As with all surgical procedures, adequate surgical audit is of paramount importance in the monitoring of efficacy and complications. For surgeons, NICE has recommended an annual workload of at least 20 cases of each primary procedure for stress urinary incontinence, and surgeons undertaking fewer than 5 cases per annum are advised to do so with the support of a clinical governance committee. These recommendations, in part, account for the relative centralization of specialist techniques like laparoscopic colposuspension; although with some of the changes detailed earlier including improvements in training, theater facilities, and patient demand, there may be a wider uptake of the procedure. There is now a general acceptance of the merits of minimal access surgery among most gynecologists and, therefore, a growing acknowledgment by hospitals of the need to embrace this form of surgery and optimize the clinical setup in order to realize all the potential benefits of laparoscopic surgery.

Laparoscopic Compared with Open Colposuspension: Success Rates, Complications, and Recovery

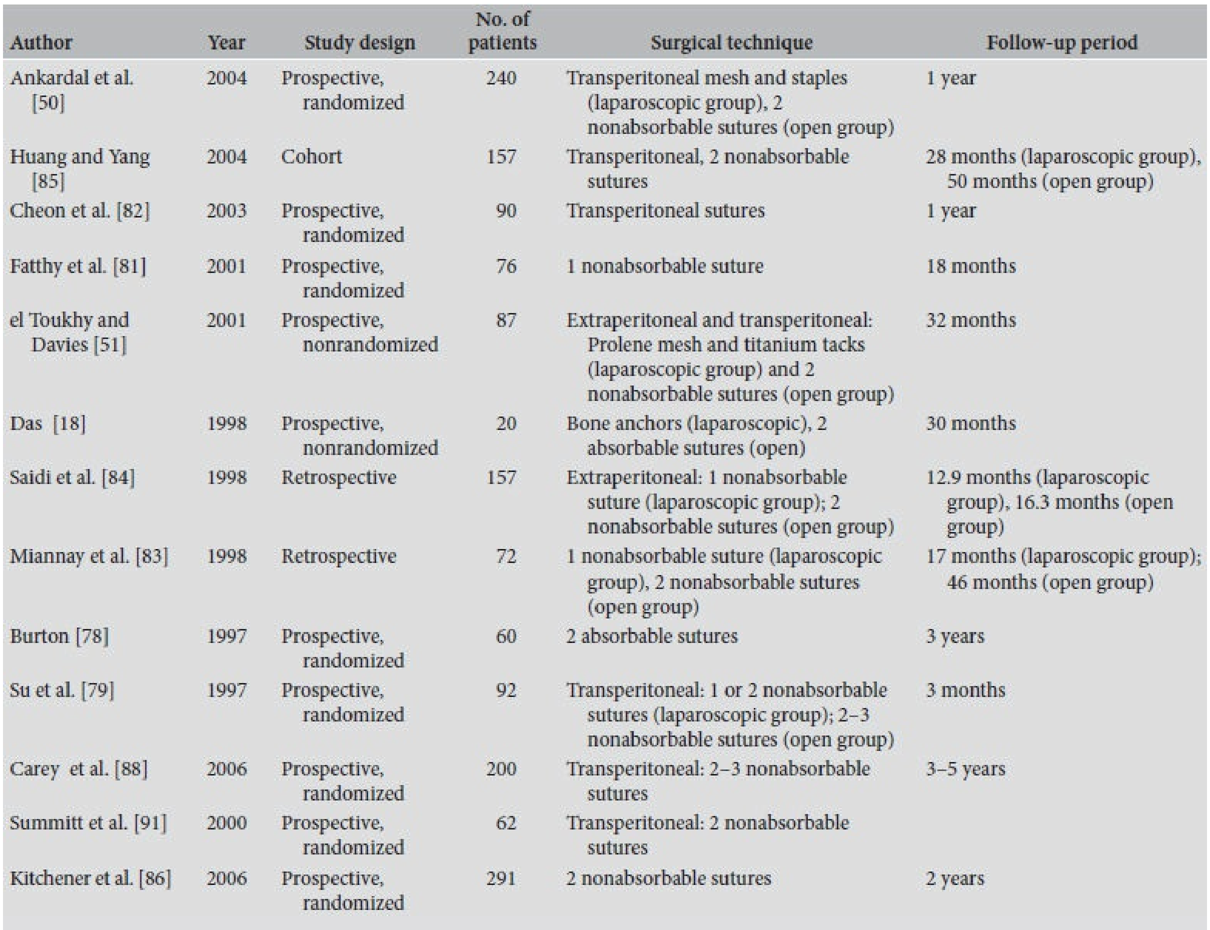
Table 99.3 shows the methodology of studies comparing the laparoscopic approach to open colposuspension. The ideal study would be a prospective randomized study, where both study arms employed the same surgical technique but differed only in their mode of abdominal access. No study achieves this and as with many comparative pelvic floor surgical studies, there is an array of techniques and outcome data employed, which partly explains the disparate findings. That being said, surveying the available evidence to date, the most reasonable conclusion is that the outcome following open and laparoscopic colposuspension is similar. This is apparent from randomized control studies, meta-analysis, and a recent Cochrane review [76].

Burton randomized 60 women to laparoscopic or open colposuspension using two absorbable sutures on either side for both techniques. He reported a lower cure rate at 1 year with the laparoscopic approach compared to the open approach (60% versus 93%) [77]. Similarly, at 3-year follow-up, the results of the laparoscopic group continued to be worse than the open group [78]. However, the author had only performed 10 laparoscopic procedures before the study and absorbable sutures were used. In addition, in the laparoscopic arm, a 12 mm needle was used, and this may have resulted in an inadequate bite of tissue for suspension. The study has not been published in a formal peer-reviewed paper, making further evaluation of the findings difficult.

Su et al. [79] investigated 92 women randomly assigned to the laparoscopic or the open route. They included in the open group those patients who were unwilling to undergo the laparoscopic route after randomization. In addition, 14 women in the laparoscopic group had a laparotomy for hysterectomy immediately following colposuspension. They found less blood loss in the laparoscopy group, similar operating time but lower success rate at 1 year compared to the open group (80.4% versus 95.6%). The follow-up period was variable, and in the majority of cases, only one suture was placed in the laparoscopic group compared to two or three sutures in the open group (placing one suture laparoscopically has been shown to have inferior cure rates to when two sutures are employed [70]). The complication rate in the open group was higher than in the laparoscopic group (17.4% versus 10.8%). This study was included in the systematic review comparing both approaches by Moehrer et al. [80]. The review found that the risk of a positive stress test at follow-up was significantly less in the open treated group. However, when a separate analysis was performed, excluding the study by Su et al. due to some of the aforementioned methodologic flaws, the higher objective cure rate reported with the open approach was no longer significant [80].

Fatthy et al. [81] showed a similar success rate for open and laparoscopic approaches. Cheon et al. [82], in a randomized study of 90 women comparing open and laparoscopic colposuspension, reported similar objective cure rates at 1 year (86% versus 85%). Three further retrospective studies showed similar success rates at 1 year between the laparoscopic and open routes when nonabsorbable sutures were used in both arms with less analgesia, shorter hospital stay, and earlier return to work as seen in the laparoscopic group in two studies [83,84]. The third study compared the anatomic result of the two procedures by assessing the bladder neck position with postoperative ultrasound and found no difference in resting, straining bladder neck position, and urethral mobility at 1 year postoperatively [85].

Table 99.3 Methodology of Studies Comparing Laparoscopic Colposuspension to Open Colposuspension



Author	Year	Study design	No. of patients	Surgical technique	Follow-up period
Ankardal et al. [50]	2004	Prospective, randomized	240	Transperitoneal mesh and staples (laparoscopic group), 2 nonabsorbable sutures (open group)	1 year
Huang and Yang [85]	2004	Cohort	157	Transperitoneal, 2 nonabsorbable sutures	28 months (laparoscopic group), 50 months (open group)
Cheon et al. [82]	2003	Prospective, randomized	90	Transperitoneal sutures	1 year
Fatthy et al. [81]	2001	Prospective, randomized	76	1 nonabsorbable suture	18 months
el Toukhy and Davies [51]	2001	Prospective, nonrandomized	87	Extraperitoneal and transperitoneal: Prolene mesh and titanium tacks (laparoscopic group) and 2 nonabsorbable sutures (open group)	32 months
Das [18]	1998	Prospective, nonrandomized	20	Bone anchors (laparoscopic), 2 absorbable sutures (open)	30 months
Saidi et al. [84]	1998	Retrospective	157	Extraperitoneal: 1 nonabsorbable suture (laparoscopic group); 2 nonabsorbable sutures (open group)	12.9 months (laparoscopic group), 16.3 months (open group)
Miannay et al. [83]	1998	Retrospective	72	1 nonabsorbable suture (laparoscopic group), 2 nonabsorbable sutures (open group)	17 months (laparoscopic group); 46 months (open group)
Burton [78]	1997	Prospective, randomized	60	2 absorbable sutures	3 years
Su et al. [79]	1997	Prospective, randomized	92	Transperitoneal: 1 or 2 nonabsorbable sutures (laparoscopic group); 2–3 nonabsorbable sutures (open group)	3 months
Carey et al. [88]	2006	Prospective, randomized	200	Transperitoneal: 2–3 nonabsorbable sutures	3–5 years
Summitt et al. [91]	2000	Prospective, randomized	62	Transperitoneal: 2 nonabsorbable sutures	
Kitchener et al. [86]	2006	Prospective, randomized	291	2 nonabsorbable sutures	2 years

In the Medical Research Council (MRC) colposuspension trial, 291 women were recruited in 6 centers in the United Kingdom [86]. Of the 144 women allocated to laparoscopic surgery, 11 received open surgery and 2 had no operation. Of the 147 women allocated to open surgery, 1 had laparoscopic surgery and 3 had no operation. On an intention-to-treat analysis at 2 years, the objective outcome (1 hour pad test) showed 80% cured in the laparoscopic group (85.4% data available) and 70% cured in the open group (79.6% data available). The subjective outcome ("perfectly happy/pleased," question 33 in the Bristol Female Urinary Tract Symptoms questionnaire) showed 55% cured in both the laparoscopic and the open group. These results demonstrated that, in the hands of experienced laparoscopic surgeons, laparoscopic surgery does not produce an inferior cure rate to open colposuspension.

The long-term efficacy of both laparoscopic and open colposuspension has been reported. Morris et al. [87] concluded that the laparoscopic approach gave a significantly higher objective cure rate after a median follow-up of 6 years. Carey et al. found no difference in self-reported stress incontinence between the two operative routes, 3–5 years following surgery [69,88]. Barr et al. [69] performed structured interviews at least 10 years following surgery, and the authors reported a deterioration in subjective cure rates (defined as no urinary leakage in last 6 months) from 71% and 67% at 6 months to 48% and 32% at 10 years for the laparoscopic and open procedures, respectively. Again, no statistical difference was noted between the two surgical approaches.

As well as objective and subjective cure rates, authors have evaluated differences in operative time, length of hospital stay, and return to normal activities, between the two operative routes. In the study by Fatthy et al. [81], the laparoscopic approach took 17 minutes longer (the same as the MRC trial) with nearly 200 mL less blood loss, 40 hours less hospital stay, and return to light work 23 days earlier. Carey et al. [88] reported a shorter operative time for the open technique (44 versus 85 minutes). In contrast, Su et al. [79] reported shorter operative time with the laparoscopic approach, although less suturing was employed. The studies by Fatthy et al. [81] and Su et al. [79] both reported longer hospital stay after open compared to laparoscopic colposuspension. Cheon et al. [82] and Carey et al. [88] reported no significant difference. The latter group did, however, report a significantly quicker return to normal activities in the laparoscopic arm of patients. It is noteworthy, however, that length of stay in hospital and time of return to work are also strongly influenced by local and cultural issues as well as surgical morbidity.

Tan et al. [89] identified 16 studies, published between 1995 and 2006 comparing the results of laparoscopic and open colposuspension for patients with stress urinary incontinence. Analysis was performed on 1807 patients, of whom 861 (47.6%) underwent laparoscopic and 946 (52.4%) underwent open colposuspension. They concluded that the former is associated with a similar subjective and objective cure (continence) rate compared to the open operation. It is also associated with a lower operative blood loss, earlier postoperative recovery, and an earlier return to work.

There have been Cochrane reviews evaluating the colposuspension procedure [76,90]. In the most recent review published in 2012, 12 trials were included [49,78,79,81,82,86–88,91–94]. In the analysis comparing open with laparoscopic colposuspension, a total of 1260 women were studied. As is often the case, pooling data from the studies poses problems as most of the trials employ different criteria to define objective and subjective levels of success. Data were analyzed from all of the studies apart from one [78] (Burton) that included visual analogue scores as outcome data. The meta-analyses of data available at less than 1 year revealed a relative risk (RR) of cure of 0.97 (95% CI 0.79–1.18). Between 1 and 5 years, there was a favoring of open surgery, albeit nonsignificant (RR 0.88, 95% CI 0.75–1.03), and if the Ankardal data [49], which included laparoscopic mesh and staples, were excluded, there was a much more apparent absence of difference in objective failure rates between the two treatment groups (RR 0.95, 95% CI 0.80–1.11). Longer-term data were only assessed in one paper [87], which favored the laparoscopic approach in the 64 women studied, although, again, this was nonsignificant (RR 1.89, 95% CI 0.99–3.59). The authors concluded that patient-reported incontinence rates at short-, medium-, and long-term follow-up showed no significant differences between open and laparoscopic retropubic colposuspension [76].

There were no significant differences in the risk for developing adverse events, in terms of perioperative complications, de novo urge symptoms or urge incontinence, detrusor overactivity, voiding difficulties, or new or recurrent prolapse. The authors did highlight four trials [86,88,93,94] that provided limited evidence of a greater tendency for laparoscopic colposuspension to have a higher rate of bladder perforation (0.6% versus 3%). Ultimately, the authors concluded that laparoscopic colposuspension should allow speedier recovery, and available evidence shows comparable effectiveness with open surgery.

Cost

Differences in costs are difficult to assess as there is a great variation in each country as to how long patients tend to stay in hospital following surgery and there are differing costs of operating time. The laparoscopic approach is generally reported to require longer operating time than the open colposuspension or midurethral sling procedures. The other cited factor against the laparoscopic approach is the increased cost of disposables associated with minimal access procedures. With greater adoption of laparoscopic surgery, there has been a continued drive for industry to produce better and more cost-effective equipment, and there is a growing competitive market for this, which ultimately may further drive down costs with no compromise on quality. It is also important to mention that the cost of sterilization of reusable instruments is rarely if ever allowed for during cost comparisons of techniques.

Dumville, as part of the COLPO (Colposuspension; is Laparoscopic Preferable to Open?) study group [95], compared the cost-effectiveness of laparoscopic colposuspension versus open colposuspension. The health outcome measure for the economic analysis used was quality-adjusted life years (QALYs). This is a measure reflecting both patient's health-related quality of life and mortality into a single index. Interestingly, in this study, both groups had a suprapubic catheter inserted at the time of surgery, and both groups were subjected to a particular postoperative trial of void regimen. This is likely to have influenced the length of inpatient stay and may have inadvertently minimized the actual differences between the two study arms in terms of length of hospital stay. Despite this, the laparoscopic group had a reduced mean length of stay in hospital and a reduced number of outpatient and GP appointments during follow-up. The total theater costs for the laparoscopic group were, as expected, markedly higher than the open surgery group (£944 versus £464), mainly due to the longer theater time used and the extra equipment required for the laparoscopic surgery. The total cost of laparoscopic surgery at 6 months of follow-up was higher than the total cost of open surgery (£1805 versus £1433), with a differential mean of £372 (95% CI 274–471). At 24 months, however, those who underwent laparoscopic surgery had higher QALYs compared with those who underwent open surgery. There had been a shorter inpatient stay and fewer postoperative visits. After 24-month analysis, the authors concluded “the laparoscopic approach might be a cost-effective alternative in the medium term, provided that there are no major cost implications from treatment failure compared with the open group.” There is very little evidence that the failure rates of the two procedures are so disparate after 2 years for the laparoscopic approach not to be cost-effective at this time interval.

Kohli et al. [96] reported a retrospective 2-year cost analysis of laparoscopic colposuspension with sutures compared with open colposuspension. They found that the laparoscopic approach was more expensive than the open approach ($4960 versus $4079). This reflected the high hourly operative room charges in North America as the laparoscopic group took on average 44 minutes longer operating time. The postoperative care costs were lower in the laparoscopic group. Persson et al. reported that a laparoscopic colposuspension is cheaper than [97] a TVT in Sweden (€1273.4 versus €1342.8) despite the TVT procedure being performed in less time. In contrast, a more recent Swedish study reported that the TVT procedure generated a lower direct cost than colposuspension, either by the open or laparoscopic approach [98]. Other studies have similarly confirmed the greater expense of the laparoscopic route compared to midurethral surgery [99].

Laparoscopic Colposuspension versus Tension-Free Vaginal Tape Procedures

With the advent of midurethral tape procedures, it is pertinent to evaluate the performance of laparoscopic colposuspension compared with these even more minimally invasive procedures. To address this issue, Dean et al. performed a systematic review identifying seven trials from the Cochrane Incontinence Review Group’s Specialised Register of Controlled Trials [100].

Of the seven studies [97,101–106], three were published as abstracts and one used Prolene mesh and tacks. This latter study found similar cure rates at 6 weeks following surgery, with the TVT arm taking less operative time, shorter hospital stay, and earlier return to work [106]. One patient in the laparoscopic group required a laparotomy to remove the tacks inadvertently placed in the bladder, as they were too difficult to remove laparoscopically. One-year data from the same study showed that the success rate of the TVT as defined by a negative stress test was 85.7%, but the laparoscopic colposuspension group success rate had fallen to 56.9% [107]. In a longer-term follow-up study, the same authors showed superior subjective and objective cure rates with TVT compared to the laparoscopic mesh colposuspension procedure [108]. The authors also concluded “if cases that were lost to follow-up were regarded as failures, the intention-to-treat analysis found no difference between the groups.” Of note, however, as discussed earlier, the mesh procedure is not synonymous with a standard colposuspension, and the findings of the Valpas papers should not be simply translated to the laparoscopic suture colposuspension technique. The use of sutures, irrespective of surgical approach, is seen to be better than the use of mesh [49].

None of the other studies analyzed by Dean et al. showed a significant superior treatment effect with either approach. When pooled results were used, the overall objective cure (a combination of a negative clinical stress and pad tests) rate was statistically higher for TVT when compared with laparoscopic colposuspension (using sutures or mesh) (RR 1.16, 95% CI 1.07–1.25). Interestingly, when the authors excluded the study by Adile et al. [101] due to methodological flaws, no significant difference between the two treatments was seen.

When urodynamics was used to objectively assess clinical outcome, again no difference was seen between the two operations. Reported differences in de novo urgency were conflicting in the studies, and the numbers of women with voiding dysfunction following different surgery were too small to satisfactorily analyze. With respect to morbidity, there were no statistically significant differences in the perioperative complication rates between laparoscopic colposuspension and TVT procedure (RR 1.07, 95% CI 0.64–1.79). The cited benefits of laparoscopic colposuspension over the open procedure were echoed for the TVT procedure over laparoscopic colposuspension. There was a shorter hospital stay by a mean of 1 day and a quicker return to normal activities. In addition, laparoscopic surgery took significantly longer than the TVT surgery by an average of 20 minutes.

Jelovsek reported longer-term data comparing TVT and laparoscopic colposuspension. A total of 72 patients were enrolled. Over a median follow-up time of 65 months, no differences were seen in patient-reported urinary incontinence or bothersome stress urinary incontinence symptoms. Of subjects in the laparoscopic Burch group, 88% reported that if they had to do it all over again, they would choose the same treatment versus 79% in the TVT group [109].

The favorable outcomes seen with midurethral slings are an encouraging development for the treatment of urinary stress incontinence. The balance has shifted toward midurethral tapes as the first-line treatment. Notwithstanding this, the merits of a colposuspension remain, and judicious use in appropriate patients ensures that a range of treatment choices is available.

CONCLUSION

Colposuspension avoids placing a permanent tape under the urethra, thereby reducing concern about the possibility of future tape erosion. Current evidence suggests that laparoscopic colposuspension performed with sutures is as effective as the open approach and the TVT procedures. The use of mesh, tacks, or staples and only one suture appears to reduce the success rate. The laparoscopic approach is associated with a quicker return to normal activity than the open procedure.

Perhaps the recent controversies associated with the placement of vaginal mesh will stimulate the rebirth of the colposuspension in its modern-day form, and a growing number of pelvic floor surgeons will be able to include it in their repertoire of anti-incontinence procedures. Each of the many available techniques offers its own set of advantages and disadvantages, and one single procedure is unlikely to offer a universal panacea. Any successful anti-incontinence procedure should take into account patient symptoms, medical comorbidities, and the presence of other pelvic floor problems. The ability to choose from a range of surgical techniques will inevitably optimize treatment for the individual woman.

The laparoscopic approach requires the surgeon to be competent in minimal access surgery skills as well as urogynecology. We believe that efforts should now be directed toward improvements in training and theater environment, both of which can act as either facilitators or barriers to surgical uptake. Long-term success rates remain the challenge for all anti-incontinence procedures.

100 Laparoscopic Sacrocolpopexy

Marcus P. Carey

INTRODUCTION

The use of laparoscopic sacral colpopexy (LSC) to treat pelvic organ prolapse has increased in recent years coinciding with a dramatic decline in transvaginal mesh use as a result of recent Food and Drug Administration warnings [1]. In the United states, the number of LSC procedures performed for prolapse exponentially increased during the 10 years from 2003 to 2012 [2]. Among urologists in the United States, in 2012, 70.1% of sacral colpopexies were performed by laparoscopy.

The main limitation of laparoscopy for the treatment of pelvic organ prolapse is the relatively small number of surgeons with sufficient laparoscopic and reconstructive pelvic floor surgical skills to perform these procedures safely and successfully. This underscores the importance of introducing LSC into urogynecology and female urology training programs [3].

Approximately 300,000 women undergo surgery for pelvic organ prolapse in the United States each year [4]. In 2010, around 196,000, 70,000, and 34,000 women underwent native tissue vaginal repairs, transvaginal mesh repairs, and sacral colpopexy procedures, respectively, for pelvic organ prolapse [4]. In a study of women from a large U.S. health maintenance organization, it was reported that by the age of 80 years, 11.1% of women had undergone surgery for pelvic organ prolapse or urinary incontinence, or both [5]. Within 4 years of the primary surgical procedure, 29.2% of these women required repeat surgery for recurrent prolapse or stress incontinence [6]. Younger patients (age less than 60 years) and women with higher grades of prolapse (pelvic organ prolapse quantification [POPQ] stages 3 and 4) are more likely to experience recurrent prolapse after vaginal repair [6,7]. The prevalence of vaginal vault prolapse following hysterectomy is approximately 10% [8]. However, estimates of the prevalence of posthysterectomy vault prolapse vary markedly from 0.2% to 43% [8–10]. Vault prolapse occurs in equal numbers following abdominal and vaginal hysterectomy [11,12].

The high rate of failure with vaginal surgery to treat vaginal vault prolapse led to the development of the abdominal sacrocolpopexy (ASC) procedure. This approach employs the retroperitoneal interposition of a suspensory prosthesis (synthetic, autologous, allograft, or xenograft) between the vaginal apex and the sacrum. ASC was originally described by Huguier in 1957 and later by Lane in 1962 [13,14]. Snyder and Krantz [15] described the attachment of the prosthesis along the full length of the rectovaginal septum. Addison et al. [16,17] described the broad attachment of the prosthesis to both the upper anterior and posterior vaginal walls. Randomized trials comparing the ACS procedure with transvaginal sacrospinous ligament fixation to treat vaginal vault prolapse demonstrated a trend toward the ACS being the more effective procedure [18–20]. In addition to the high success rate reported with the ACS procedure, other advantages include the preservation of vaginal capacity resulting in maintenance of coital function, the use of synthetic material resulting in durable support, and the use of the synthetic graft on both anterior and posterior vaginal aspects providing for balanced support of the various vaginal sites and an acceptable vaginal axis. Significant problems associated with the ASC operation include de novo postoperative stress incontinence, intraoperative hemorrhage, dyspareunia, mesh erosion, and use of a laparotomy incision [14,15,17,21–23].

LSC was first described by Nezhat et al. in 1994 although Wattiez et al. claim to have first performed this procedure in 1991 [24,25]. In addition to treating posthysterectomy vault prolapse, LSC has been used concomitantly with laparoscopic total and subtotal hysterectomy for uterovaginal prolapse. The proposed advantages of the LSC over the ASC include

1. An enhanced view of the pelvic and intra-abdominal anatomy compared to the abdominal approach
2. The avoidance of a major laparotomy incision
3. Less postoperative pain, shorter time in hospital, and reduced risk of wound complications

4. A quicker return to normal activities

The LSC takes advantage of the known high success rate of the traditional ASC combined with the benefits of laparoscopic surgery. The LSC should be performed in an identical manner to the ASC with the only difference being the smaller laparoscopic incisions.

ANATOMIC CONSIDERATIONS

Following hysterectomy, the upper third of the vagina (including the vault) is supported by two mechanisms:

> *Direct* support for the vaginal vault is provided by the parametrium (cardinal and uterosacral ligaments) and paracolpium fibers. These fibers act like suspensory ligaments and arise from the fascia of the piriformis muscle, sacroiliac joint, and lateral sacrum and insert into the lateral upper third of the vagina.
>
> *Indirect* support for the vaginal vault is provided by the levator plate, formed by the fusion of the right and left levator ani muscles between the rectum and coccyx.

Vaginal vault prolapse occurs as a consequence of failure of these direct and indirect supporting mechanisms. This is likely to involve weakness of the muscular pelvic floor and suspensory fibers of the parametrium and upper paracolpium [26,27].

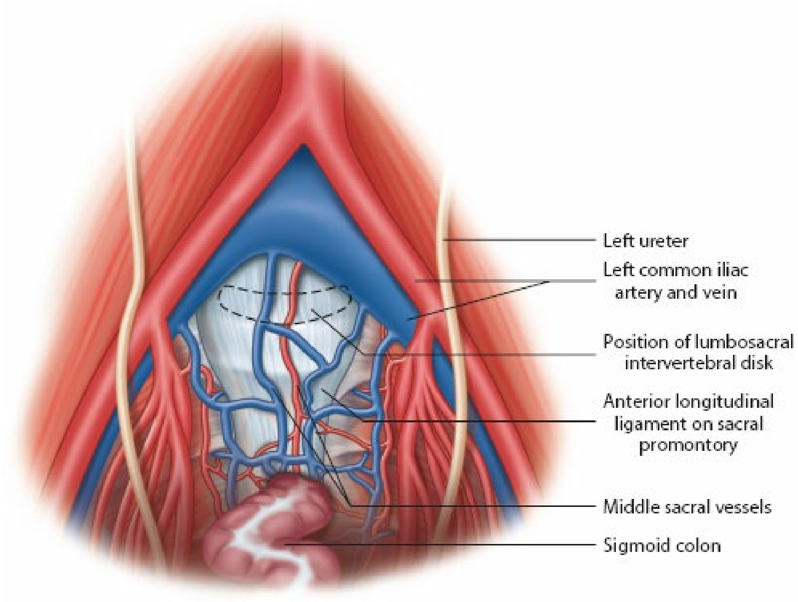
Recent work evaluating the fibromuscular composition of the vaginal wall in women with and without enterocele failed to demonstrate any focal "defect" of the vaginal muscularis [28]. Based on these anatomic considerations, it is not surprising that a site-specific endopelvic fascial repair approach to the treatment of a vaginal apical defect is likely to carry an unacceptably high failure rate [29,30].

For women with vaginal vault prolapse, surgical repair should generally be directed toward restoring vault support and a normal vaginal axis. These anatomic considerations lend credibility to the concept of the ASC and LSC procedures.

Anatomy of the Sacral Promontory

The presacral space is bounded superiorly by lumbosacral intervertebral disk and laterally by the right common iliac artery and left common iliac vein (Figure 100.1). The right ureter is identified coursing in the right lateral aspect of the presacral space. The sacral promontory and presacral space are usually covered by the sigmoid colon. The sigmoid colon at this point is attached to the peritoneum, which is reflected over the left psoas major muscle and iliacus muscle. Once the sigmoid colon is retracted to the left side, the sacral promontory is easily identified. The presacral space and sacral promontory are accessed by gently lifting up the peritoneum directly over the sacral promontory and performing a midline longitudinal incision. This approach into the presacral space will avoid damage to the right common iliac artery and left common iliac vein. The middle sacral artery and vein are easily identified lying directly on the middle aspect of the sacrum. The middle sacral artery originates as a single branch from the posterior aspect of the aorta. The middle sacral vein arises from the vessels emerging beneath the common iliac veins and drains into the inferior vena cava. Some women have an extensive venous plexus in the presacral space, and damage to these vessels can result in dramatic hemorrhage. The middle sacral artery gives off small branches that run laterally on the sacrum to either anastomose with the lateral sacral arteries or directly supply the ventral sacral nerve roots. Damage to these fine vessels can result in bleeding and ischemic injury to the ventral sacral nerve roots.

The hypogastric plexus of nerves descends into the pelvis anterior to the bifurcation of the aorta, enters the presacral space between the common iliac arteries, and is anterior to the middle sacral artery and vein. This plexus carries the autonomic nerves of the pelvic viscera. Extensive damage to this plexus of nerves may result in bladder, bowel, and sexual dysfunction. When performing a LSC procedure, careful dissection is recommended in order to reduce the risk of nerve damage. After entering the presacral space, the anterior longitudinal ligament is exposed by gentle blunt dissection of the presacral tissues over the sacral promontory. Sharp dissection and the use of ablative techniques to access the anterior longitudinal sacral ligament should be avoided. When securing the prosthetic material to the sacral promontory, the surgeon should avoid excessive use of sutures or stapling devices onto the sacral promontory. When performing a LSC procedure, the author uses only one or two sutures to secure the prosthesis onto the anterior longitudinal ligament on the sacral promontory (i.e., at the level of the upper part of the fifth lumbar vertebra) and has not encountered a case of mesh detachment from the sacral promontory with this approach.



Left ureter
Left common iliac artery and vein

Sigmoid colon

Figure 100.1 The presacral space is bounded by the lumbosacral intervertebral disk above and laterally by the right common iliac artery and left common iliac vein. The middle sacral artery and vein course over the anterior longitudinal ligament on the sacral promontory.

CLINICAL ASSESSMENT AND PATIENT SELECTION

Clinical assessment is undertaken in the usual fashion. This includes obtaining a detailed history with particular emphasis on any symptoms associated with the vaginal vault prolapse, especially urinary, bowel, and coital symptoms. A detailed general and pelvic examination is undertaken. It is important for the clinician to identify all the vaginal defects accurately so that they can be corrected at the time of surgery. The patient should be examined for signs of stress incontinence with the prolapse present and also for any anorectal pathology, including rectal prolapse.

Urodynamic studies should be made available to patients with associated urinary symptoms. Imaging of the pelvic floor and anorectal physiological testing are recommended as indicated.

Indications

Currently, there is no consensus on the exact indications for both ASC and LSC procedures. The LSC is indicated for patients with symptomatic and significant prolapse of the vaginal vault who are considered appropriate candidates for an ASC. This approach is suitable for younger patients wishing to preserve coital function and in whom there are no contraindications to laparoscopic surgery. Walters and Ridgeway [31] recommended "sacral colpopexy with polypropylene mesh (preferably by minimally invasive route) in younger women, those with severe prolapse or recurrences after vaginal surgery, and women with prolapsed, short vaginas". Gadonneix et al. [32] reported that 89% of 46 consecutive patients presenting with multiple compartment prolapse could be treated by LSC.

The LSC procedure should be made available to patients with significant vaginal vault prolapse with no contraindications to laparoscopy. Typically, these women have had a previous hysterectomy and an International Continence Society POPQ classification of stage 2 or greater prolapse at the vaginal vault site [7]. Patients with significant stage 1 vault prolapse are sometimes offered this approach. LSC can also be used in conjunction with a hysterectomy and subtotal hysterectomy to treat marked uterine prolapse of stage 2 or greater in younger women [13,30,33]. LSC treats vaginal vault prolapse as well as high cystoceles and rectoceles when the mesh is extended onto the upper anterior and posterior vaginal walls [34]. On occasion, the LSC procedure with extension of mesh anteriorly and in combination with a laparoscopic paravaginal repair is offered to women with a recurrent cystocele, as this combination of procedures is very effective in treating recurrent high cystoceles.

LSC is a complex operation requiring both advanced laparoscopic and reconstructive pelvic surgery skills. Only surgeons competent in this operative technique should undertake this surgery.

Contraindications

Vaginal operations may be more appropriate for frail women who do not wish to preserve coital function. LSC is not indicated for women with minor degrees of vault prolapse. This procedure is also not suitable for patients who otherwise have a contraindication to laparoscopic surgery. In these women, an ASC or vaginal surgery to treat the vault prolapse should be offered.

Relative contraindications to LSC are

- Extensive intra-abdominal adhesions
- Morbid obesity
- Elderly patients
- Inflammatory bowel diseases (especially Crohn’s disease)
- Immunocompromised patients
- Chronic pelvic pain
- Prior pelvic radiation therapy

Absolute contraindications to LSC are

- Currently taking anticoagulation medication
- Active inflammatory bowel disease
- Current pelvic or vaginal sepsis
- Sacral abnormalities (e.g., sacral agenesis, sacral meningomyelocele)
- Recognized intraoperative bowel perforation
- Inability to safely access the anterior longitudinal ligament on the sacral promontory
- Any contraindication to laparoscopy

SURGICAL TECHNIQUE

A standardized technique for LSC does not exist. Surgery is performed under general anesthesia with muscle relaxation. A major challenge is the achievement and maintenance of adequate surgical exposure of the vaginal vault and sacral promontory. A steep Trendelenburg position, preoperative bowel preparation, avoidance of nitrous oxide anesthesia, and an adequate number of operating ports all facilitate good surgical exposure. Left lateral tilting of the patient can also be employed [35]. Laparoscopic bowel retractors appear to be of limited benefit. Following induction with general anesthesia, the woman is placed in a low lithotomy position using Allen stirrups. The use of Allen stirrups allows the patient to be repositioned during surgery without the need to redrape. Repositioning may be required when concomitant vaginal surgery is undertaken.

Standard techniques are used to introduce a 10 mm operating laparoscope at the umbilicus. Under laparoscopic vision, two ports (for the right-handed surgeon a 10 mm port on the patient’s left and a 5 mm port on the patient’s right) are inserted through the anterior abdominal wall into the peritoneal cavity. In order to avoid injury to the inferior epigastric artery and vein and damage to the lateral cutaneous nerve to the thigh, these ports are sited two fingerbreadths above and two fingerbreadths medial to the anterior superior iliac spine. A further 5 mm port is introduced suprapubically in the midline under laparoscopic vision.

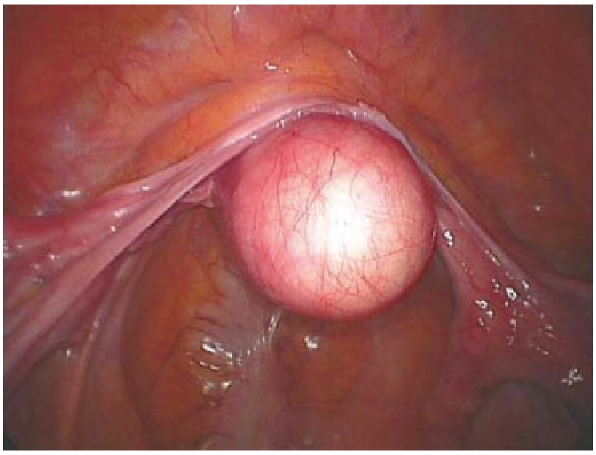

Figure 100.2 The vagina is elevated using a vaginal probe. This facilitates the dissection of the peritoneum, bladder, and rectum off the upper vagina.

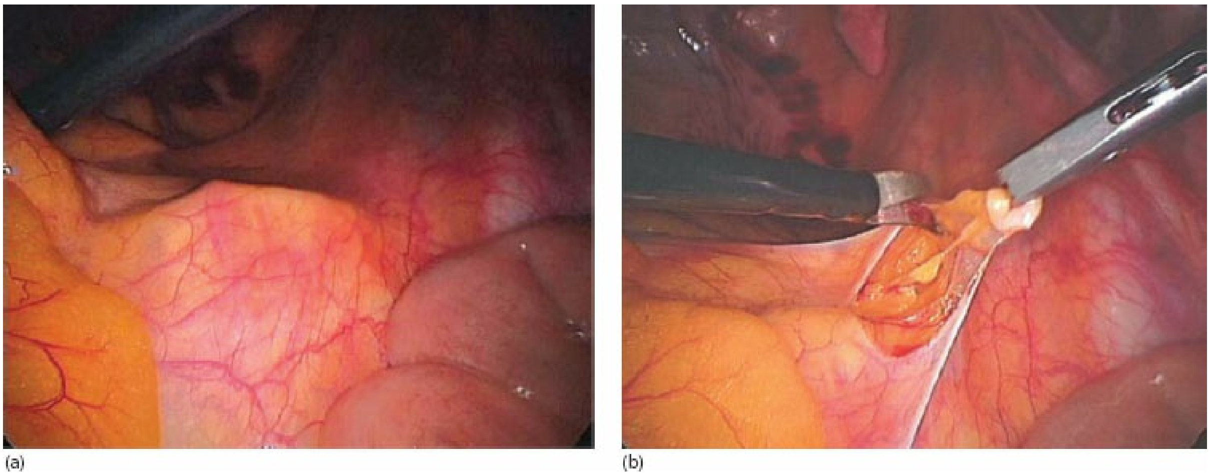
A vaginal probe or vaginal elevator is inserted to identify the vaginal vault. With the vagina elevated cranially using the vaginal probe (Figure 100.2), the peritoneum is opened transversely at the vaginal apex. This dissection continues posteriorly into the rectovaginal septum so that the peritoneum is dissected off the upper half of the posterior vaginal wall. At around this point, the rectovaginal septum is entered and the rectum is dissected off the middle and lower posterior vaginal wall. On occasion, dissection can be facilitated by using a rectal probe. This dissection is carried out in the midline and extended laterally on both sides to the medial aspect of the uterosacral ligaments. The uterosacral ligaments are optimally visualized when the vaginal probe is elevated toward the anterior abdominal wall.

The bladder is then dissected off the upper anterior vaginal wall. This dissection continues to approximately the midpoint of the anterior vaginal wall. Dissection is continued laterally toward both the bladder pillars, but generally dissection of the bladder pillars is avoided. This is to reduce intraoperative bleeding and injury to the autonomic nerves to the bladder.

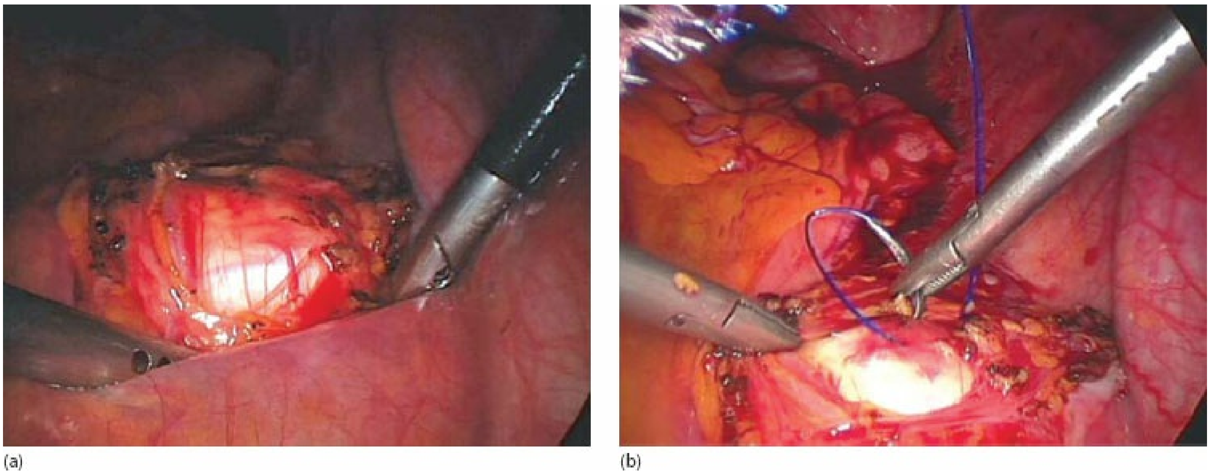
Once the peritoneum has been dissected off the upper vagina, along with dissection of the bladder and rectum, the sacral promontory is identified. Often, the sigmoid colon obscures the sacral promontory and needs to be reflected to the patient’s left. The sacral promontory is usually an easily recognizable and accessible structure (Figure 100.3a). However, in obese patients, the sacral promontory may be difficult to access. Prior to dissection in this region, the right ureter should be carefully identified. The peritoneum over the sacral promontory is grasped and elevated. A vertical incision is made into the peritoneum in the midline to allow entry into the presacral space (Figure 100.3b).

The peritoneum is further dissected in a caudal direction on the right of the rectum and sigmoid colon and below the right ureter into the cul-de-sac to join the posterior vaginal peritoneal dissection. Once this dissection is completed, the tissues in the presacral space over the sacral promontory are carefully reflected laterally so that the glistening white fibers of the anterior longitudinal ligament are exposed (Figure 100.4a). At this point, it is important to carefully identify any vascular structures on the sacral promontory in the midline so that injury to these structures can be avoided when the prosthesis is attached to the sacral promontory. Two rectangular pieces of mesh, a type 1 lightweight polypropylene mesh [36], are then cut to size, the first being 15 × 4.5 cm and the second being 5 × 4.5 cm. The larger piece of mesh is used to support the posterior vaginal wall and vault, and the smaller piece of mesh is used to support the anterior vaginal wall and vault. The larger mesh is introduced into the pelvis through the left 10 mm port. Using delayed absorbable monofilament sutures throughout, this mesh is attached to the posterior vaginal wall with four to six sutures. The smaller mesh is then introduced into the pelvis and attached to the upper anterior vaginal wall with four sutures. Two sutures are placed at the vaginal vault and through both anterior and posterior pieces of mesh. Alternatively, a precut Y-shaped mesh (e.g., Upsylon™ mesh, Boston Scientific, Boston, MA; Restorelle Y™ mesh, Coloplast, Humlebaek, Denmark) may be used.



(a) (b)

Figure 100.3 (a) The sacral promontory is easily recognizable and accessible during laparoscopic sacral colpopexy. (b) The peritoneum over the sacral promontory is elevated and a vertical incision is made into the peritoneum in the midline to allow safe entry into the presacral space.



(a) (b)

Figure 100.4 (a) The tissues in the presacral space are carefully reflected laterally exposing the glistening, white fibers of the anterior longitudinal ligament on the sacral promontory. (b) A suture is passed in turn through the mesh and into the anterior longitudinal ligament on the sacral promontory in the midline.

The point of attachment of the mesh onto the sacral promontory is defined. The mesh is fixed to the anterior longitudinal ligament on the sacral promontory without placing tension on the vagina. A permanent suture is passed in turn through the mesh and into the anterior longitudinal ligament in the middle of the sacral promontory, with care taken to avoid injury to any vessels at this site. Occasionally, a second bite into the anterior longitudinal ligament is taken (Figure 100.4b). The suture is then passed again through the mesh and tied, anchoring the mesh onto the sacral promontory. Excess mesh above the knot is excised and removed from the abdomen (Figures 100.5 and 100.6). The peritoneum is closed with a continuous delayed absorbable monofilament suture starting at the sacral promontory. Alternatively, a barbed suture (e.g., 2/0 V-Loc$^{\text{TM}}$, Covidien, Mansfield, MA) may be used to close the peritoneum over the mesh. Closure of the peritoneum completely isolates the prosthesis from the intra-abdominal viscera and contributes to the obliteration of the pouch of Douglas. Occasionally, the pouch of Douglas may remain deep on the left side in which case a left-sided Moschcowitz and Halban procedures can be performed to reduce the possibility of enterocele formation.

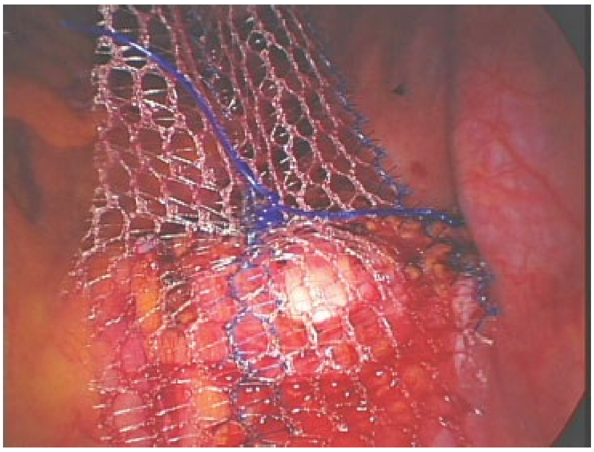


Figure 100.5 Mesh is attached to the anterior longitudinal ligament on the sacral promontory in the midline with a Prolene suture.

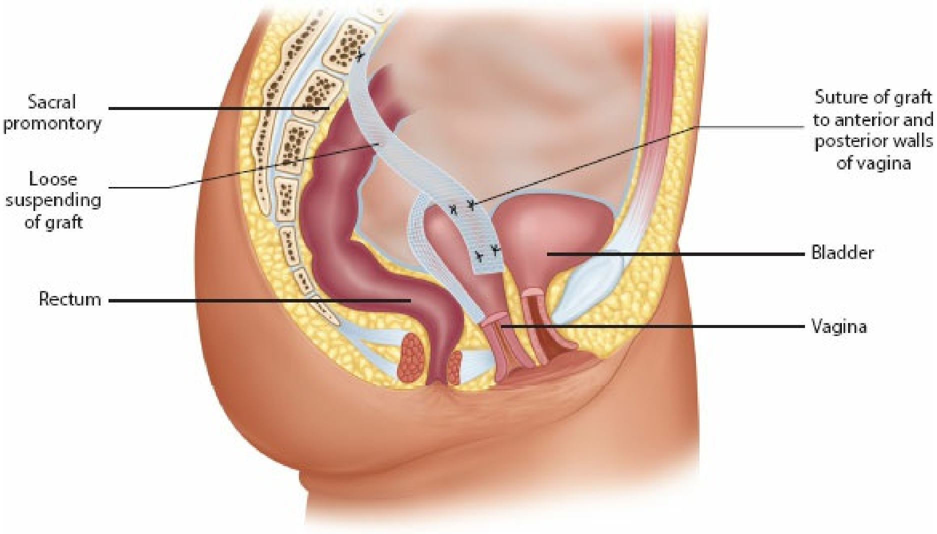
Types of Prosthesis

Ideally, the prosthesis used for LSC should be durable over a patient's lifetime, user friendly, and cost-effective and have a minimal risk of complications including erosion, infection, chronic inflammation, tissue contraction, pain, and dyspareunia. A variety of synthetic meshes and biological grafts have been described for both ASC and LSC. There is insufficient research to provide surgeons with answers as to whether synthetic meshes are more durable than biological grafts or whether specific meshes are superior to others with respect to clinical outcomes and complications. In a review of surgery for apical prolapse, Barber and Maher concluded that polypropylene mesh is the preferred graft sacral colpopexy [37].

Surgeons should base their selection of synthetic mesh used for LSC on a thorough understanding of the important biomechanical and biocompatible properties of each available mesh. There is an emerging consensus that lightweight, open-weave, monofilament polypropylene meshes are the most suitable of the existing meshes for use in surgery for pelvic organ prolapse. New-generation meshes specifically designed for pelvic organ prolapse surgery will require appropriate animal and clinical evaluation before being recommended for use in prolapse surgery.



Sacral promontory
Loose suspending of graft
Rectum
Suture of graft to anterior and posterior walls of vagina
Bladder
Vagina

Figure 100.6 Mesh is sutured to the vaginal vault with extension down the upper anterior and posterior vaginal walls. The mesh is then sutured to the sacral promontory without placing tension on the vaginal vault.

Although biological grafts are unlikely to erode, poor durability remains a major concern. FitzGerald et al. [38] reported a high prevalence of prolapse recurrence following ASC using freeze-dried, irradiated donor fascia. At 12 months, after ASC, 43% experienced failure and this increased to 83% at 17 months. Of the 16 women who underwent repeat ASC with mesh, no graft material from initial ASC was identified in 13 (81%) cases, indicating a high rate of graft degradation and resorption. The authors concluded that the use of freeze-dried, irradiated donor fascia for ASC was associated with an unacceptably high failure rate.

Culligan et al. [39] reported on an RCT of 115 subjects comparing porcine dermis with polypropylene mesh for LSC. At 12 months, subjective and objective outcome were similar in both groups. The objective cure rates were 80.7% and 86.2% for porcine dermis and mesh groups, respectively.

Until more clinical information becomes available on the use of biological grafts for ASC and LSC procedures, with the possible exception of porcine dermis, biological grafts should be reserved for specific indications. These indications might include extremely thin vaginal epithelium, replacement for mesh that has required removal, prior pelvic irradiation, and situations of high risk for mesh infection (e.g., bowel resection during combined surgery for genital and rectal prolapse). However, there remains a lack of evidence to support the use of biological prostheses over mesh in these circumstances.

Sacral Promontory Fixation

Various methods of attaching the suspending prosthesis onto the sacral promontory at LSC have been reported. These include sutures, bone anchors, staples, and helical tacks [12,32,34,35,40,41]. There is a lack of research comparing the various methods of fixation of the prosthesis onto the sacral promontory. Due to the technical difficulties involved in laparoscopic suturing with LSC, some surgeons have preferred bone anchors and staples to sutures.

Surgeons have described attachment of the prosthesis to different points on the sacrum. Birnbaum advocated placement of the prosthesis at the level of S3–S4 [42]. Sutton et al. [43] advocated placement of the prosthesis at the level of S1–S2 in order to reduce the risk of massive sacral bleeding. The author’s preference has been to use the anterior longitudinal ligament on the sacral promontory and to attach the mesh with sutures. The sacral promontory is the most accessible point on the sacrum and is particularly well visualized at laparoscopic surgery. Mesh should not be fixed to the lumbosacral intervertebral disk because of the risk of discitis, hemorrhage, and pain from damage to the sensory nerve supply [44]. Superior visualization at the sacral promontory allows the surgeon to avoid damage to vascular structures more easily and to control excessive sacral bleeding than does the hollow of the sacrum. Use of the sacral promontory has no detectable negative effect on the vaginal axis [43].

Robotic Assistance

The use of robotic assistance for laparoscopic sacrocolpopexy is described in Chapter 103.

Perioperative Care

It is the author’s practice that patients be administered a limited bowel preparation in the afternoon of the day prior to surgery. Patients should have an oral intake of clear fluids only during the 12 hour period prior to the commencement of fasting before surgery. Bowel preparation is used in order to improve surgical exposure rather than for anticipated bowel trauma. The potential disadvantages of bowel preparation include dehydration, electrolyte disturbance, patient discomfort, and intraoperation diarrhea. Intravenous broad-spectrum antibiotic therapy and subcutaneous thrombotic prophylaxis are administered with anesthesia induction and continued postoperatively. Handling of the mesh is kept to a minimum. Maintaining hemostasis, liberal use of pelvic irrigation, evacuation of blood from the pelvis, and use of monofilament sutures to attach the mesh onto the vagina are all important measures undertaken to reduce the risk of mesh erosion. At the completion of surgery, cystoscopy may be undertaken to exclude ureteric or bladder injury. Digital rectal and vaginal examination should be performed to exclude the presence of perforating sutures.

Following discharge from hospital, patients should avoid strenuous activity for 3–4 weeks. By this time, the mesh will have become incorporated into the tissues and patients can then resume activities of normal daily living. Patients should avoid sexual intercourse for at least 6 weeks following surgery. Pelvic floor exercises may be recommenced any time after surgery [45].

CONCOMITANT LAPAROSCOPIC HYSTERECTOMY OR SUBTOTAL HYSTERECTOMY

The principles of LSC may be applied to uterovaginal prolapse by combining LSC with either laparoscopic total hysterectomy or subtotal hysterectomy (Figure 100.7). A recent review of LSC performed concomitantly with supracervical (subtotal) hysterectomy reported an anatomic success rate of 90%–100%, subject success rate of 80%–95%, and mean reoperation rate of 3% [46].

CONCOMITANT ANTI-INCONTINENCE SURGERY

Urodynamic assessment is appropriate for women with symptomatic stress incontinence and vaginal vault prolapse. If urodynamic stress incontinence is demonstrated, then concomitant anti-incontinence surgery, in addition to the LSC operation, is indicated. Laparoscopic colposus-pension or a midurethral tape procedure—for example, the tension-free vaginal tape (TVT) operation—can be employed. Occasionally, a transurethral bulking agent is indicated for women with a rigid urethra and, typically, previous failed anti-incontinence surgery. The simplicity and demonstrated effectiveness of the TVT procedure makes this an attractive option over the laparoscopic colposuspension procedure. In a randomized trial of 72 women, Paraiso et al. found the TVT procedure to result in significantly greater objective and subjective cure rates for stress incontinence than laparoscopic Burch colposuspension [47]. This finding was supported by Valpas et al. [48]. Furthermore, the opposing vector effect of combining LSC with laparoscopic colposuspension may result in persistence of postoperative stress incontinence.

The role of anti-incontinence surgery for occult stress incontinence during surgery for pelvic organ prolapse remains the subject of ongoing debate. Nygaard et al. [22] emphasized the clinical challenge of patients with occult stress incontinence and vault prolapse. A systematic review by Maher et al. was unable to determine whether or not “potential stress urinary incontinence detected on reduction of prolapse prior to surgery is best treated with formal continence surgery at the time of prolapse surgery, rather than being left untreated” [20]. Misrai et al. reported the development of de novo stress urinary incontinence in 13% women after LSC. In this study, 53 women without preoperative stress urinary incontinence or occult stress incontinence were assessed [21].

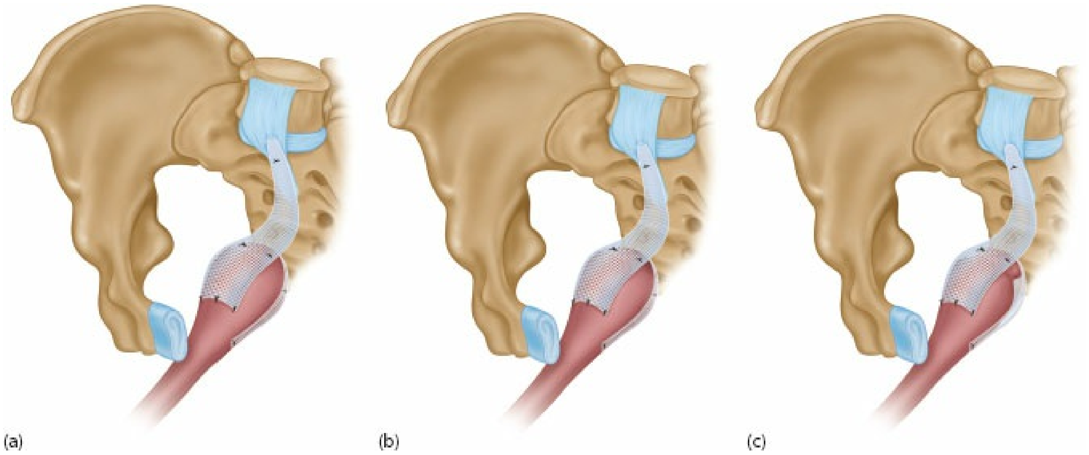


Figure 100.7 Three types of laparoscopic sacral colpopexy (LSC). (a) LSC for posthysterectomy vault prolapse. (b) LSC used in conjunction with laparoscopic total hysterectomy. (c) LSC used concomitantly with laparoscopic subtotal hysterectomy.

Based on the current knowledge, the decision to offer concomitant anti-incontinence surgery during LSC is up to the clinical judgment of the surgeon after a careful discussion with the patient. The author gives patients the option of a concomitant TVT procedure or laparoscopic colposuspension during the LSC procedure when occult stress incontinence is present. Patients should always be warned of the possibility of persisting or de novo urinary incontinence developing following LSC, whether or not anti-incontinence surgery is also performed. The prevalence of de novo postoperative urinary incontinence is approximately 15%–18% [49].

RESULTS

To date, only a small number of studies on LSC have been reported [12,13,24–30,32,40,41,50,51]. All studies report high success rates and low morbidity with the LSC procedure. However, the different study methodologies employed make the outcome data difficult to collate. It is difficult to draw any conclusions about the long-term outcomes for LSC due to a lack of a standardized technique, wide variation in the definition of outcomes, and lack of control for potential confounders, especially concomitant surgery. In some series, the majority of subjects underwent laparoscopic sacral hysteropexy (LSH) rather than LSC [13,32,34]. The surgical outcomes in these studies did not differentiate between LSC and LSH.

Higgs et al. [12] reported on 140 consecutive cases treated by LSC of whom 103 were available for long-term follow-up [12]. This is the largest case series of LSC reported to date with a median follow-up of 66 months. A prior vaginal hysterectomy had been performed in 48% of cases and prior abdominal hysterectomy in 52%. Prolene mesh was used in all cases and fixed to the sacrum by either sutures or staples. Concomitant surgeries included laparoscopic colposuspension (37.8%), paravaginal repair (19.4%), vaginal repair (19.4%), rectopexy (3.8%), anal sphincter repair (1.9%), and transurethral collagen injection (1%). The average age of the patients was 58 years and the mean duration of surgery was 145 minutes overall and 107 minutes if LSC was the only procedure. Review was conducted independent of the surgeon. Of the 140 women, 66 were available for follow-up examination and 92% (objective success rate) of these demonstrated good long-term vault support. A total of 103 women completed follow-up questionnaires and the subjective success rate was 62% with 64 of the 103 women reviewed reporting no “presence of a lump.”

Rozet et al. [13] reported on a large case series of 363 women treated by either LSC or LSH with mesh interposition between 1996 and 2002. Of the 363 cases, 97 (26.7%) underwent LSC (82 women had posthysterectomy vault prolapse and 12 underwent combined LSC and hysterectomy). The other 266 (73.3%) cases underwent LSH with mesh interposition. A polyester mesh, silicone coated on one side, was used with anterior and posterior mesh extensions. The mesh was sutured onto the sacral promontory and the peritoneum closed over the mesh. This study reported outcomes for the whole group and a subanalysis of patients who underwent LSC was not performed. A concomitant TVT procedure was performed in 163 (45%) cases, all of whom demonstrated the signs of stress incontinence preoperatively. The average age of the 363 subjects was 63 years and the average operating time 97 minutes. The prevalence of recurrent prolapse was only 4%.

Sarlos et al. reported on a 5-year follow-up study of 68 subjects treated by LSC. Complete anatomical cure (i.e., stage 0 prolapse in any compartment) was reported in 83.8% of subjects with a 3.5% reoperation rate. Subjective cure was reported in 95.3% of subjects [52].

Comparative Studies

Paraiso et al. [53] compared 56 women with 61 women treated by LSC and ASC, respectively, in a nonrandomized, observational study. LSC required a significantly longer mean operating time than ASC (269 versus 218 minutes). However, LSC was associated with significantly less blood loss and a shorter hospital stay. In the LSC group, 11% of subjects required “further procedures for the pelvic floor, excluding injections” compared with 5% in the ASC group. Similar complication rates were observed in both groups.

Klauschie et al. [54] compared the anatomic and perioperative outcomes for 43 women treated by LSC with 41 women ASC in a nonrandomized, retrospective, observational study. At 1 year, the mean improvement in the POPQ C-point from baseline was similar in both groups. The baseline to 1 year C-point improvement was 7.73 and 7.81 cm for the LSC and ASC, respectively.

Geller et al. [55] compared the short-term (6 weeks) outcomes of robotic LSC with ASC in a nonrandomized, retrospective, observational study. Of the 178 subjects treated, 73 and 105 underwent robotic LSC and ASC, respectively. The mean operating time was longer for robotic LSC than ASC (328 versus 225 minutes) but the mean blood loss was less for robotic LSC (103 versus 255 mL). At follow-up, there was a significant, but not clinically relevant, improvement in the median POPQ C-point score for the robotic compared to the abdominal group (−9 versus −8 cm, $p = 0.008$).

Marcickiewicz et al. [56] compared 60 women with 51 women treated by LSC and vaginal sacrospinous colpopexy (VSC), respectively, in a nonrandomized, observational study. The operating time was significantly longer for the LSC group (median: 129 minutes) compared to the VSC group (median: 62 minutes). Complications and days in hospital were similar in both groups. The median follow-up period was 33.6 and 28.4 months for the LSC and VSC groups, respectively. No recurrent vault prolapse occurred in either group, but 25% and 27.4% of subject in the LSC and VSC groups, respectively, had cystoceles at follow-up. In the LSC group, 16.7% of subjects had rectoceles compared with 0% in the VSC group at follow-up.

Anger et al. randomized 78 women to either robotic (robotic sacral colpopexy [RSC]) or LSC [57]. Compared to RSC, LSC took, on average, 24.4 minutes less time ($p = 0.03$). RSC was more expensive than LSC but outcomes at 6 months and complications were similar in both groups.

COMPLICATIONS

Just over 3.7 million women underwent surgery for pelvic organ prolapse from 1979 to 1997 in the United States; this included 31,387 women with laparoscopically performed prolapse surgery. Complications in association with all the various procedures used to treat prolapse occurred in only 5.5% of cases. In women who underwent laparoscopic surgery to manage pelvic organ prolapse, complications were identified in only 6.6% of patients, which is comparable with other prolapse operations. Women treated laparoscopically had a significantly higher risk of pulmonary edema but a lower risk of urinary complications [58].

Higgs et al. [12] reported that immediate and short-term complications of LSC were rare. However, the mesh erosion rate was high at 9%. When the mesh was introduced vaginally, the erosion rate was 20% but only 6% when introduced laparoscopically. The transvaginal introduction of the mesh was performed in 20 cases but abandoned in favor of laparoscopic introduction after the authors noticed a high erosion rate with this technique. The mesh erosion rate reported by Geller et al. following robotic LSC was also 6% [55].

The main complications of LSC reported by Rozet et al. included eight conversions to ASC, three vaginal mesh erosions, two mesh infections, one bowel obstruction requiring bowel resection, and one case of spondylitis. No case of postoperative dyspareunia was reported [13].

In the series reported by Cosson et al., conversion from LSC to ASC was required for 7.8% of cases [33]. One rectal and two bladder injuries were reported. Reoperation for hemorrhage or hematoma was required in three women. A conversion rate of 5% from robotic LSC to ASC was reported by Geller et al. [55].

CONCLUSION

Vaginal vault prolapse following hysterectomy is a challenging clinical problem. The goals of surgery when treating vaginal vault prolapse are

- The relief of patients’ symptoms
- The correction of vaginal vault prolapse by restoring the normal pelvic anatomy where feasible
- The correction of coexisting urinary, coital, and lower bowel dysfunction
- The avoidance of the development of urinary, coital, and lower bowel dysfunction
- The achievement of a durable result, which in some cases may require the use of prosthetic materials

The “best” operation for treating vaginal vault prolapse remains the subject of ongoing debate. In treating vaginal vault prolapse, vaginal, abdominal, and laparoscopic approaches should not be viewed as competing procedures [59]. The choice of operation to treat vaginal vault prolapse depends on many factors: the surgeon’s training and experience will influence the choice of surgery, and a recommendation for a specific operation can only be made after careful clinical assessment and after taking into consideration the patient’s age, medical condition, coital activity, level of physical activity, and a history of failed prior surgery.

Systematic review of the surgical management of prolapse has demonstrated the ASC procedure to be associated with a lower recurrence of vault prolapse and less dyspareunia than vaginal approaches [18–20,22]. However, when compared to vaginal approaches, ASC required a longer operating time and patients were slower to return to activities of normal daily living. LSC should be performed in a similar fashion to ASC. Based on the reported experiences of many surgeons over the past 50 years [22] and upon personal experience of ASC and LSC procedures, the following important principles of ASC and LSC are proposed:

- Careful patient selection
- Appropriate level of surgical experience and expertise
- Use of a biocompatible prosthesis
- A broad area of prosthesis attachment to the vaginal vault and upper anterior and posterior vagina
- Fixation of the prosthesis to the anterior longitudinal ligament on the sacral promontory rather than to the sacral hollow
- Placement of the prosthesis without tension to reduce the risk of postoperative urinary incontinence

From the limited available data, LSC appears to be a highly effective procedure for the treatment of vaginal vault and marked uterovaginal prolapse. The LSC procedure combines the accepted effectiveness of ASC over vaginal operations for vault prolapse with the significant benefits of laparoscopic surgery. These benefits include superior surgical visualization, less pain, and quicker return to activities of normal daily living. The major limitation of LSC is the high degree of laparoscopic and reconstructive pelvic surgical skills required to perform this operation effectively and safely. With continued advances in laparoscopic equipment (including robotics) and more widespread training in advanced laparoscopic surgery, LSC is likely to gain in popularity. Currently, there is a paucity of data on the effectiveness, functional outcome, and safety of LSC. Further prospective studies, including more comparative studies, are required to evaluate the role of the LSC procedure.

101 Laparoscopic Sacrohysteropexy

Helen Jefferis, Natalia Price, and Simon Jackson

LAPAROSCOPIC HYSTEROPEXY

Hysteropexy should be considered when it is appropriate to offer a surgical remedy for uterine prolapse.

The absolute indication is fertility preservation in women who have not yet completed childbearing. However, this is a small group of patients; most women presenting requiring surgery for prolapse have no desire for further children, indeed the majority are postmenopausal.

In the authors' experience, the other more prevalent indications for hysteropexy include patient request and superior outcome. The latter is a contentious statement; clinical data is still sparse and will be discussed in this chapter. However, when there is loss of apical support, traditional vaginal hysterectomy will not correct defects. This is most readily apparent when women present with procidentia; it is self-evident that hysterectomy will not treat vaginal eversion. If hysterectomy is performed, additional vaginal suspension needs to be provided, usually either by sacrospinous fixation or sacrocolpopexy.

Hysteropexy, in our view, offers a more logical approach, and furthermore avoids vaginal mesh, with the attendant extrusion risk it carries.

THE TRADITIONAL APPROACH FOR UTERINE PROLAPSE

Vaginal hysterectomy has long been the standard approach for management of uterine prolapse, with the first successful planned case being credited to Langenbeck in 1813. While it has served the gynecologist well for many years, its continued use raises some significant questions. Vaginal hysterectomy fails to address the underlying deficiency in connective tissue pelvic floor support [1] that causes prolapse; indeed, the uterosacral ligaments are cut during the operation—it is hardly surprising that recurrent prolapse rates are so high, with rates of up to 40% described in the literature [2,3]. Recurrence can manifest with vaginal vault eversion, or more commonly recurrent enterocoele/cystocele. We know that cystocele commonly arises because of loss of apical type 1 vaginal support [4], and until apical support is established, it will recur. Repeated colporrhaphy may ultimately shorten, narrow, and scar the vagina.

Furthermore, hysterectomy removes a healthy organ which may play a role in patients' individual and sexual identity. It certainly isn't playing a role in their prolapse etiology; uterine prolapse is merely a sign of support failure, not the underlying cause! Vaginal hysterectomy is associated with significant postoperative morbidity. Up to one in four women may develop a vault hematoma following vaginal hysterectomy.

Increasingly, women are requesting uterine conservation [5]. This may be due to the wish to preserve fertility, or due to the belief that female identity is bound up in the female genital organs. It frequently arises after they have researched literature and the internet themselves and become aware that there are alternatives to hysterectomy. The overall rate of hysterectomy as treatment for menstrual dysfunction is also declining significantly.

THE HISTORY OF UTERINE PRESERVING PROLAPSE SURGERY

The concept of uterine preservation surgery for pelvic organ prolapse is not new.

In 1888, Archibald Donald first described the Manchester repair as an alternative to vaginal hysterectomy for patients with uterine prolapse, although this may have been a more useful technique for patients with an elongated cervix rather than a true uterine descent. In 1934, Victor Bonney highlighted the passive role of the uterus in uterovaginal prolapse, telling us it was merely the symptom of underlying poor pelvic floor support [6]. Subsequent surgeons have developed techniques for uterine preservation via a vaginal, abdominal, or laparoscopic approach.

Vaginal Approach

In 1966, Williams [7] described a technique for transvaginal uterosacral–cervical ligament plication and reported on outcomes for 20 women undergoing this procedure, with 3 "failures" encountered within a 6-month follow-up period. His method involved a posterior colpotomy with division of the uterosacral ligaments from the cervix, plication across the midline, and reinsertion into the cervix. The cardinal ligaments are then plicated anteriorly across the midline.

The concept of sacrospinous hysteropexy was first described by Richardson et al. [8] in 1989. The cervix or uterosacral ligament is transfixed to the sacrospinous ligament using either permanent or delayed absorbable sutures. In 2001, Maher [9] reported a small comparison study between sacrospinous hysteropexy and vaginal hysterectomy with sacrospinous vault fixation, with no differences in objective or subjective outcomes at follow-up. Other studies have suggested that sacrospinous hysteropexy has a shorter operative time and reduced blood loss as compared to vaginal hysterectomy [10]. One study also reported less postoperative incidence of overactive bladder symptoms in the sacrospinous hysteropexy group [11]. Dietz et al. [12] describe an increased risk of anterior compartment prolapse following sacrospinous hysteropexy with an incidence of up to 40%. Sacrospinous hysteropexy is the most studied vaginal technique for uterine preservation prolapse surgery; however, in general, the studies assessing it are of poor quality, with small numbers, of short follow-up periods, of lack of controls, and with limited functional outcome data.

The technique of posterior vaginal slingplasty [13] was first described in 2001, using a mesh kit to create "neo-uterosacral ligaments." One prospective comparison study quoted a 91.4% patient satisfaction rate postsurgery [14], but cumulative data suggest a high incidence of mesh complications with up to 21% mesh erosion rate [15].

Abdominal Approach

A number of methods for abdominal hysteropexy have been described, including transfixing the uterus to the anterior abdominal wall and ventral fixation to the pectineal ligaments. Most techniques use the sacral promontory as the fixation point, giving rise to the term abdominal sacrohysteropexy.

Abdominal suture sacrohysteropexy [16] was described as early as 1957, with the uterine fundus being fixed to the sacral promontory with silk sutures. More recent techniques have utilized a variety of synthetic meshes to aid fixation. In 1993, Addison [17] first described a technique for resuspending the uterus to the sacrum using Mersilene^{TM} mesh. Leron and Stanton [18] followed up 13 women undergoing abdominal sacrohysteropexy and found it to be a safe and effective surgery for the management of uterine prolapse.

Roovers et al. [19] reported on a comparison between sacrohysteropexy and vaginal hysterectomy with vault fixation; recurrence was higher in the abdominal surgery group (22%) than in the vaginal hysterectomy group (2.5%). Costantini et al. [20], however, found no subjective or objective difference in functional outcomes when comparing a group of patients undergoing sacrohysteropexy with those undergoing hysterectomy with sacrocolpopexy. Sacrohysteropexy was associated with a shorter operative time and hospital stay, with a reduction seen in intraoperative blood loss. It is difficult to interpret data reporting comparisons between abdominal sacrohysteropexy and hysterectomy due to variations used in surgical technique and differences in mesh type, size, shape, and attachment points.

Laparoscopic Approach

Laparoscopic abdominal surgery has, with very few exceptions, replaced laparotomy in many centers. The laparoscope confers better vision than laparotomy, allowing a magnified, high definition view. Furthermore, the long instruments allow better pelvic access, particularly behind the uterus, than laparotomy confers.

A number of laparoscopic uterine suspension procedures have been described using different methods.

Laparoscopic ventrosuspension proposes suturing the round ligaments to the rectus sheath. The round ligament is not however particularly robust, and perhaps as expected, it has been shown to have poor outcomes, with one case series of nine women reporting recurrent prolapse in all but one patient within 6 months [21]. Chen et al. [22] used mesh to suspend the uterus by attachment to the anterior abdominal wall. While they reported good outcomes, all patients experienced significant pain or dragging sensations over the mesh attachment site. Laparoscopic uterosacral ligament plication was first described by Wu et al. in 1997, with good results in a small case series [23]. Maher et al. [24] modified this technique to include reattachment of the uterosacral ligaments to the cervix and closure of the pouch of Douglas, with an objective success rate of 79% in 43 women at 12 months.

Recently, techniques have focused on using the sacral promontory as a point of fixation. Krause et al. [25] followed up 81 women undergoing laparoscopic sacral suture hysteropexy, placing sutures through the posterior aspect of the cervix, and transfixing to the sacral promontory via the right uterosacral ligament. Objective correction of prolapse was seen in 94% of patients.

Cutner et al. [26] developed the technique of laparoscopic uterine sling suspension. The peritoneum is opened over the sacral promontory and the rectum is reflected laterally. A tunnel is created by blunt dissection underneath the peritoneum from the sacral promontory to the insertion of the uterosacral ligament complex into the cervix on either side. Mersilene tape on a needle is placed through the cervix, through the uterosacral ligaments, and through the peritoneal tunnels on each side before being tacked to the sacral promontory bilaterally to suspend the uterus. This technique aims for the sling to resemble newly created uterosacral ligaments.

Oxford’s experience with hysteropexy has shown that mesh, when attached to the posterior aspect of the cervix, or to the cervical stump following hysterectomy, has a high avulsion rate. We therefore developed a method of complete cervical encirclage (The Oxford Hysteropexy, Price et al. 2010) using a bifurcated polypropylene mesh [27]. Initial follow-up studies [28] show good outcomes with significant improvement ($p < 0.001$) in all parameters of International Consultation on Incontinence Questionnaires-Vaginal Symptoms (ICIQ-VS) and Pelvic Organ Prolapse Quantification (POP-Q) scores postsurgery.

The rest of this chapter looks at the technique of laparoscopic hysteropexy in more detail.

AIMS OF LAPAROSCOPIC HYSTEROPEXY

- To restore and reinforce uterine support by suspending the uterus from the sacral promontory using Type 1 polypropylene mesh. Two strong attachment points are used; the cervix and the anterior longitudinal ligament overlying the sacral promontory.
- To restore vaginal length without compromising caliber.
- By restoring apical support, a reduction in anterior prolapse is seen, consistent with the importance of restoring level 1 support in cystocele repair.
- By restoring apical support, a reduction in enterocoele is seen; low rectocele, however, frequently requires a concurrent vaginal repair.

The theoretical advantage is that this type of repair, by augmenting weak connective tissue with prosthetic prolene, confers stronger apical support resulting in lower recurrence rates. It allows the patient to retain their fertility; and by avoiding vaginal surgery, there is a lower potential for dyspareunia and sexual dysfunction.

TECHNIQUE: THE OXFORD HYSTEROPEXY

The procedure is performed under general anesthesia with the patient supine and in semilithotomy position. A urinary catheter and uterine manipulator are inserted. A four-port laparoscopic technique is used with 10 mm umbilical, two 5 mm lateral, and a 12 mm suprapubic port inserted. After identifying the sacral promontory, the peritoneum is incised with bipolar graspers and monopolar scissors to identify a safe window of periosteum. A peritoneal relaxing incision is then used medial to the right ureter to retract it from the surgical site and extended into the pelvis, lateral to the rectum. The right uterosacral ligament is identified and the peritoneum is opened over this, where the uterosacral ligaments insert into the cervix. A flap of peritoneum is mobilized to facilitate reperitonization. The vesicouterine peritoneum is incised to reflect the bladder away and bilateral avascular windows are created in the broad ligament, lateral to the uterine arteries, at the level of the internal os.

The authors use a bifurcated polypropylene Type 1 macroporous nonabsorbable mesh (ProLite^{TM}; Atrium Medical Corporation), bringing the arms of the mesh through the broad ligament windows. This is transfixed to the anterior cervix using nondissolvable, nonabsorbable polyester 2-0 sutures

(Ethibond®). The mesh is attached to the sacral promontory under moderate tension using two to three 5 mm helical fasteners (Pro-Tack®, Covidien). The mesh is then completely reperitonized using Monocryl® sutures [29] (Figures 101.1 and 101.2). The technique has evolved over time; initially reperitonization was not performed, however after two patients undergoing subsequent laparoscopies were found to have bowel adhesions to the mesh, this adaptation was introduced.

Approximate operating times in the authors' unit are 45–60 minutes, although senior trainees under supervision usually require about 90 minutes.

ANATOMICAL ANOMALIES

The Oxford Hysteropexy is often straightforward; it is less technically challenging than laparoscopic sacrocolpopexy. However, surgery can be complicated by unexpected anatomical anomalies and the surgeon should be aware of these to minimize risk. Less experienced laparoscopic surgeons would be well advised to consent patients for alternative options, such as vaginal surgery, should anatomical anomalies make laparoscopic surgery too challenging.

Sacral Promontory

The aorta and vena cava generally bifurcate above L5; there is a safe window at L5/S1 for mesh fixation (see Figure 101.3). However, low bifurcations are seen relatively commonly and, unless visualized, dissection and promontory fixation can result in great vessel trauma and life-threatening hemorrhage (see Figure 101.4). The left common iliac vein can be particularly difficult to identify as it traverses the lumbar spine. Positive peritoneal insufflation pressure, in combination with steep Trendelenberg tilt, can cause venous emptying and the venous appearances are sometimes not dissimilar to peritoneum (see Figure 101.5).

Fat around the sacral promontory makes dissection more difficult and sacral fat doesn't necessarily correlate with body mass index; many larger patients have an easy sacral promontory and vice versa.

Beware the boggy sacral promontory (*called the pillow sign, on account of the similarity to pressing on a pillow*); when the laparoscopic instruments palpate soft tissue rather than firm sacral promontory, you are either encountering periosteal fat, or low bifurcating great vessels; dissect carefully!

Pelvic Sidewall

There is usually a very safe window between the rectosigmoid medially and the ureter laterally that can be opened and used to bury the sacral mesh tail. However, low iliac vein anomalies can be encountered (see Figure 101.6), so the safe technique is to lift the peritoneum off the pelvic sidewall before incising.

Broad Ligament

There is usually a large avascular window in the broad ligament lateral to the uterine artery that can be safely opened. However, large venous anomalies can occur, and identifying an avascular window can be problematic (see Figure 101.7). *Beware: veins and peritoneum both look blue*!

LAPAROSCOPIC APPROACH

Over recent years, there is ever growing interest in a laparoscopic approach to surgery, with many new techniques being adopted to modify procedures previously performed via the open or vaginal route. One major advantage is the magnified image giving excellent intraoperative visualization of the pelvic anatomy. The other significant advantage is improved access to parts of the pelvis that are difficult to reach via an abdominal incision. In particular, access to the Pouch of Douglas is enhanced at laparoscopic hysteropexy, compared with laparotomy. General advantages of laparoscopic compared to open surgery are reduced hospital stay, reduced need for analgesia, quicker recovery, and minimal blood loss. There is suggestion that adhesion formation is also reduced.

The main disadvantage of laparoscopic surgery is the initial increase in operating time while the surgeon learns laparoscopic techniques. Focused training and use of skills labs and laparoscopic simulators can help to address this issue. As a new generation of surgeons develop, trained from the outset in laparoscopic techniques, such concerns will become obsolete.

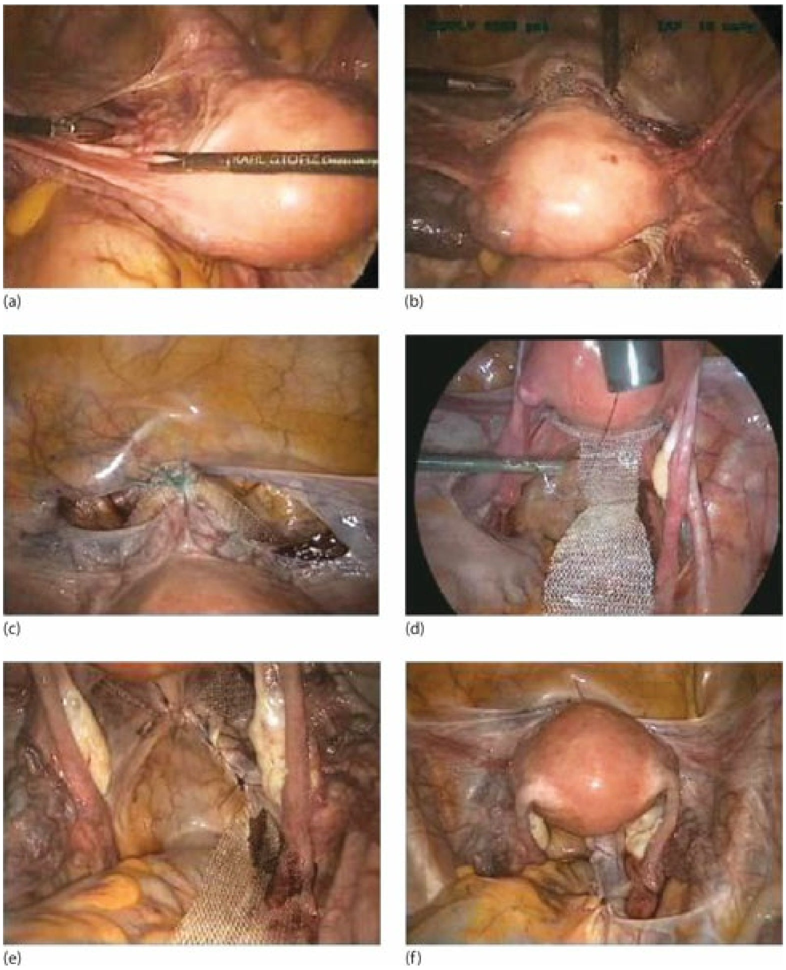

Figure 101.1 The surgical technique of laparoscopic hysteropexy: (a) Opening of the left broad ligament. (b) Mesh inserted through windows in the broad ligament. (c) Suturing of the mesh over the anterior cervix. (d, e) Peritonization of the mesh prior to fixation to the sacral promontory. (f) Mesh is fixed to sacral promontory and peritonization completed. (Reproduced from Price N et al., *Br J Obstet Gynaecol*, 117, 62, 2010. With permission.)

Robotic surgery may also have a place in the future although its benefit in gynecological surgery is still highly debatable; some contend that the learning curve for robotic surgery is quicker than conventional laparoscopic surgery.

Many skilled laparoscopic surgeons, in fact, find that if they are in a situation where open surgery is required, the operating times are slower and visualization of the anatomy is poorer.

OUTCOMES

Outcome data post laparoscopic hysteropexy are sparse. One prospective observational study [28] has reported outcomes following laparoscopic sacrohysteropexy in 140 women. Follow-up time varied between 1 and 4 years. Eighty-nine percent of women felt their prolapse was “very much” or “much” better. There was a significant improvement ($p < 0.001$) in all parameters of ICIQ-VS and POP-Q scores postsurgery. Four percent of women experienced further apical prolapse of which half underwent further surgical intervention. This compares favorably with the risk of vault prolapse following vaginal hysterectomy [30]. One reason for recurrent apical prolapse was the initial mesh either being left too loose or stretching in vivo. This was simply treated by mesh plication (Prolene® or Ethibond nonabsorbable sutures). The authors have now modified their technique and are using a more robust mesh, 5 cm in width compared with a previous 3 cm mesh that was more susceptible to stretch. The rate of serious complications was 4%, and comprised of bowel adhesions (prior to the modified reperitonization technique), broad ligament vascular injury and one pulmonary embolus. Ninety-two percent of women when asked would recommend the operation to a friend.

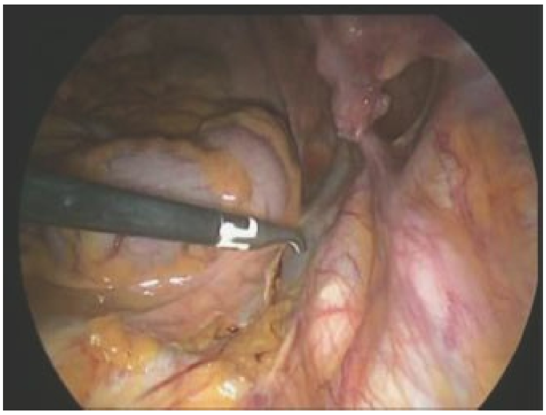

Figure 101.6 Low right iliac vein on pelvic sidewall.

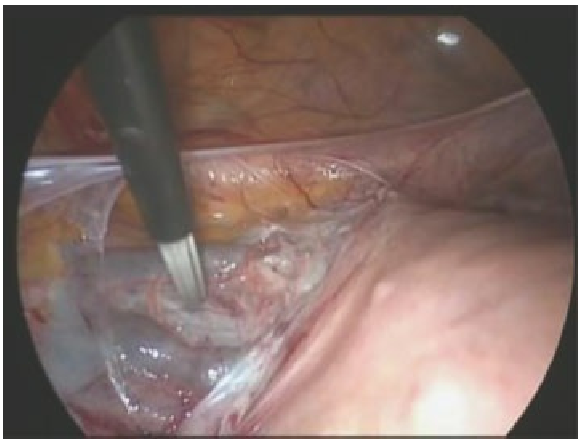

Figure 101.7 Large vein in the broad ligament. A safe window can be found in most cases.

As this is still a relatively new technique, more outcome data over a longer time frame is needed to enable comparison with more traditional approaches. The outcomes of the Vault or Uterine prolapse surgery Evaluation (VUE) study [31] (randomized multicenter trial comparing uterine preservation surgery with vaginal hysterectomy) are eagerly awaited, although the methodology does allow any surgical hysteropexy technique to be incorporated, and this will adversely affect the power of the study.

DISADVANTAGES

Vaginal hysterectomy eliminates the possibility of uterine or cervical pathology, and there are incidences of unexpected pathology being detected at pathological examination of the removed uterus [32]. However, this benefit is less relevant with current advances in minimally invasive treatment of abnormal uterine bleeding. The cervical screening program is reducing cervical cancer incidence, and endometrial cancer classically presents at an early stage with uterine bleeding. Therefore, hysterectomy, to prevent future malignancy, seems irrational and totally unnecessary. There may be some value in screening women listed for laparoscopic sacrohysteropexy with an ultrasound scan before surgery.

FERTILITY FOLLOWING UTERINE PRESERVATION SURGERY

Theoretically, one advantage of sacrohysteropexy is retention of reproductive potential. It may therefore be the preferred approach for younger patients who may not have completed their family. Patients must however be counseled that data for pregnancy outcomes following the procedure are scarce, and the impact of the pregnancy on the surgery and indeed the effect of the surgery on the pregnancy are unknown. With the Oxford hysteropexy, the mesh encircles the cervix and vaginal birth is therefore not possible; in effect, the mesh acts as a cervical suture. There is also concern that uterine blood flow may be compromised as the mesh potentially surrounds the uterine arteries, although it is likely that a rich collateral supply is formed.

Since introducing hysteropexy as our standard approach to uterine prolapse, the authors have been aware of three patients who have subsequently conceived. One patient has been followed through to delivery in conjunction with her obstetrician [33]. Uterine artery Doppler studies at 23 weeks of gestation showed no compromise to blood flow. Serial growth scans showed a normally grown fetus, and the patient underwent elective cesarean delivery at 39 weeks delivering a healthy infant of normal birth weight. The patient has since required surgical correction of anterior vaginal wall prolapse, although obviously it is not clear if this is related to carrying a pregnancy or whether she would have had recurrence of prolapse anyway. The other two patients are in early pregnancy at the time of writing and will be reported on in the near future.

USE OF MESH

The use of Type 1 mesh is well established in pelvic reconstruction surgery with common usage in sacrocolpopexy and mid urethral slings. However, the medical community has become aware of implant complications in recent years; hips and breast implants have been associated with complications that have attracted a high media profile, and in gynecology mesh for prolapse and incontinence is now under intense scrutiny. This has been secondary to a realization that vaginal mesh extrusion rates are higher than previously thought and current media and public attention, in many cases associated with litigation, particularly in the United States and Scotland. The Medicines and Healthcare Products Regulatory Agency (MHRA) [34] and the Royal College of Obstetricians and Gynaecologists (RCOG) [35] have both issued guidance for urogynecologists surrounding the use of mesh in prolapse and incontinence surgery.

Certainly, the use of transvaginal mesh for vaginal prolapse appears to have a relatively high complication rate with the incidence of mesh erosion reported in the literature being 10%–18% [36]. This is secondary to mesh lying adjacent to the vaginal wall, which has been weakened by a surgical incision and subsequent scar. The mesh extrusion rate with an abdominal approach is considerably less, as the vaginal incision is avoided. Sacrocolpopexy mesh extrusion rates of 2%–11% have been reported [37,38]. In the authors’ experience, all of the vaginal extrusion complications seen have been secondary to nonabsorbable sutures (Ethibond), and since switching to absorbable sutures (Monocryl) we have not, in the past 4 years, had any mesh extrusion. There appears to be a lower rate of mesh extrusion associated with an abdominal approach [39].

With the Oxford hysteropexy, the polypropylene mesh does not approximate to the vaginal wall, lying at the level of the internal os. We have not seen, in an 8-year series of more than 500 cases, any vaginal mesh extrusion. Following initial concerns regarding bowel adhesions to mesh, the technique has been modified to completely reperitonize the mesh and subsequent to this modification in 2008, no further bowel adhesions or other mesh complications have been reported.

NICE

The National Institute for Health and Clinical Excellence (NICE) has published guidance for surgeons undertaking uterine mesh suspension procedures, as summarized in the following [40].

- Current evidence on the safety and efficacy of mesh suspension slings for uterine prolapse repair is inadequate.
- This procedure should only be performed by surgeons specializing in pelvic organ prolapse.
- Units carrying out these procedures should have arrangements for clinical governance, consent, and audit.
- Patients should be given clear written information regarding the uncertainty about the safety and outcome of the procedure.
- All cases should be entered onto the British Society for Urogynecology database.

SUMMARY

Uterine preservation surgery is increasing in popularity both with surgeons and patients. Fertility is preserved and this remains the one absolute indication for hysteropexy. Other theoretical advantages include stronger apical support, reduced vaginal surgery, associated vaginal dysfunction and psychological wellbeing, and reduced surgical morbidity. More good quality data are needed to enable clinicians to make evidence-based decisions regarding choice of prolapse surgery. It is to be hoped that the VUE study into different techniques of apical support will inform this debate.

Prevention, Recognition, and Treatment of Complications in Laparoscopic Pelvic Floor Surgery

Christopher Maher and Nir Haya

INTRODUCTION

Gynecologists have led the surgical specialties in recognizing the benefits to our patients of reduced postoperative pain, hospital admissions, and quicker return to normal activities associated with laparoscopy. Improved optics, lighting, instrumentation, and technology over the last 15 years have seen an explosion in operative general gynecology surgery previously performed via laparotomy. Over the next decade, as laparoscopic suturing techniques are mastered, the laparoscope is likely to play an increasingly important role in female pelvic floor surgery. It is vital while laparoscopic pelvic floor surgery is in its infancy that we are competent in the prevention, recognition, and treatment of complications associated with this mode of access to the abdomen.

In recent years, the rate of complications from gynecological laparoscopy ranges from 4 to 8/1000 [1–3] diagnostic procedures and increases from 4 to 180/1000 operative gynecology surgeries [3–7]. Risk factors for gynecological laparoscopic complications include establishing laparoscopic access [5,6], concomitant laparoscopic hysterectomy [3,8], and surgeon inexperience [4,9].

ACCESS COMPLICATIONS

At least 50% of all reported complications at laparoscopic surgery occur at time of entry to the abdomen [5,6]. The majority of gynecologists prefer the closed (Veress needle) technique to the open technique [1,10]. The major complications related to entry include vascular and bowel injuries and associated postoperative hernia formation.

Open and Closed Technique

Although entry-related complications using the closed approach are uncommon, they can be fatal and occur in 0.31–2.4/1000 procedures [1,4,8,9,11]. Chapron reported that major vascular injuries occurred five times more frequently during the closed technique as compared to the open approach. Of the 44 reported cases in the literature between 1982 and 1997, 82% followed the closed and 17% followed the open technique [12].

A large Dutch review retrospectively compared the open (12,444 patients) and closed access (489,335). They found that the incidence of major vascular was 0.075% using the closed approach and 0% with the open approach ($p < 0.05$). The incidence of visceral damage was 0.083% with the closed technique as compared to 0.048% with the open ($p > 0.05$) [13].

In a randomized controlled trial (RCT), 150 subjects undergoing cholecystectomy were allocated to the open or closed approach. Major complications were reported in 3/75 (4%) of the closed as compared to 1/75 (1.3%) of the open ($p < 0.05$) [14]. The open approach was also significantly faster to perform. In a smaller RCT of 50 patients undergoing laparoscopic surgery, no difference in complications was observed, but the open approach took half the time of the closed approach to obtain access [15].

In contrast, a more recent questionnaire review of Dutch gynecologists reported that the complication rate in those undergoing open laparoscopy was significantly higher compared to those undergoing closed laparoscopy. The complication rate among those undergoing open laparoscopy ($n = 579$) was 1.38% as compared to 0.12% in the closed group ($n = 20{,}027$; $p = 0.001$). While the rate of vascular injuries was the same in both groups, the rates of gastrointestinal, wound infections, and failed access were significantly greater in the open group. The rate of open laparoscopy among Dutch gynecologists was only 2% and was reserved for those with previous laparotomy, those with suspected adhesions, and the very obese or thin. The authors concluded that the closed approach was safer than the open approach. An alternative message is that gynecologists should not perform procedures that they perform rarely in patients at high risk of complications. In our own tertiary referral urogynecology practice, the open technique is used exclusively. In a recent Cochrane review comparing open and closed access for laparoscopic entry, 17 trials evaluated 3040 individuals. Overall, there was no advantage in using any single technique in preventing major complications. Extraperitoneal insufflations and failed entry were both less frequent in the open technique compared to the closed approach [16].

It has been demonstrated that 50% of women with previous midline vertical incisions and 20% with low transverse incisions have some degree of periumbilical adhesions [17]. When there is concern regarding the safety of blindly introducing the insufflating needle at the umbilicus, an alternative site of placement is the left upper quadrant 3 cm below the costal margin in the midclavicular line (Palmer's point, Figure 102.1a). In retrospective audits, no significant complications have been reported with this approach [18,19].

Trocar-Associated Complications

In an attempt to minimize the risk associated with accessing the abdominal cavity, increased attention has been focused on trocar design. The traditional pyramidal trocar (Figure 102.2) cuts through the tissue, and safety shields (Figure 102.2) have been added to minimize the risk to the abdominal wall or of perforation of intra-abdominal vessels or a viscus. The cutting blade retracts into the plastic sleeve after the abdominal wall has been penetrated. The incidence of major vascular injuries from trocars and Veress needle averages around 0.1% [20–22] and remains unchanged despite the use of the safety shield in a large retrospective series reported by Saville and Woods. Bhoyrul et al. [23] reported that 87% of deaths from vascular injuries and 91% of bowel injuries at time of entry involved trocars with safety shields. They concluded that despite the blade retracting soon after entry into the peritoneum, the momentary presence of the blade in the abdominal cavity as seen in Figure 102.3 is all that is required for injuries to occur. Surgeons should not overestimate the level of safety associated with this device.

Conical or blunt tip trocars have been designed to minimize the risk associated with bladed trocars (Figure 102.2). They dilate the fascia and muscular tissues, thus decreasing the potential trauma as it enters the abdominal cavity. Conical tips require a greater entry force to the abdomen than sharper pyramidal [24] and leave a defect approximately 50% narrower than the sharper pyramidal [25]. Leibl, in a nonrandomized study, demonstrated that the reduced wound defect following the use of conical trocars was clinically relevant, with incisional hernia being reported 10 times more frequently after the pyramidal as compared to the conical trocar [26]. In a further study, there were no reported injuries to blood vessels of the anterior abdominal wall in the conical group as compared to 0.83% for the cutting trocar [21]. In more recent RCTs, the radially expanding conical trocar (Step^{TM}, InnerDyne, Inc., Sunnyvale, CA) had less cannula site bleeding, reduced pain, less wound complications, and higher patient satisfaction as compared to the pyramidal trocar [27,28]. Munro and Tarnay [29] recently demonstrated that the fascial and muscular defect from a 12 mm blunt trocar resulted in a similar fascial defect to the 8 mm pyramidal trocar and suggested that the fascial defects from 12 mm blunt trocars do not need closing, a view supported by others [27,30].

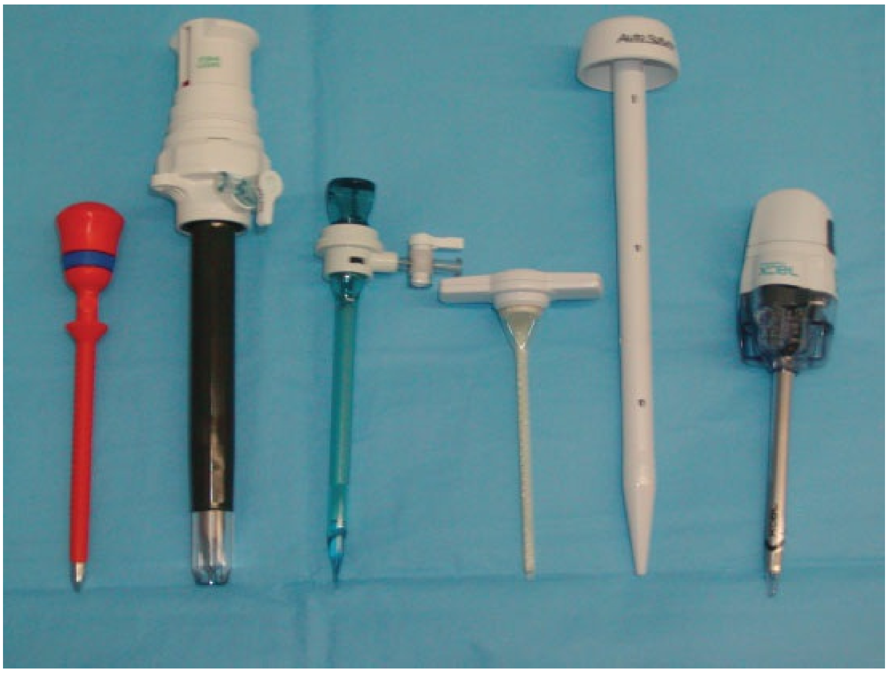

Figure 102.2 A variety of trocar designs. From left to right: pyramidal trocar (E.M.T., Warriewood, New South Wales, Australia), shielded trocar (Versaport, Tyco, Norwalk, CT), conical trocar (Separator, Applied Medical, Santa Margarita, CA), conical trocar (Step, Tyco, Norwalk, CT), and optical access trocar (Courtesy of Optiview, Ethicon, Endosurgery, Cincinnati, OH).

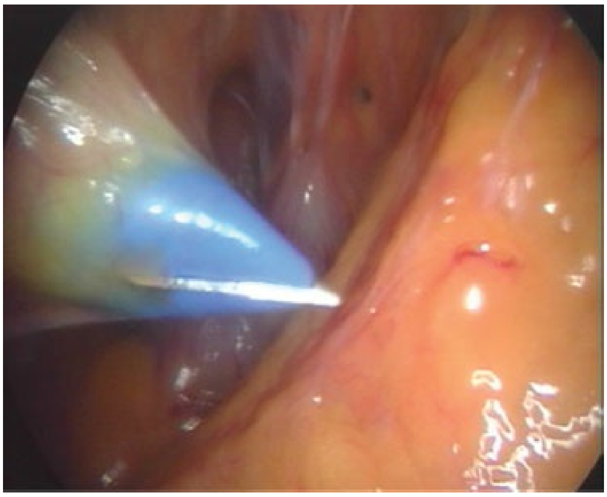

Figure 102.3 Blade of a safety shield trocar, present momentarily prior to retracting, in an abdomen with adhesions.

Optical access trocars (Figure 102.2) are designed to decrease the injury to vessels and viscera by allowing the surgeon to visualize abdominal wall placement during entry. Two optical access systems are available: one utilizes a bladed trocar that strikes the fascia and peritoneum under vision (Visiport, United States Surgical, Norwalk, CT), and the other utilizes a nonbladed trocar where a clear conical tip that is rotated under laparoscopic vision as it rotates through the layers (Optiview, Ethicon Endosurgery, Cincinnati, OH). Video 102.1 demonstrates the technique of a subumbilical optical access entry.

Optical access trocars are designed to decrease the injury to vessels and viscera by allowing the surgeon to identify each layer of the abdominal wall and avoiding inadvertent injuries during entry due to a lack of vision. In a single randomized comparison, direct optical was quicker to perform than both the open [31] and closed [32] approaches without any difference in bleeding or vascular or bowel injuries. In 2013, the same group in a large RCT (n = 228) of obese women (body mass index 30–40 kg/m^2) undergoing benign gynecology surgery again demonstrated reduced entry time and blood loss in the optical access group with a tendency to reduced vascular and bowel injuries as compared to open entry technique [33]. While the superiority of optical access approach compared to alternative entry techniques has been demonstrated, further validation of these outcomes outside of the single research group is required.

An important advantage of laparoscopy over laparotomy is the lower rate of wound complications and hernias. In one study, the incidence of wound infection after open colposuspension was 11% as compared to 1% after the laparoscopic approach [34]. Magrina has estimated that the incidence of trocar hernias after laparoscopic gynecology surgery was 10–100 times lower than laparotomy [35]. He found that the incidence of hernia after laparoscopy ranged from 0.06% to 1% as compared to 13% 5 years after gynecological laparotomy.

The incidence of incisional hernia increases to 3% with the use of 12 mm trocars [36]. It is largely accepted that while 5 mm trocars do not require fascial closure, when bladed trocars 10 mm or greater are utilized, the defects should be closed to minimize the risk of bowel entrapment or incisional hernia. Video 102.2 presents a 56-year-old lady who represented 4 days post–laparoscopic sacral colpopexy with symptoms of small bowel obstruction. The video demonstrates a small bowel entrapped in the 10 mm trocar site. The bowel was able to be reduced with traction from bowel forceps with the bowel mucosa being viable. This trocar defect at the original surgery was closed with 2.0 polydioxanone (PDS) suture. Following this complication, we utilize a trocar site closure device for all 10 mm trocars. The technique is demonstrated in Video 102.3; however, this technique in our experience is associated with increased trocar site pain postoperatively.

Preliminary studies have demonstrated that the blunt trocars will significantly reduce the incidence of trocar site hernia [26], and many believe they do not need to be closed [29,30].

Secondary Trocars

Secondary trocars are required for operative pelvic floor surgery. The correct positioning of these trocars is vital to minimize damage to the vasculature of the anterior abdominal wall (Figure 102.1a and b) and to allow laparoscopic suturing in a safe and biomechanically friendly position for the surgical team.

A thorough knowledge of the vasculature of the anterior abdominal wall is required to minimize and treat perforation of the vessels. The inferior epigastric artery arises from the external iliac artery, passes superior to the inguinal ligament, and travels superiorly and medially to the lateral edge of the rectus muscle. Its position deep to the rectus muscle and superficial to the peritoneum allows for relatively easy localization laparoscopically (Figure 102.4).

The superficial epigastric artery arises from the femoral artery near the inguinal ring and courses medially above the rectus muscle toward the midline. The smallest branch of the femoral artery, the superficial circumflex iliac artery, runs laterally to supply the skin and superficial fascia.

Perforation of the inferior epigastric artery will produce retroperitoneal or intraperitoneal bleeding. Perforation of the superficial epigastric artery will result in intramuscular or subcutaneous bleeding. The deep circumflex iliac artery arises from the external iliac artery opposite the inferior epigastric artery and runs posterior to the inguinal canal to the anterior superior iliac spine where it anastomoses with a variety of vessels. Figure 102.1a demonstrates the course of the anterior abdominal wall vessels.

The surgeon can use transillumination for locating superficial abdominal wall vessels, but intraperitoneal identification is required for the inferior epigastric artery. When the inferior epigastric artery is difficult to visualize, intra-abdominal landmarks can be helpful. It usually arises from the inguinal canal medial to the round ligament and travels cranially lateral to the obliterated umbilical arteries. The lower ports are placed as in Figure 102.1a and b lateral to the inferior epigastric and medial to the deep circumflex vessels. If further trocars are required, they can be sited in the midline suprapubically or at the level of the umbilicus lateral to the edge of the rectus muscle. If a 10 mm trocar or greater is required for introducing mesh, the harmonic scalpel, or the removal of pathology, this is placed either on the side of the surgeon or at the suprapubic site, if utilized.

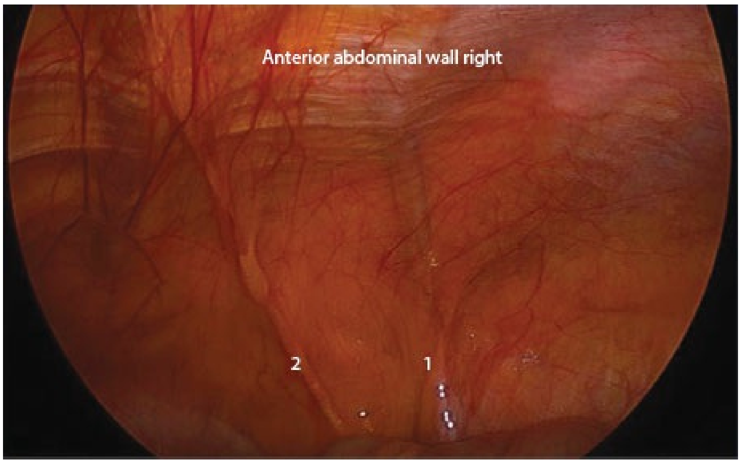

Figure 102.4 Laparoscopic localization of the right inferior epigastric artery (1) lateral to the obliterated umbilical artery (2).

Even after all these preventive measures are employed, experienced laparoscopic surgeons may still be faced with arterial bleeding from the inferior epigastric artery. The offending trocar should not be removed as this denotes the location of the artery that may become difficult to visualize as the hematoma spreads. If the bleeding is recognized early and the inferior epigastric artery can be identified, both ends of the transected vessel can be diathermied with bipolar forceps (Figure 102.5a). If this is unsuccessful, a No. 12 Foley catheter can be passed through the 5 mm trocar and the Foley balloon inflated to 10–15 cm^3 with sterile water. The trocar is then removed over the catheter and firm traction, secured with an umbilical cord clamp overnight (Figure 102.5b). The following morning, the clamp and catheter are removed. If this fails to secure the vessel, a CT-1 needle is passed through the abdominal wall into the abdomen and passed from inside the abdomen to the outside using laparoscopic needle holders and tied both cephalic and caudal to the trocar. The sutures are removed the following morning (Figure 102.5c). Finally, the inferior epigastric vessel can also be secured with sutures introduced through a small abdominal wall incision and two passes of the trocar site closure device (Endoclose^{TM}, Covidien, Mansfield, MA) on either side of the vessel. The suture is then tied above the sheath and the skin incision is closed. This is very similar to the technique utilized for closing large trocar defects in Video 102.3.

BOWEL INJURIES

The incidence of bowel injuries at gynecological laparoscopy varies from 0% to 0.5% [7,37]. Approximately one-half of these injuries occur during entry [3,8,38], and the large and small bowel are equally involved [4,39]. As there appears to be no significant difference in the rate of bowel injuries with either the closed or open approach, little can be done to minimize the occurrence of the injury except that the damage may be more readily detected intraoperatively with the open technique [40]. After reviewing the literature, Magrina calculated that only 43% of bowel injuries at laparoscopic surgery were diagnosed intraoperatively [35]. The mortality rate from bowel injuries in gynecological laparoscopy ranges from 2.5% to 5% [21,41], but this has been shown to increase to 21% in those with a delayed diagnosis of bowel injury [42].

Direct Injuries

If there is a recognized Veress injury to the bowel at the time of surgery and there is no associated fecal spill, it is likely that the injury can be managed expectantly. Although no clear guidelines exist in nine cases of Veress injuries to the bowel treated expectantly, there were no complications [1,8,38]. Trocar damage to the small bowel mandates careful inspection of the whole bowel to ensure no through-and-through injuries have occurred. Simple small injuries to the small and large bowel should be repaired in one or two layers of interrupted sutures, the pelvis irrigated, and antibiotics commenced. Postoperatively, the patient is kept nil by mouth until flatus is passed. Video 102.4 demonstrates a small bowel trocar injury that was identified at surgery. We carefully checked to ensure a through-and-through injury had not occurred and the small bowel was repaired in two layers of interrupted 3.0 PDS as shown. There were no postoperative sequelae.

Electrosurgical Injuries

Electrosurgical injuries are more commonly seen in bowel injuries that are diagnosed postoperatively. Brosens estimated that the average time to diagnosis after needle or trocar injury to bowel was 1.3 days as compared to 10.4 days for electrosurgical burns [42].

Electrical injuries to the intestine are not always diagnosed intraoperatively, or their appearance leads the surgeon toward conservative treatment [43]. It is suggested that burns less than 5 mm in diameter can be treated expectantly [44]. If the area of blanching exceeds 5 mm, it is estimated that the thermal damage may exceed up to 5 cm from the apparent injury and resection should be considered [45].

In patients presenting postoperatively with abdominal pain or bowel symptoms, a computerized tomography (CT) of the abdomen and pelvis with oral and intravenous contrast should be undertaken to assess the integrity of the bowel and urinary system. Alhilli et al. [46] recently reported on a cohort of 205 women who presented within 42 days of gynecology surgery with symptoms possibly suggestive of bowel complications that 38 (18.5%) had bowel injuries. While contrast CT scan definitively diagnosed three cases that were not suspected clinically, the further three cases were not confirmed on imaging demonstrating the value of early consultation with a surgical colleague and early recourse to surgical assessment and management. Damaged bowel must be repaired or resected with or without a temporary colostomy as early as possible to minimize morbidity and mortality. All necrotic tissue should be removed to minimize the risk of abscess formation.

Prevention of Bowel Injuries

The most significant reduction in bowel complications during laparoscopic pelvic floor surgery will arise from preventing damage. The focus of attention should lie on careful adhesiolysis and enterolysis and the detection of injuries intraoperatively rather than postoperatively. A multidisciplinary group of Dutch surgeons recently performed a systematic review on the impact of adhesions in pelvic surgery. They reported on 2565 cases in 16 studies where adhesiolysis was required and reported an enterotomy rate of 5.8%. This rate increased to 8.7% in lower gastroenterology surgery and was 4.8% at gynecology surgery. The rate of enterotomy was also significantly lower if the surgery was performed laparoscopically (1.8%) as compared to laparotomy (8.9%) [47].

During adhesiolysis and enterolysis, sharp dissection with minimal diathermy will be beneficial in preventing inadvertent bowel damage. Careful inspections of the bowel for hematoma or serosal damage that may suggest breaches of the mucosa and the performance of the underwater test, if there is any concern regarding the integrity of the bowel, are all useful in allowing the intraoperative rather than postoperative diagnosis of bowel damage. The underwater test involves holding any area of the bowel suspected of damage under warmed saline looking for gas or bowel leakage. If the laparoscopic pelvic floor surgeon is faced with an abdomen of morbidly dense adhesions, it may be prudent to remember that in a large prospective RCT the vaginal approach to vault prolapse has been shown to be equally effective as the abdominal route [48] and the conversion to the vaginal approach may be the safest approach. At LSC, four (1.5%) bowel injuries in 261 cases were reported. A rectal [49] and colon [50] injury were repaired laparoscopically without sequelae, and two small bowel injuries were diagnosed postoperatively and underwent subsequent laparotomy [51].

Bowel Preparation

Bowel preparation prior to surgery was utilized—first, to remove the bulky intraluminal contents to improve surgical field vision and bowel handling, and second, to decrease the risk of peritoneal and wound contamination if the bowel was inadvertently opened. Neither of these beliefs have been confirmed in RCTs in elective operative gynecology [52] or colorectal surgery [53]. Bowel preparation results in the transfer of fluid and electrolytes to the bowel lumen that may result in hypokalemia and hypothermia and should be utilized perhaps only in those with higher risk of bowel injury such as those with known adhesions or diverticular disease.

Few studies have evaluated gastrointestinal morbidity following sacral colpopexy. In a retrospective review of 390 cases of LSC, Warner et al. reported that the rate of bowel complications including ileus, small bowel obstruction, or bowel injury was 2.3% [54]. The peritoneum was closed over the mesh in this series. In comparison, 1 in 20 women in the colpopexy and urinary reduction efforts trial experienced significant gastrointestinal morbidity after open sacral colpopexy where closure of the peritoneum was optional. Of 322 women in the study, 19 had symptoms of possible ileus or small bowel obstruction; of these, 4 had reoperation for small bowel obstruction, 11 were readmitted for medical management, and 4 had a prolonged initial hospitalization for gastrointestinal symptoms [55]. In a recent publication comparing robotic and laparoscopic approach to sacral colpopexy, again where closure of peritoneum was optional, the rate of small bowel obstruction was 2.6% [56]. The question raised is whether the relatively simple task of closing the peritoneum after sacral colpopexy has a role in minimizing postoperative bowel complications and would be easily answered by a subanalysis of these two papers. Contrary to this, Elneil et al. [57] reported no postoperative bowel complications in a series of 128 cases where the mesh was not buried at time of sacral colpopexy.

LEARNING CURVE AND LAPAROSCOPIC COMPLICATIONS

Improving the laparoscopic experience of the surgeon may prove to be one of the simplest means of minimizing morbidity associated with bowel injuries at gynecologic laparoscopy. Brosens reported that a gynecologist performing less than 100 laparoscopies a year had a five times higher rate of bowel injuries than those performing more than 100 laparoscopies a year [38]. The learning curve associated with LSC has long been considered a barrier to uptake of the technique. Claerhout et al. [58] demonstrated competency based on four outcome measures: complication rate, conversion rate, operating time, and anatomical outcomes achieved after 60 cases. Operating time declined rapidly after the first 30 cases and continued to decline before plateauing after 90 cases. Akladios et al. [59] retrospectively reviewed their first 47 cases and demonstrated a uniform decrease in operating time over the study period; however, the operating time decreased most significantly over the first 30 cases. Similarly, Mustafa et al. [60] demonstrated that during the first 48 cases that operating time decreased uniformly and that mastery was obtained after 30–40 cases. Reassuringly, during studies [59–61] that have evaluated implementation of LSC, no significant change in complication rate was identified during the learning phase; however, given that the significant complication rate is less than 5%, this is not surprising. Skills can be improved in a variety of means including training programs, skills workshops, and operating with colleagues.

INJURIES TO THE BLADDER

Inadvertent cystotomy has been reported in 4% of laparoscopic colposuspensions [62]. In 261 published LSC procedures, 5 (1.9%) inadvertent cystotomies were reported, all of which were repaired laparoscopically at the initial surgery without complication [49–51]. A gas filled urinary bag or blood in the urine means bladder trauma till proven otherwise and warrants careful laparoscopic inspection of the bladder distended to 300 mL and cystoscopy. Cystotomies should be repaired in two layers so that the bladder is watertight at 300 mL. After repair, cystoscopy should be performed with the laparoscope in place, to ensure that there are no other unrecognized injuries and that the ureters are patent.

After a watertight cystotomy repair, the catheter can safely be removed at 4 days [51]. If concomitant continence surgery is performed, the nursing staff and the patient should be vigilant during the trial of void to ensure the bladder is not grossly over distended.

Postoperative cystoscopy is vital to minimize lower urinary tract complications following pelvic floor surgery as it is the unrecognized cystotomy that may cause vesicovaginal fistula [63]. Inadvertent cystotomy can occur during adhesiolysis at LSC: a continuous 2.0 polyglactin suture on a CT-2 needle then closes the defect in two layers. In the first layer, care is taken to ensure that the mucosa and detrusor muscle are included. This layer is inverted during the more superficial closure of the second layer. Problems can also be encountered during the repair of a large cystotomy at the time of a difficult hysterectomy.

URETERIC INJURIES

Ureteric injuries following pelvic floor surgery are reported in 3% of cases [64,65]. The morbidity associated with ureteric injury can be dramatically reduced if identified intraoperatively using postoperative cystoscopy and intravenous indigo carmine [64,65]. If indigo carmine is not clearly visible following laparoscopic pelvic floor repair, the injury is likely to be related to kinking of the ureter in the lateral retropubic space or in relation to the uterosacral/cardinal ligament sutures during sacral colpopexy or vault suspending procedures. Lateral retropubic or vault suspending sutures should be removed one at a time till the ureteric patency is obtained. The sutures are then replaced at a lower level and ureteric patency is again confirmed. If patency is not confirmed with the removal of the sutures, retrograde dye studies and intraoperative urological consultation are required.

Laparoscopic hysterectomy is associated with a 0.7%–1.4% risk of ureteric injury [3,66] that is at least 10 times greater than at vaginal hysterectomy [8]. Most of these injuries are related to clamping, incision, or diathermy damage. Ureteric injuries related to concomitant laparoscopic hysterectomy usually require ureteric reimplantation by urological colleagues. One small study retrospectively compared laparoscopic hysterectomy performed with and without ureteric catheters and suggested that ureteric catheters may decrease the risk of ureteric injury [67]. Just less than 10 minutes was required to place the catheters, but no other prospective evaluation of routine ureteric catheters at laparoscopic pelvic floor surgery is available.

SACRAL BLEEDING

Presacral venous bleeding during LSC is uncommon but potentially life-threatening. The presacral fascia covers and protects the underlying plexus, which consists of venous network both on and beneath the surface of the sacral periosteum as seen in Figure 102.6. Inadvertent manipulation outside this avascular presacral space may tear the fascia and cause damage of underlying thin-walled veins, which are devoid of valves. It is well documented that conventional measures for hemostasis are ineffective in managing presacral hemorrhage [67]. Coagulation and suturing should be avoided because they can aggravate bleeding resulting in significant blood loss.

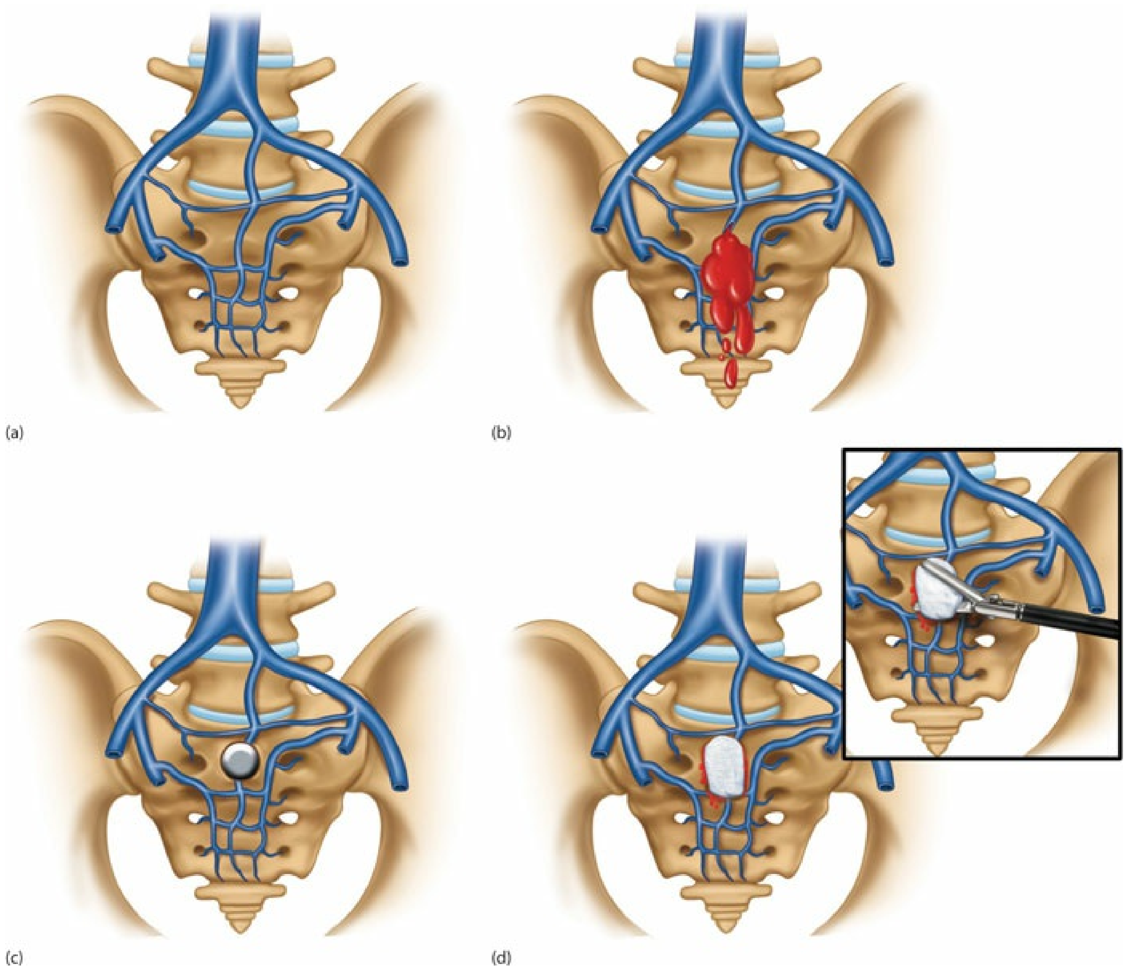

Figure 102.6 (a) Presacral venous plexus (IVC, inferior vena cava; MSV, middle sacral vein), (b) bleeding site with ruptured middle sacral vein, (c) bleeding controlled by insertion of sterile titanium thumbtack, and (d) bleeding site pressed with hemostatic matrix agent.

Surgeons should have a planned approach to this problem, and the author initially applies immediate direct pressure over the bleeding site using small tampon gauze for 5 minutes to temporarily control the bleeding. If bleeding persists, traditionally pelvic packing and the use of sterile metallic or titanium thumbtacks are employed (Figure 102.6c). Packing has the disadvantage of reoperation for removing the packs and risk of rebleeding [68]. More recently, surgeons have reported successfully using a hemostatic matrix agent such as FloSeal (Baxter, United States) or Surgicel Fibrillar (Ethicon, United States) followed by gauze pressure for 5 minutes [68] (Figure 102.6d).

OSTEOMYELITIS/DISCITIS

de Tayrac and Sentilhes recently reported the rate of serious sacral infection following sacral colpopexy to be less than 1% and to be 0.18% after LSC [69]. Although a rare condition, it has been reported after the use of both sutures and tacks into the sacrum and after open laparoscopic and robotic approaches. Potential exacerbating factors include concomitant hysterectomy, mesh exposure, the use of braided sutures or the placement of sutures and tackers deep into the periosteum at robotic sacral colpopexy without tactile feedback [70], and fixation into the L5–S1 intervertebral disc [71]. After cadaveric and CT analysis of the sacrum, Good et al. [71] determined the L5–S1 disc to be the most prominent structure in the presacral space, and insertion of the mesh into the “true sacrum” should be 1.5 cm distal to the S5–L1 disc to minimize serious sacral infections. We perform minimal sacral dissection and simply attach the mesh at the most prominent site on the sacral promontory that appears to compliment Good’s recommendation. Some surgeons attach the mesh to the lower part of the body of the L5 because of easier access.

COMPLICATIONS RELATED TO PNEUMOPERITONEUM

Subcutaneous emphysema arises as carbon dioxide leaks into or is absorbed by subcutaneous tissue. Leaks to the extraperitoneal tissues can occur at entry, with opening of extraperitoneal spaces or through existing undetected hernia. The LSC involves significant retroperitoneal dissection, increasing the risk of subcutaneous emphysema that is usually quite innocuous. Significant or sudden subcutaneous emphysema around the face, neck, and chest must alert to the possibility of mediastinal emphysema. This usually arises from a congenital defect of the diaphragm but can also occur after trauma associated with upper abdominal surgery.

Gas embolism can occur if gas enters the vascular system and usually occurs during or shortly after insufflation. The sudden development of hypotension, bradycardia, or arrhythmias at this time should immediately raise suspicion of gas embolism. While relatively rare occurring in 0.0014% [13], the mortality rate is as high as 28% [72]. The pneumoperitoneum should be released and the procedure abandoned as soon as feasible.

ANESTHETIC COMPLICATIONS

The gynecologist must be aware of the cardiovascular changes associated with operative laparoscopy. Most of the changes are due to establishment and maintenance of pneumoperitoneum or Trendelenburg positioning. Carbon dioxide remains the most widely used distension media but is rapidly absorbed from the peritoneum and may cause hypercarbia and acidosis. Hypercarbia is associated with arrhythmias, increased cardiac output, and decreased systemic vascular resistance. Hyperventilation minimizes the impact of hypercarbia.

Steep Trendelenburg may be required for posterior compartment or vault suspending procedures and results in increased central venous pressure and decreased arterial pressure and cardiac output. Atelectasis and decreased pulmonary compliance can occur but are usually well controlled with general anesthesia, neuromuscular blockade, endotracheal intubation, and controlled ventilation. Both pneumoperitoneum and Trendelenburg position reduce femoral venous flow increasing the risk of thrombotic complications.

CONCLUSION

Laparoscopic pelvic floor surgery affords the surgeon and the patient significant advantages, but complications are related to obtaining access, surgeon inexperience, and associated laparoscopic hysterectomy. The judicious use of open approach or access via the left upper quadrant may be beneficial in minimizing access-related complications. Newer optical entry trocars may serve to decrease morbidity associated with closed or open access techniques. Careful dissection during adhesiolysis and cautious and appropriate use of electrical current will decrease bowel injuries. Vigilance during surgery is required to detect and manage complications intraoperatively, rather than postoperatively. An experienced operating room staff including assistants, scrub sisters, and anesthetists, who are enthusiastic regarding laparoscopic surgery, is vital to minimize complications associated with laparoscopic pelvic floor surgery. Finally, following surgical complication, it is vital to investigate the clinical and surgical decisions that may have led to an unwanted outcome. Video recording of all surgical procedures compliments postoperative evaluation of complications and is recommended as an important measure to improve surgical and clinical healthcare.

103 The Role of Robotic Surgery

Orfhlaith E. O’Sullivan and Barry A. O’Reilly

ROBOT-ASSISTED SURGERY

Surgical robots were developed to facilitate minimally invasive surgery and to assist surgeons in performing procedures that could otherwise be technically challenging using traditional open or laparoscopic techniques. The development of robotic surgery was aided by the Defense Advanced Research Projects Agency, who funded research into the possibility of a remote surgery program for battlefield triage. In 1999, the first da Vinci® System was introduced to the market, and in 2000 it was cleared by the Food and Drug Authority (FDA) for minimally invasive surgery including urological procedures. Subsequently, in 2005 the da Vinci Surgical System became the only robotic system to be granted FDA approval for gynecological surgery in the United States. In Europe, it has full regulatory clearance and has the Conformité Européenne mark since 1999 [1]. Since gaining FDA approval, the role of the robot in urological and gynecological surgery has increased with many traditional procedures now being performed with a robot assistance, including radical prostatectomy, cystectomy, nephrectomy, pediatric procedures, and stricture surgery [2–4]; within gynecology, these include hysterectomy (for benign and malignant disease), prolapse surgery (sacrocolpopexy/hysteropexy), myomectomy, tubal surgery, and endometriotic and adnexal surgery [5]. It is claimed that robot-assisted surgery is associated with clinical benefits for the patient such as reduced estimated blood loss (EBL), decreased blood transfusion requirements, shorter length of stay (LOS), and reduced perioperative pain and analgesic requirements. The benefits for the surgeon include the potential for greater precision, lower error rates, shorter learning curves, and superior ergonomics than conventional laparoscopy. By December 2012, there were 2,585 da Vinci Surgical Systems installed in approximately 2,025 hospitals worldwide with approximately 450,000 robot-assisted procedures performed in 2012, an increase of approximately 25% compared to 2011 [6].

HEALTH TECHNOLOGY ASSESSMENTS

The idea of a health technology assessment was first conceptualized in the United States in 1967, with the Congressional Office of Technology Assessment being established in 1972 [7]. The general definition of technology assessment used was “a comprehensive form of policy research that examines the short- and long-term social consequences of the application or use of technology.” The Health technology assessments (HTAs) are based on three principles that the assessment: (1) is based on evidence-based knowledge, (2) is all encompassing and interdisciplinary, and (3) is aimed at decision making. This makes them an ideal tool and reference point for systematic reviews of new technology. The HTAs must be performed by an impartial body using evidence-based information on efficacy and comparisons with available alternatives in a timely fashion. Equally, the analysis must be transparent and deal with issues of quality-adjusted life-years and cost–benefit analysis as appropriate to the geographical area served. They are a valuable tool for health care policy making and decision making by governments. In general, the bodies performing the HTA are made up of expert advisors across a broad spectrum of areas in health, finance, and ethics. Recently, five HTAs have been conducted on robotic surgery, in Australia (2009) [8], Belgium (2009) [9], Canada (2010 [10], 2011 [11]), and Ireland (2012) [12]. They concluded that based on the evidence available, the robot-assisted surgery may have a significant impact on many clinical outcomes in patients undergoing hysterectomy. In general, robotic surgery can have an impact on reducing hospitalization costs, but the investment made in acquiring this technology is significant, and institutions that choose to adopt it should make efforts to monitor its costs and outcomes in order to maximize cost-effectiveness within their own center. To decrease costs, centers should maximize caseloads, consider keeping the robot operational for longer durations if possible, and use the technology for multiple indications, particularly those with greater potential impact on important patient outcomes and savings on institutional costs. One of the key advantages of using robotic technology for gynecological procedures is the reduction in surgeon fatigue and the ability to perform complex surgery with a minimal invasive technique.

COST ASSOCIATED WITH ROBOT-ASSISTED SURGERY

This is covered in Chapter 105.

DA VINCI SURGICAL SYSTEM

The first da Vinci Surgical System was a simple three-armed robot with an upgrade in 2003 providing the fourth (retractor) arm. The system consists of three main components: the console from where the surgeon controls the operation, the patient side cart with four interactive robotic arms to which the operating instruments are attached, and the vision system (Figure 103.1). The EndoWrist® instruments used during surgery combines 7 degrees of freedom, with 90 degrees of articulation to provide a range of motion superior to the human hand. It also combines intuitive motion and fingertip control with motion scaling and tremor reduction technology to provide instruments with greater capabilities, and improved surgical dexterity. The latest model the da Vinci Xi Surgical System (2014) allows for more efficient anatomical access with crystal clear 3D-HD visualization. The principle of robotic surgery is that the surgeon operates unscrubbed while seated at the console, from which they are able to view the operating field in three dimensions through a stereoscopic viewer.

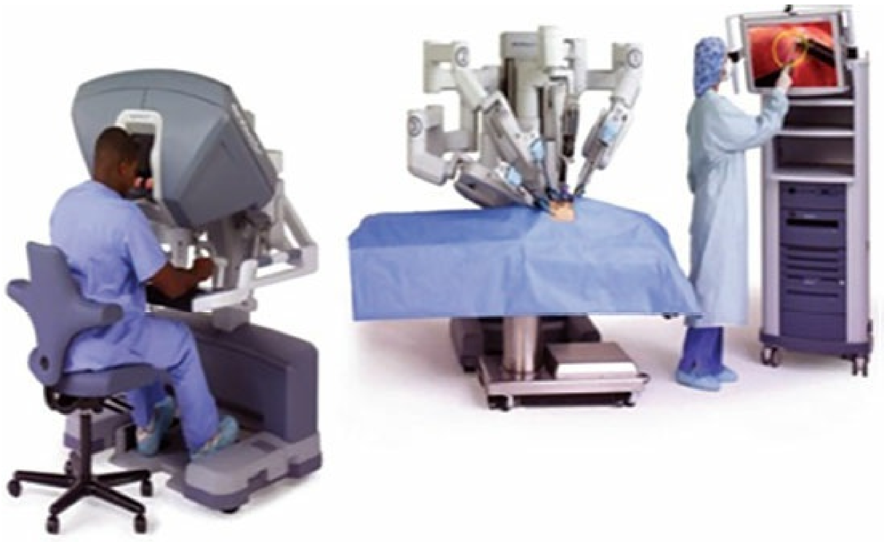

Figure 103.1 The main components of the da Vinci Surgical System. (Courtesy of Intuitive Surgical, Inc., Sunnyvale, CA.)

Robot-Assisted Surgery

The robot-assisted surgery is performed across a large spectrum of surgical specialties; these include cardiothoracic, head and neck, and general surgery, gynecology, and urology.

FEMALE UROLOGY AND UROGYNECOLOGICAL SURGERY

Sacrocolpopexy

The abdominal sacrocolpopexy remains the gold standard for the treatment of vaginal vault prolapse (VVP) despite the introduction of newer techniques such as vaginal mesh kits [13]. It is associated with success rates of 74%–98%, a low recurrence rate, and reduced dyspareunia [14] when compared with vaginal sacrospinous fixation. Laparoscopic sacrocolpopexy has been shown to have similar outcomes with reoperation rates of approximately 6%–7% and a mesh erosion rate of 3% [15]. Furthermore, the conversion rates reduced with increased operator experience [15]. A study by Akladios assessing learning curves in robotic surgery highlighted that once the learning curve is complete, the 1-year cure rate was 98%; however, there was a 20% de novo dyspareunia rate [16]. A recent study on rate, type, and cost of the pelvic organ prolapse (POP) surgery revealed that in France, 38.8% of the POP surgical admissions were for vault repair, of this 56% were for sacrocolpopexy/sacrohysteropexy and the remaining 44% for sacrospinous ligament fixation [17].

Despite the large number of papers published on robot-assisted sacrocolpopexy, there are a limited number of randomized controlled trials comparing laparoscopic with robotic sacrocolpopexy with main end points of operation time, pain, functional activity symptoms, cost, anatomical support, and quality of life [18,19]. There were no functional differences between the two groups, while the robot-assisted approach was associated with an increased cost, increased operative time, and increased pain. This finding of increased pain postoperatively is at odds with other studies, which show either similar or reduced pain scores with robotic surgery [20]. A further study by White comparing three approaches, the robotic, laparoscopic, and single port, revealed no difference in pain, LOS, blood loss, or operating time between the three [20], with the POP-Q scores at 6 months showing good apical support and prolapse reduction. Further studies confirm good functional results using the robot showing it to be efficacious in the management of the VVP [21]. Geller et al. [22] in a retrospective study comparing open with robotic sacrocolpopexy showed the robotic approach to be associated with improved POP-Q C, reduced blood loss, and length of hospital stay. Elliot et al. reported on 30 cases operated on robotically with a mean follow-up time of 24 months. They concluded that robotic sacrocolpopexy was associated with decreased length of hospital stay, a low complication rate, and high patient satisfaction [23]. Gocmen's case series looking at the short-term outcomes over a period of 1 year in 12 cases found there were no conversions to an open procedure and no recurrence. They further stated that the robotic approach may assist the surgeon in dissecting over the sacral promontory [24]. Open sacrocolpopexy is generally associated with greater blood loss, longer hospital stay, delayed return of bowel function, increased postoperative pain, and increased wound complications [25]. A drawback with regard to laparoscopic sacrocolpopexy is the associated technical difficulty in placing sutures [26].

Ploumidis in a retrospective review of 94 cases undergoing robot-assisted sacrocolpopexy with specific regard to complications found one case in which a Clavien grade 3 postoperative complication occurred [27]. Subsequently, there was one case of mesh erosion during a follow-up period of 36 months. Matthews et al. in a prospective study of 85 cases of robot-assisted sacrocolpopexy and robot-assisted sacrocervicopexy concluded these are effective, efficient, and safe procedures. There were two cases of mesh erosion in the robot-assisted sacrocolpopexy group [28]. In 2014, Serati et al. published a meta-analysis and systematic review [29]. The data on 1488 robot-assisted sacrocolpopexies were collected from 27 studies, published from 2006 to 2013. The results revealed objective and subjective cure rates ranged from 84% to 100% and from 92% to 95%, respectively. The conversion rate to open surgery was <1% (range: 0%–5%). Intraoperative and severe postoperative complications and mesh erosion rates were 3% (range: 0%–19%), 2% (range: 0%–8%), and 2% (range: 0%–8%), respectively. They concluded that surgical-related outcomes have improved with increased experience, with an estimated learning curve of about 10–20 procedures. A robot-assisted sacrocolpopexy is a safe and feasible procedure for POP; it allows the execution of complex surgical steps via minimally invasive surgery without medium- and long-term anatomic detriments.

Robot-Assisted Sacrocolpopexy: The Technique

The robot-assisted sacrocolpopexy was first described in 2004 by DiMarco [30] as follows: the procedure combines the use of standard laparoscopy with the da Vinci robotic system. One camera port, two robotic ports, and two standard laparoscopic ports are placed. Standard laparoscopic dissection is used for initial anterior and posterior vaginal mobilization and exposure of the sacral promontory. The da Vinci robot is then docked and used to suture a silicone Y-shaped graft from the vagina to the sacral promontory. The culdoplasty, with plication of the uterosacral ligaments, is then performed, with the final step, retroperitonealization of the graft.

However, over the last number of years with increased surgeon take-up of this technology, the procedure has been modified. In our current practice, the patient is placed in moderate to steep Trendelenburg, and the legs are then placed in the low lithotomy position. Once the positioning is satisfactory, the ports are placed in a W shape with the camera port two fingerbreadths above the umbilicus, the next two ports are placed four fingerbreadths inferolateral to the camera port bilaterally, and the remaining two ports are placed four fingerbreadths superolateral to the preceding two ports

(Figure 103.2). The robot is then docked, the camera arm attaching to the camera port, and the instrument arms subsequently attached and instruments introduced under direct vision. The assistant port is the left superolateral port to facilitate introduction of sutures and ports. Dissection is then performed by the surgeon sitting at the console via the robot, to aid dissection a vaginal and rectal manipulators are introduced (Figure 103.3). The anterior and posterior vaginal walls are mobilized, and following this the sacral promontory is exposed, and a track created to allow the peritoneum to be closed over the mesh. The Y-shaped mesh is then attached from the anterior and posterior walls of the vagina to the anterior longitudinal ligament using permanent sutures, e.g., Gore-Tex. Finally, the peritoneum is then closed over the graft (Video 103.1) [31].

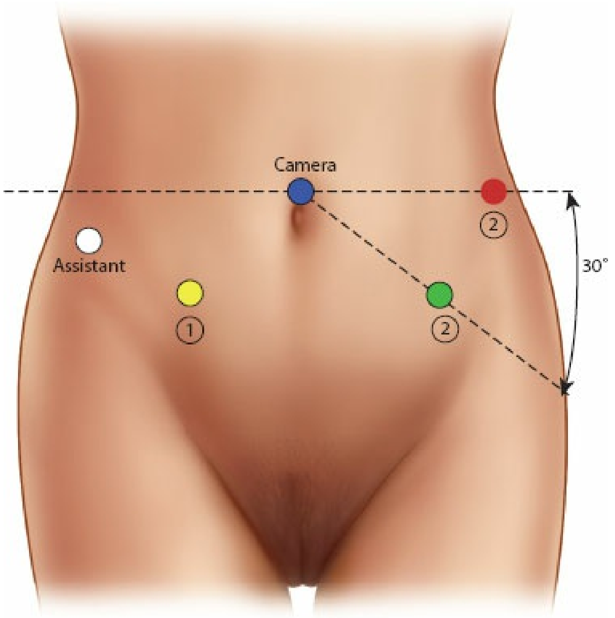

Figure 103.2 Port placement for robot-assisted sacrocolpopexy. (Courtesy of Intuitive Surgical, Inc., Sunnyvale, CA.)

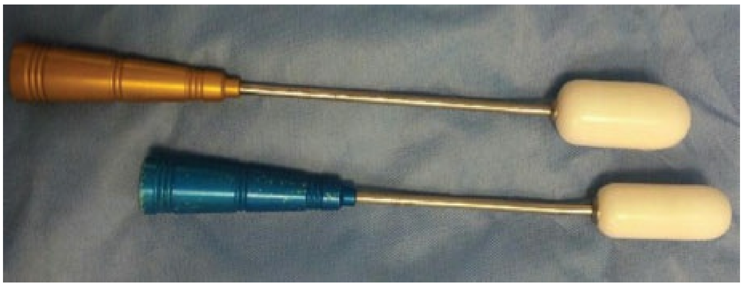

Figure 103.3 Rectal and vaginal manipulators.

Overall robot-assisted sacrocolpopexy is associated with increased operative time compared to the laparoscopic approach [32]. Many publications include training operative times and the operative times for fellows/trainees. While we are aware the learning curves are short, the inclusion of these operative times presents a bias in the times reported. Therefore, to correctly comment on operative times publications should report openly on which times are included. Compared to an open abdominal sacrocolpopexy, the LOS is shorter and the EBL lower, with both approaches having similar complication rates. The evidence available suggests comparable safety and efficacy when comparing robot-assisted to open sacrocolpopexy. The surgical technique used in open/laparoscopic/robot-assisted sacrocolpopexy varies depending on the surgeon across all stages of the procedure. Many papers fail to describe the technique used to perform the surgery, thus making comparison in terms of operation time and outcomes difficult. A consensus is required with regard to the optimal operative technique used to perform a sacrocolpopexy irrespective of approach used.

Hysteropexy

Hysteropexy utilizes many techniques to restore uterine anatomy. Approaches including abdominal, vaginal, and laparoscopic are effective in the management of uterine prolapse where uterine preservation is required [33]. The success rates are similar for all three approaches varying from 87% to 98% [34–36]. Successful pregnancies have been reported following laparoscopic hysteropexy; however, the long-term effects of pregnancy on the surgery are not yet fully appreciated [37]. Lee et al. in their study on the safety and feasibility of sacrohysteropexy for the treatment of prolapse concluded that the surgery was associated with minimal blood loss and had excellent subjective and objective success rates, making it a safe and feasible surgical option in the management of POP where uterine preservation is required [38].

Continent Urinary Diversions

Bladder emptying disorders, which can arise from neurogenic diseases, oncological surgery, or idiopathic causes, are traditionally treated with clean intermittent self-catheterization (CISC). However, in the subset unable to perform CISC, continent urinary diversion (CUD) is an appropriate surgical alternative. The cutaneous appendicovesicostomy initially described by Mitrofanoff in 1980 [39] remains the most commonly performed CUD, followed by the Yang–Monti procedure [40], which uses small pieces of ileum to create a cutaneous ileovesicostomy. These procedures are traditionally performed via lower abdominal incision. Due to technical difficulties, the laparoscopic approaches have failed to achieve widespread adoption. A recently published case series found the robot-assisted approach to be a safe, feasible alternative to both the open and laparoscopic approach in adults [41].

Vesicovaginal Fistula Repair

Another area of urogynecology where the robot-assisted approach has been used is vesicovaginal fistula repair. The robot technology allows a complicated laparoscopic procedure to be performed safely with good results. Vesicovaginal fistulae have been effectively treated using the robot-assisted approach with minimal blood loss, short LOS, and recurrence rates [42,43]. The robot-assisted approach has been used successfully to treat rarer fistulae such as vesicocervical and vesicouterine fistula (1%–4% of urogenital fistulae). Traditionally, these fistulae are surgically managed via an open approach, as they are not accessible transvaginally. The robot aids in the complex dissection and reconstructive techniques required for this type of surgery (Video 103.2) [44,45]. 🎥

TRAINING IN ROBOTIC SURGERY

Traditionally, the surgical apprenticeship relied on the Halstedian model of “see one, do one, teach one.” However, with time it has become evident that this model is inadequate to train surgeons to the highest level without impacting on patient care [46]. The concept of training and surgical education has evolved considerably. Many colleges/boards responsible for the training of surgeons have implemented prerequisites that must be achieved to attain certification to perform surgery. Furthermore, surgeons are required to maintain and update their skills by achieving educational targets. The American Board of Surgeons requires a surgeon to achieve 90 hours of continued medical education credits every 3 years to maintain certification. To facilitate this, the Society of American Gastroenterologists and Endoscopic Surgeons has developed an online university that features journal club, online assessment program, and guidelines. Robot-assisted surgery has created new challenges to ensure proper training and avoid subjecting patients to unnecessary risk. Increased scrutiny of credentialing and medicolegal aspects of robotic surgery have reinforced the importance of training and have led to a number of papers outlining pathways to facilitate this [47,48]. The learning tools for robotic surgery include simulators, dual consoles, robotic courses, and proctoring.

TRAINING COURSES

Training courses on robotic surgery are typically performed using inanimate, animal, or cadaver models. The length of the course varies from several hours to several days, sometimes even weeks in a mini-fellowship situation. The content depends on the attendees at the course. Inanimate exercises offer a cost-effective and robot-agnostic approach to training surgeons [49–51]. They can be designed to target specific (or a subset of) technical skills needed to understand the basic functionality of a robotic system [47,52]. With various levels of difficulty, a continuum of inanimate exercises can guide surgeons of different abilities through their initial learning curves. Inanimate exercises for learning the fundamentals of laparoscopic surgery can be expanded to effectively target robot-specific skills [53]. In order to be useful training tools, inanimate exercises must challenge both specific technical skills of using a robotic surgical system and have validated metrics so that surgeons can accurately track their performance [54].

It is certain that the advent of excellent surgical simulators and structured inanimate exercises has provided tools for novice surgeons to acquire console skills in a safe and structured environment. This will enhance their operating performance and reduce aspects of the learning curve such as operating time; however, the lack of availability of in vivo training opportunities greatly limits the applicability of this method of surgical training [55].

Dual Console

The introduction of the da Vinci Si Surgical System has given surgeons a second robotic console, facilitating collaboration between the proctor and trainee. The mentoring console has two collaborative modes: (1) The swap mode allows the mentor and trainee to operate simultaneously and actively swap control of the robotic arms. (2) The nudge mode allows them to have control simultaneously, sharing the two robotic arms.

Live Surgery and Proctoring

Live case observation remains an important component of a robotic training program [56] and allows the trainee to become familiar with the steps of a specific robotic procedure. Proctoring is defined as direct supervision by an expert during the initial phase of training and the learning curve [56]. It provides a safe environment during the introduction of a new technique and prevents surgeons from performing procedures before they have mastered the technique.

The reality is that simulators, dual consoles, and robotic courses should play an important role in bridging the gap between early surgical skills and effective performance using the robot in a clinical setting without subjecting patients to unnecessary risk. It is also important to have tools that provide an objective means by which to evaluate a trainee's performance in anticipation of their ultimate graduation [57]. Physicians in training can acquire robotic surgery competency. Participants who acquire skills faster regain robotic skills faster after a training hiatus, but, on retraining, all participants can regain equivalent competence. This information provides a benchmark for a simulator training program [58]. One institution has incorporated a graduated program of resident and fellow console involvement based on level of training. They found this approach did not significantly hinder operating room efficiency [59]. However, once acquired, the robotic surgical skills deteriorate without use. In one study, robotic surgical skills degraded significantly within 4 weeks of inactivity in newly trained surgeons [60]. The University of Toronto in a pilot study assessing robotic skill training concluded that the implementation of a multidisciplinary, simulation-based robotic surgery basic skills training curriculum revealed significantly improved basic robotic skills among novice trainees, regardless of specialty or level of training. The competency-based training was associated with significantly better acquisition of basic robotic skills.

LEARNING CURVES

The learning curve associated with laparoscopic sacrocolpopexy has been shown to be linear in nature with the turning point between 18–24 cases in one study [16] and 30–60 cases in another [61].

A recent study assessing the learning curves associated with a robot-assisted laparoscopic colorectal surgery revealed that it consisted of three distinct phases [62]. The first phase or the initial phase occurred over the first 15 cases, during this phase the operating time decreased. The second phase or plateau phase occurred over the next 10 cases; during this phase, the operator becomes more competent with the robotic technology. The third phase or the mastery phase occurred for the subsequent cases. During the mastery phase, the complexity of the cases undertaken increased.

With regard to gynecological surgery, the learning curves reported range from 20 cases for hysterectomy and pelvic lymphadenopathy for endometrial cancer [63], to 50 cases for benign hysterectomies [64], to 10 cases for sacrocolpopexy [65]. The learning curve associated with laparoscopic sacrocolpopexy has been shown to be linear in nature with the turning point between 18 and 24 cases [16]. The robotic approach maintains the benefits of laparoscopy while reducing the technical difficulties [21,23,66].

Knot tying has been shown to be a technical challenge for laparoscopic sacrocolpopexy due to the limited dexterity of the instruments [67]. These challenges are not present in the robot-assisted surgery where studies have shown that due to the instrument grip strength sutures can be tightened effectively [68]. In New York, a study comparing the learning curves for robot versus laparoscopic surgical skills highlighted that with regard to suturing and dexterity skills, the robot allowed for quicker performance than laparoscopy [69]. Ng et al. made the following recommendations to shorten the learning curve. First, have a designated theater team, with no introduction of new members until 20 cases have been performed. Second, patient positioning is of paramount importance and should be standardized for all cases, and finally, familiarization with the instruments sets is required before any deviation is considered [70].

SAFETY IN ROBOT-ASSISTED SURGERY

Problems with Instrumentation

The introduction of new technology brings new challenges especially for the surgeon and the theater team. A recent survey of urologists on intraoperative robot malfunction found that breakdown intraoperatively is uncommon; however, it does occur, highlighting the need to counsel patients and to have a contingency plan. Furthermore, they recommend conventional laparoscopic suturing should be maintained as a requirement on the curriculum, thus allowing the surgery to continue using minimally invasive approach [71]. Murphy et al. [72] in their review reported a device failure rate of 0.2%–0.4%. A report of technical challenges faced by surgeons performing robot-assisted gynecological oncological procedures showed 8% were associated with problems with robotic technology. Of this 8% of cases, 18% involved malfunction of robotic arms, 18% involved light or camera cords, and the remainder included a variety of problems, including malfunction of Maryland bipolar instrument (9%). A further 9% were attributed to power failure requiring rebooting of the robot. Port problems occurred in 18%, and 27% had miscellaneous problems. An estimated average of 25 minutes was added to each case in order to solve the robot-related technological problems. Despite these problems, no cases required conversion to laparotomy. It is noteworthy that the robotic surgeon solved all these problems with the assistance of robotic surgery staff. They conclude that all surgeons performing robotic surgery must become familiar with troubleshooting robotic technology and associated equipment. Failure to do so may add time and technical difficulty to robotic cases [73]. The FDA maintains a database of manufacturer and user facility device experience (MAUDE) where all users of devices report robot malfunctions and their outcomes. In 2008, a review of the MAUDE database identified 168 reported cases of robot malfunction approximately 4.8% of which was associated with patient injury. However, with time the MAUDE database reported incidences of instrument failure have increased with 528 reports of 565 instrument failures over 2 years between January 2009 and December 2010. Friedman et al. divided the instrument failures into five groups depending on the reported failure: (1) wrist or tool-tip failures (n = 285), (2) cautery instrument failures (n = 174), (3) instrument shaft failures (n = 76), (4) cable failure (n = 29), and (5) control housing failures (n = 1) [74]. In general surgery in a single university unit, Buchs et al. recorded a robotic malfunction rate of 3.4% (18/526) over a 7-year period. Instrument failure accounted for 50% (9/18) of cases, 22% (4/18) occurred due to robotic arm failures, 16% (3/18) derived from console errors, the remaining 12% (2/18) failure occurred in the optic unit. Of note, the failure rate decreased with increased operator and team experience [75]. With specific regard to gynecological oncology, Finan et al. reported a technology failure rate of 8.02%. They advocated that surgeons and their team should be specifically trained to troubleshoot for these issues [73].

Neurological Injuries

Patient positioning is of great importance to minimize the potential adversarial outcomes associated with long operative times. In a single unit study, nerve injury associated with positioning during urological robotic surgery had an incidence of 6.6%. It is of concern that 23% of these persisted beyond 6 months. The injury rate was significantly affected by operative time and American Society of Anesthesiologists group. Therefore, patients undergoing long surgeries should be counseled regard the risk of nerve injury especially if they have multiple comorbidities [76].

General Safety

Checklists have been used as an intervention to prevent these failures by promoting a team-working culture, standardizing practice, allowing the detection of potential errors, and improving patient safety as a whole. One example is the World Health Organization surgical safety checklist. Another example, the Healthcare Failure Mode and Effects Analysis (HFMEA) protocol has been widely used across organizations. The HFMEA is a powerful systems evaluation tool developed by the U.S. Department of Veterans Affairs National Center for Patient Safety. It is a step-by-step process that involves the multidisciplinary team in identifying potential causes of error within a system through the use of flow diagrams, hazards scoring, and decision tree analysis. Potential errors are prioritized according to severity, frequency/probability, criticality, detectability, and existing control measures. The final process includes taking steps to implement solutions, minimize errors, and avoid adverse events [77]. In a recent study using the HFMEA, specific hazards were identified, e.g., patient positioning, port placement, robot docking/de-docking, and robotic and laparoscopic equipment checks, which were considered to be important in robot-assisted urological procedures and which are not extensively covered by other checklists [78]. A unit-specific robot-specific checklist was developed with the aim of allowing the detection of potential errors and improving patient safety as a whole.

SURGEON ERGONOMICS

Robot-assisted laparoscopic surgery attempts to overcome some of the limitations of laparoscopic surgery while retaining the benefits of a minimally invasive approach. Specific improvements associated with robot-assisted surgery include better visualization through the use of three-dimensional magnification, availability of tools with 7 degrees of freedom that mimic hand movements along with improved ergonomics, and more intuitive hand–eye coordination when controlling surgical instruments [79–81]. However, this has been achieved at the cost of haptic and tactile feedback, as a result of the instruments not being directly manipulated by the surgeon [82]. It is yet to be seen whether tactile feedback can be achieved through increased sophistication of the computer software.

There is limited primary data available in regard to the effect of using the robotic device on surgeon morbidity and discomfort. A pilot study by Lawson et al. [83] assessed the differences between musculoskeletal discomfort and ergonomic strain in laparoscopic versus robotic surgery for gastric bypass surgery. They found that robotic cases were associated with more discomfort in the neck, while laparoscopic cases were associated with greater discomfort in the upper back and in both shoulders.

Furthermore, analysis of ergonomic positioning during the procedures found that laparoscopic surgery was associated with poorer ergonomic positioning of the upper arm, lower arm, wrist, and wrist twist, while robot-assisted surgery scored lower for trunk positioning. A recent study assessing the ergonomics of the surgeons’ physical workload during both laparoscopic and robot-assisted procedures found the physical workload and the perception of effort were greater for laparoscopic procedures. During the standard laparoscopic procedures, there was a greater physical activity in the trapezius and dorsolumbar muscles. Mental stress was identical for the two groups, while the heart rate was significantly raised in the standard laparoscopy group confirming greater physical expenditure [84].

However, the ability to generalize based on studies for specific surgical indications is limited, as the advantage of robotic-assisted surgery significantly depends on the type of the procedure [81]. The EBL was reported as lower in the robot-assisted group compared to open surgery. This may be secondary to the improved visualization achieved using the robot and subsequent improved surgical precision.

The traditional limitations on laparoscopic surgery performed with straight-stick instruments have been superseded by the EndoWrist instruments in robotic-assisted surgery. These allow for a wider scope of practice and manipulation. Furthermore, robot-assisted surgery is associated with improved visualization thus allowing for improved surgical precision, which could account for the associated reduced blood loss when undertaking complicated surgical cases.

With obesity increasing throughout the developed world, patient habitus often precludes them from laparoscopic surgery. However, they may have robot-assisted surgery performed with similar benefits. More complex procedures can be undertaken robotically than with traditional straight stick surgery. Obesity is traditionally associated with an increase in perioperative morbidity and mortality [85]. Buchs et al. [86] in perioperative risk assessment of 884 patients undergoing robot-assisted surgery found a BMI of >30 did not influence morbidity or mortality. Eddib et al. studied the effect of morbid obesity on outcomes in robot-assisted gynecological surgery. They found that morbid obesity did not appear to be associated with an increased risk of morbidity. Furthermore, while morbid obesity is associated with an increased procedure time, it had no effect on outcomes. Therefore, robotic surgery offered an ideal approach, allowing minimally invasive surgery in these technically challenging patients, with no significant increase in morbidity [87]. Robotic surgery may provide benefits in terms of wound infection and conversion rates [88]. Comparing the laparoscopic and robot-assisted approach in obese patients, there was no difference in outcome, a longer operating time and reduced LOS [89,90]. Studies have shown a fourfold higher conversion rate with the laparoscopic approach in obese women undergoing hysterectomy compared with nonobese women [91]. Body surface area has been shown as a predictor for conversion during laparoscopic colorectal surgery [92]. However, robot-assisted hysterectomy has not been shown to have a higher conversion rate in obese women [93]. Many authors allude to the potential reduction in surgeon strain with regard to surgery in the obese patient; however, no specific studies have been published.

CONCLUSION

The robot-assisted surgery aims to offer the benefits of minimally invasive surgery, such as reduced postoperative pain, shorter hospital stay, quicker recovery time alongside the specific benefits associated with robotic surgery including less technically demanding, shorter learning curve, and ergonomic benefits [31].

There are significant limitations with the quality of the published data analyzing the advantages and disadvantages of robot-assisted surgery. This makes it difficult to know whether the advantages claimed by the protagonists are genuine, and until robust trials are performed, the validity of the claims of benefits to patients and surgeons must be questioned [8–11]. Some of the limitations include a low quality of evidence when the studies were graded according to the National Health and Medical Council hierarchy of evidence [94]. There is a paucity of long-term functional and outcome data associated with robot-assisted surgery and its effect on the patient’s quality of life. Furthermore, there is limited data available for gynecological procedures such as prolapse surgery in the form of sacrocolpopexy/hysteropexy, where only one randomized control trial (RCT) exists. A recent editorial in the *International Urogynecology Journal* highlighted nicely the limitations and difficulties faced when trying to conducted an RCT in robotic-assisted surgery [95].

The robot system may allow minimally invasive approaches to be used where conventional laparoscopic approaches would otherwise not be possible [96]. It also allows for improved visualization and subsequent improved surgical precision.

From the available published literature, most studies conclude that robot-assisted surgery is feasible and technically safe with acceptable early operative outcomes that appear to be comparable to those achieved with open or laparoscopic surgery. However, more robust studies need to be conducted to answer the question of which modality is associated with the greater long-term results.

104 Vesicoscopy

Philippe Grange and Chrysanthos Kouriefs

INTRODUCTION

Vesicoscopy is an elegant minimally invasive technique applying the principles of laparoscopic surgery to the bladder. The suprapubic percutaneous transluminal route allows a variety of procedures that would otherwise not be accessible via transurethral endoscopic surgery. In this chapter, we will describe our experience with vesicoscopic procedures in female patients and explain the most common indications for such procedures. We will critically discuss the use of vesicoscopy as reported in the literature and conclude with the future of vesicoscopy.

MATERIALS AND METHODS

Our Experience to Date

Between 2007 and 2014, 25 female patients underwent 33 vesicoscopic procedural steps under the same mentoring team at three sites: King's College Hospital, London, United Kingdom, $n = 20$; Polykliniki Ygeia, Limassol, Cyprus, $n = 3$; and Universitätsklinikum Hamburg-Eppendorf, Hamburg, Germany, $n = 2$. The age of the patients ranged from 13 to 67 and their BMI from 17 to 60. Vesicoscopy was chosen in congenital, acquired, and iatrogenic conditions including incontinence, ureterovesical reflux, voiding dysfunction, foreign bodies, endometriosis, and ureteric strictures. The intended procedures were ureteric replantation $n = 13$, vesicovaginal fistula (VVF) repair $n = 9$, foreign body extraction $n = 5$, antegrade ureterectomy $n = 3$, bladder diverticulum $n = 2$, and tissue excision, $n = 1$. Vesicoscopy was performed as a standalone approach in 13 patients and in combination with other approaches in 12 cases, with vaginal approach $n = 8$, with both vaginal approach and transperitoneal laparoscopy $n = 1$, and with retroperitoneoscopy in the supine position $n = 3$.

Standard Technique

In cases of antireflux ureteric replantation, the patient is in the supine position; the legs are flat and the arms rest along the body; the urethral catheter is inserted after cleaning and draping to allow intraoperative access. We find it ergonomically comfortable to use a moderate head-down position and whenever possible to sit and work from the left side of the patient. If an assistant is needed, which is not always the case, he or she will sit on the right side of the patient. The imaging screen display stands at the feet of the patient. When it is necessary to access the vagina or urethra, the assistant sits between the patient's legs.

The bladder is distended using CO_2 gas supplied from a standard laparoscopic insufflator connected to a Foley catheter at a pressure setting of 15 mm Hg. Should the patient present with any lower abdominal scar and history of pelvic surgery or if the distended bladder is not palpable, we feel it is appropriate to perform a suprapubic ultrasound scan first. This harmless investigation helps to identify risks related to the presence of a bowel loop, vascular abnormality, or insufficient bladder distension. Translucent visible ports are placed under direct 0° camera vision. The primary 5 mm access port is inserted 2 cm above the symphysis pubis on the midline. A twist and push maneuver splits the successive layers of tissues clearly visible through the translucent blunt tip of the trocar. In the presence of a "Pfannenstiel," we place our port below that incision. Two further 5 mm ports are inserted on either side of the primary port on the same horizontal line, fairly close to each other (Figure 104.1).

The next crucial step consists of suspending the anterior wall of the bladder to the abdominal wall with a single stitch inserted with an "in and out" maneuver on either side of the midline port using a specific reusable or disposable device, releasing and catching back a 2-0 monofilament suture. This prevents the bladder from collapsing if a port is inadvertently retrieved or if the patient suddenly strains on "anesthetics grounds." Once all three ports are in place, the 0° scope is replaced by 30°, inserted into the right port, and stabilized by a motorized camera holder. We work from the two ports, closer to the surgeon.

Combined Procedure with Vaginal Access

We combine the vaginal approach and the vesicoscopic route in procedures such as vaginal fistula repair. The patient is placed in the Lloyd-Davis position. At the “vesicoscopic end,” little differs from the generic access apart from the screen display standing at the right leg of the patient. At the “vaginal end,” the surgeon sits between the patient’s legs and should ideally have an ancillary screen display at the head of the patient (Figure 104.2).

Combined Procedure with Retroperitoneoscopy in Supine Position

We combine vesicoscopy and supine retroperitoneoscopy in procedures such as ureteric remnant excision. The patient is placed in the supine position with the side to be operated on exactly at the edge of the table, the leg straight, and the arm held above the thorax. The opposite leg is generously flexed to allow the introduction of a semirigid ureteroscope that will help in differentiating the ureter from the surrounding postoperative fibrotic scar tissues. The surgeon is at the left side of the patient for the vesicoscopic step, looking at a screen placed at the patient’s feet. For the ureteroscopic step, the surgeon stands on the right side of the patient looking at a screen placed on the left side of the patient. For the supine retroperitoneoscopic step, the surgeon sits at the side of the patient looking at a screen on the contralateral side (Figure 104.3).

RESULTS

Vesicovaginal Fistula

Nine patients suffering from incontinence related to a complex VVF not suitable for simple vaginal approach underwent a combined vaginal and vesicoscopic repair. The reasons for this choice were narrow introitus, high location, involvement of ureters, and radiation therapy. The detail of the technique is described in a separate publication [1]. The vaginal surgeon, at the beginning of the procedure, obliterates the fistula track by various means to allow bladder distension. When the time comes to excise the fistula tract, he or she gives crucial information on the softness of tissues on palpation, allowing an accurate and complete excision of the fibrotic tissues, which is the key to successful repair. Finally, at the end of the repair, the vaginal surgeon can retrim, mobilize further, and suture the vaginal vault. The vesicoscopic surgeon carries out a resection that should not be restricted by the proximity of the ureter. Whenever necessary, it must be displaced and replanted. This has been the case for three of our patients who underwent one bilateral and two simple antireflux reimplantations (one for stricture, one due to proximity). The generous mobilization of the bladder wall allows the vesicoscopic surgeon to suture well-vascularized tissues without tension in a watertight fashion (Figure 104.4).

Ectopic Ureter in Duplex System

One teenage patient had been suffering from day and night incontinence for 17 years since she was born. She unfortunately had a long history including surgical treatments for stress urinary incontinence with a colposuspension and injection of bulking agents. She was eventually referred to our urogynecology unit and was diagnosed with an ectopic ureter in a left duplex system. She underwent a successful vesicoscopic reimplantation. A double-barrel extravesical ureteroneocystostomy was performed purely through the transvesical route. She was dry on the same evening. At follow-up, the left system was not obstructed. As expected from the choice of technique, the left lower ureter shows grade I reflux, which we do not intend to treat (Figure 104.5a).

Distal Ureteric Stricture

Two adult patients in their 60s presented with distal ureteric strictures. One was following radiation therapy. The second morbidly obese patient had a distal right stricture after the endoscopic treatment of a low-grade distal transitional cell carcinoma (TCC). Both underwent a distal resection and proximal replantation in the form of a ureteroneocystostomy using the vesicoscopic route. At follow-up, both patients presented with satisfactory results: a nonobstructed normally functioning kidney. At 40 months ureteroscopic follow-up, no TCC recurrence was demonstrated [2].

Reflux: Simple Antireflux System

Four adult patients with recurrent infections and pain in the context of grade III reflux were treated with a vesicoscopic antireflux procedure. One patient underwent a bilateral procedure (Cohen submucosal advancement) in two separate operations. The other three patients underwent unilateral replantation, one with the Cohen [3] submucosal advancement technique and two with the Leadbetter and Politano proximal ureteroneocystostomy technique, reimplanting the ureteric orifice at its original site [4]. All cases were successful with no complications at follow-up (Figure 104.5b).

Bilateral Reflux: Combined Vesicoscopy and Supine Nephroureterectomy

One further patient presented with severe bilateral grade V reflux with a nonfunctioning kidney on the right side and grade III on the left side. She underwent a combined vesicoscopic left antireflux procedure using the Leadbetter–Politano reimplantation technique. Two ports only were used for the instruments, while the vision was provided by a high-definition (HD) distal chip flexible cystoscope inserted transurethrally. At the same time, the right ureter was disconnected from the bladder, dissected transvesically in a retrograde manner up to the obliterated ligament. When the former ureteric orifice defect was closed, the lower ureter was buried into the extravesical space. Finally, a right nephroureterectomy was completed using the supine retroperitoneoscopic technique described in our video presentation [5]. The supine retroperitoneoscopy allows straightforward antegrade dissection of the ureter down to the obliterated ligament, which is the upper limit of the vesicoscopic approach: making both approaches complementary. In this patient with low BMI, two 5 mm ports and one 11 mm port were used for the supine nephroureterectomy. The kidney was retrieved after morcellation, leaving her with only a 15 mm visible scar in addition to two 5 mm scars and two other suprapubic 5 mm scars.

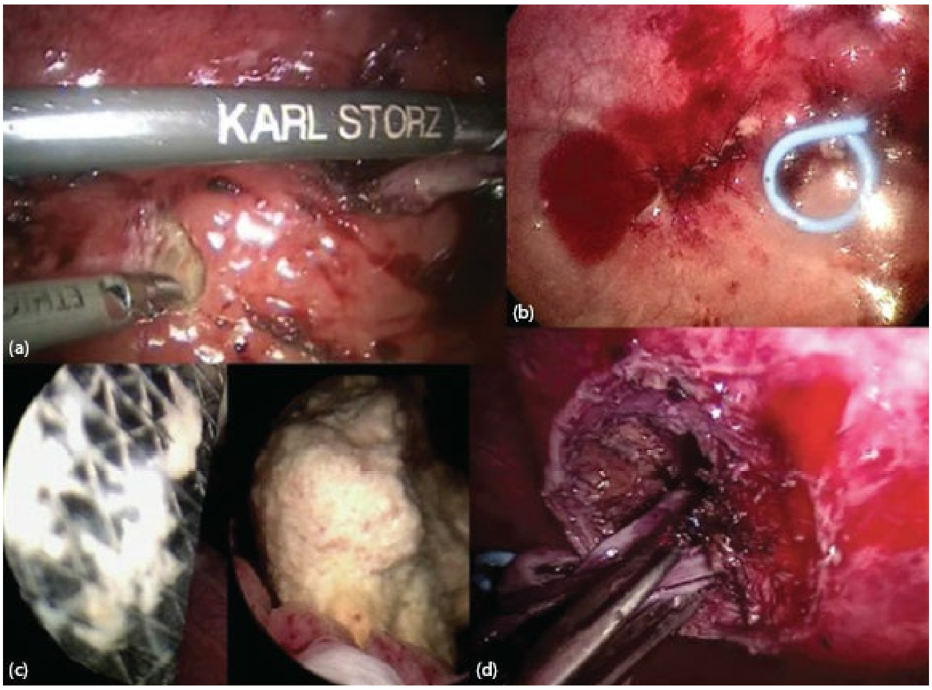

Figure 104.5 (a) Ureteroneocystostomy, (b) left Cohen procedure, (c) encrusted nail file, and (d) bladder diverticulum.

Reflux: Ureteric Remnant Postnephrectomy

Chronic ureteric reflux was also the cause in the symptoms of another patient with a high BMI who presented with infection and pain related to a ureteric remnant left after simple laparoscopic nephrectomy for a poorly functioning chronically infected kidney. She underwent a combined vesicoscopy and retroperitoneoscopy in the supine position. The latter with the help of a semirigid ureteroscope allowed identification in the fibrotic scar tissue, the safe mobilization of the iliac vessels, and the antegrade dissection of the ureter down to the obliterated ligament. The former enabled the disconnection of the ureteric orifice, retrograde dissection of the ureteric stump up to the obliterated ligament, and antegrade extraction of the whole remaining specimen prior to closing the defect of the ureteric orifice (Figure 104.6).

Congenital Pelvic Nephroureteric Remnant

A third patient underwent a combined supine retroperitoneoscopy and vesicoscopy. This 13-year-old teenager was found to have a congenital ureterocele and retrovesical right pelvic mass. No functioning kidney was present on that side. The vesicoscopy allowed the transvesical excision of the ureterocele and the retrograde dissection of a short megaureter. It was unclear from that route where the upper part of the mass was actually ending. The addition of a supine retroperitoneoscopic step allowed the safe identification and final dissection of the pelvic nephric remnant, which was then easily retrieved. The bladder defect was closed transvesically.

Bladder Diverticulectomy

Vesicoscopy has gained popularity in adult urology for bladder diverticulectomy, a condition that is frequently associated to bladder neck obstruction in men. We have carried out a bladder diverticulectomy on two female patients presenting with voiding dysfunction, infection, and a large urinary residual. The technique in women does not differ from its counterpart in men. Insertion of a double J stent is recommended due to expected proximity between the pelvic ureter and diverticulum. Both cases were uneventful and successful from an anatomical and functional point of view (Figure 104.5d).

Bladder Endometriosis

A nodule of endometriosis located on the ureteric bar between the ureteric orifices was excised, and the bladder sutured. Follow-up at 4 years was unremarkable. We are not aware of similar case reported in the literature using that route (Figure 104.7a).

Foreign Bodies

One 29-year-old patient presented with an encrusted nail file protruding from the bladder into the vagina. Vesicoscopy facilitated easy removal of the foreign body, which could not be removed transvaginally because of a large calculus round the nail file. We subsequently repaired her fistula vaginally, but she died from the progression of a rapidly spreading metastatic cancer unknown at the time of her first presentation (Figure 104.5c).

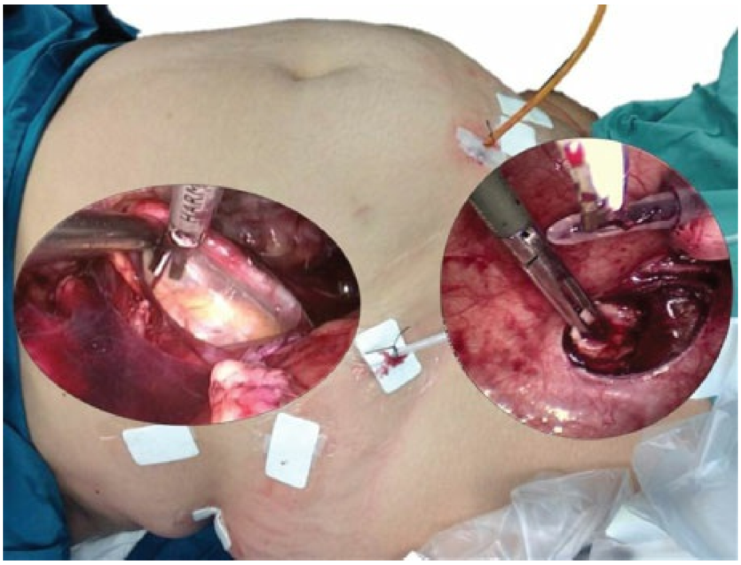

Figure 104.6 In supine position, antegrade retroperitoneoscopic (ureteroscope lifting the ureter) and retrograde vesicoscopic dissection of a ureteric remnant.

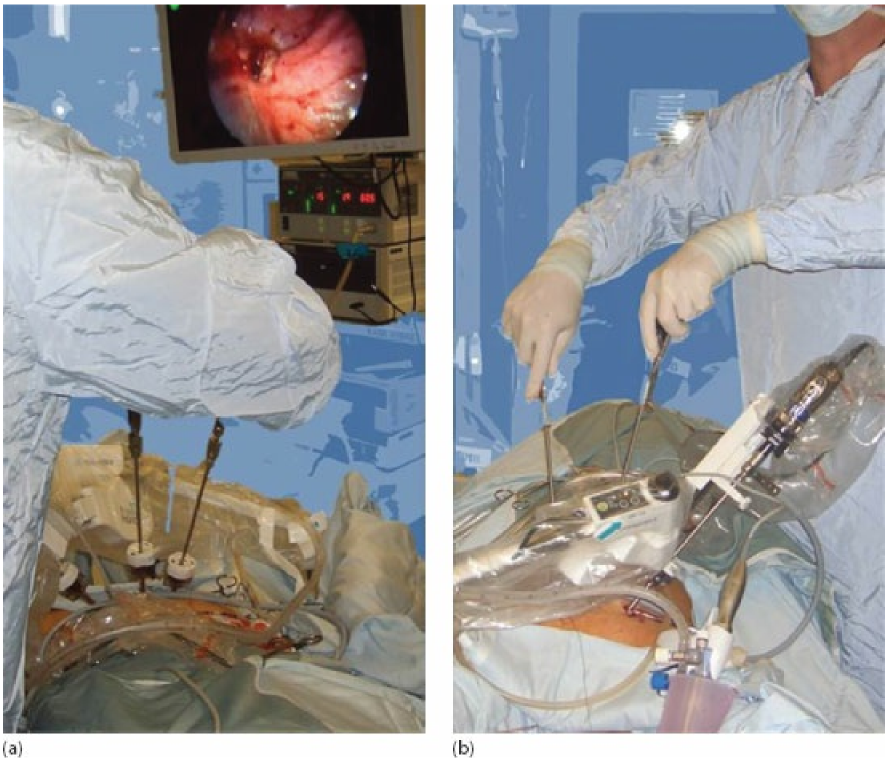

Figure 104.7 Excision of bladder endometriosis (a) operator in standing “toreador” position (b).

Three other patients were treated for complications related to various types of tapes inserted for stress urinary incontinence that had totally or partly transected the urethra or bladder neck. All three patients were tertiary referrals with a long history of endoscopic, vaginal, and open reinterventions. One tape that was infected was totally removed through the vesicoscopic route. Two others were partly resected. One patient suffered increasing dysuria afterwards; the bladder urothelium was normal, but the mesh was still exposed into the urethra. She underwent a second vesicoscopic procedure, allowing the complete removal of the tape purely through the vesicoscopic route with minimal damage to the posterior wall of the urethra and bladder neck (Figure 104.8).

Postoperative Events

Despite the “minimally invasive” branding, postoperative pain must not be underestimated. The vast majority of the patients irrespective of the indication or technique were in need of a strong proactive pain management for 48 hours or longer. No adverse events or complications were recorded using the Clavien–Dindo classification. One patient having a fistula repair had an intraoperative peritoneal gas leak that was managed with an umbilical drain for the duration of the procedure. We report one delayed dysuria after partial resection of an eroded tape that needed a reintervention at 6 months and one failed attempt to repair a VVF in a woman with a BMI of 60 who had a history of cesarean section for placenta percreta. She suffered a massive hemorrhage requiring an emergency hysterectomy and partial cystectomy. She received a total of 100 units of blood and blood products and underwent embolization, following which she lost three toes on her left foot and part of her left buttock. She is dry with a suprapubic catheter in situ, which has considerably improved her quality of life. All other procedures were successful, although one young woman died 18 months after her procedure from metastatic lung cancer.

DISCUSSION

Bladder Distension: Gas vs. Liquid?

One could ask if there is any specific reason to prefer gas or liquid for bladder distension and why it should differ between transluminal and endoluminal surgery. Typically, gas is used in vesicoscopy (a sensible choice for a technique inspired by laparoscopy), and liquid is used in cystoscopy (also a sensible option to fill an organ meant for storing urine). However, the literature suggests that a wider use of gas is a long missed opportunity: Bristow demonstrated experimentally in 1893 the benefits of using gas over liquid to dilate the bladder in suprapubic cystostomy [6]. Faulds reported in 1904 the advantages of using gas for cystoscopy with improved vision for the surgeon and comfort for the patient [7]. Further evidence came in the twentieth century [8,9]. Bridging the gap between evidence and evidence-based practice is not the purpose of this chapter, although a less scientific, but important, advantage of the gas is what keeps our socks dry.

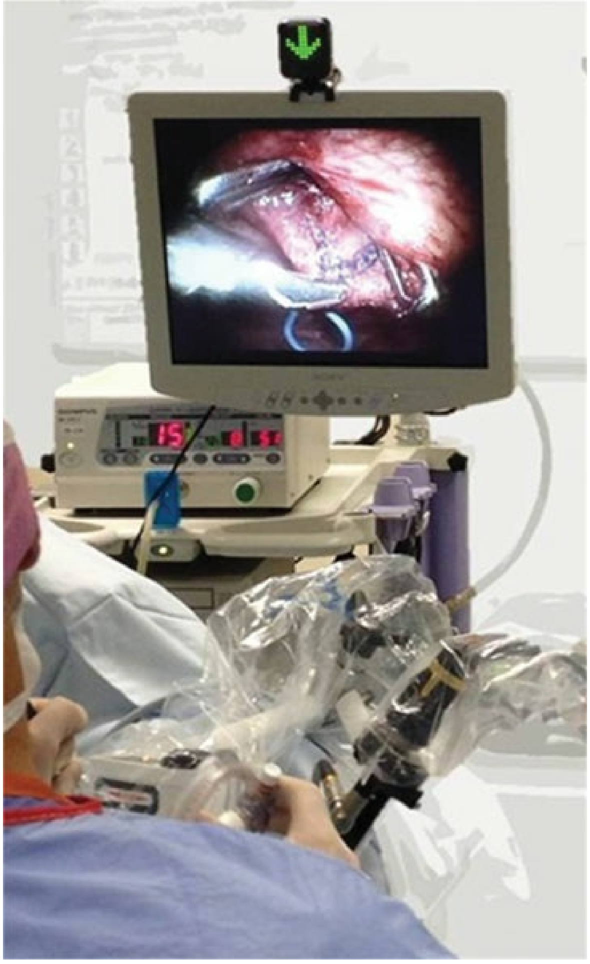

Figure 104.8 An exposed urethral tape is dissected using a transurethral laparoscopic grasper as a retractor.

Port Access: To See or Not to See?

Percutaneous access to the bladder has been mastered by generations of surgeons who have inserted suprapubic catheters for centuries in acute or chronic circumstances of urinary bladder distension; the vesicoscopic access used here does not deviate much from this routine task, and one could be tempted to blindly insert the primary port. Instead, we prefer the visible insertion of nonsharp ports for these reasons: knowing that blind insertion carries the same morbidity and mortality as major pelvic operations [10], we cannot find any good reason at teaching institutions to prefer blind over visible and sharp over blunt tip insertion. The use of a Step-port^{TM} under cystoscopic control is an option; we prefer the nonsharp tip of a translucent port [11].

Bladder Suspension: Stitch or Balloon-Tip Port?

We do not consider balloon-tip trocars as an alternative to 5 mm trocars and a suspension stitch. Needles or energy devices may just pop the balloon of the ports [12]. To suspend the bladder wall, rather than driving a straight needle–mounted suture, we prefer to use a dedicated device. This avoids straining on the fulcrum point of the needle driver, which could stretch the bladder point of entry resulting in gas leakage developing in the cave of Retzius and a reduction in the working space in the bladder.

Why Place Ports So Close to Each Other?

The position of our ports inevitably leads to some clashes as most ports have disproportionately large heads without any technological need. This limits the triangulation of our instruments (Figure 104.1). In a series of four fistula repairs, a wider and higher port position has been described, which certainly reduces instrument clashes and allows more triangulation; however, this increases the risk of an injury to the peritoneum, leading to intraoperative pneumoperitoneum and postoperative peritoneal urine leak as shown with the reported 50% Clavien–Dindo IIb complications [13]. We have in our series only one case of intraoperative gas leak and no case of postoperative urine leakage. Should an intraperitoneal gas leak happen, we recommend exploring it systematically and placing a 14-gauge soft silicone drain through a 5 mm port at the umbilical site, which allows flattening of the abdomen at the cost of an acceptable leak of gas at a rate of 3 L/minute, which is easily compensated by modern insufflators.

Which Port Site for Camera?

It has always been our choice in any pelvic surgery to breach the "triangulation rule" and place the camera into the right side port. Although a side view requires some mental adaptation, this is a small price to pay compared with the benefit of an ergonomic setting. It allows working seated reducing fatigue, which eventually benefits the patient and addresses some ergonomic issues [14]. In support to our claim, we argue that no pilot would be allowed to fly over the sea for 6 hours or more in a standing laparoscopic surgeon position. However, not everybody would agree as shown by one of the experienced surgeons we have trained in this technique (Figure 104.7a). The "toreador" position carries its own risk of surgeon neck and arm injury. The limited triangulation between ports is an issue only to anthropomorphic minds, figuring that the camera head should stay between the shoulders. Picasso has demonstrated a long time ago that there are perfectly workable alternatives.

Why Camera Holding Device When We Have Numerous Assistants Keen to Help?

Beyond declared conflict of interest, the reason we prefer a motorized camera holder to its human counterpart is that it gives a perfectly stable picture and reduces the stress related to misunderstanding or tension between the surgeon and assistant. The assistant is often not needed anymore or at least not in that unrewarding role. It is also worth exploring the concept of solo surgery.

Semantics

Percutaneous cystoscopic surgery has been reported over two decades in different situations. It came first in male urology before finding its application in female urology. In 1990, Badlani et al. reported "a percutaneous cystolithotripsy" and predicted a growing role for "percutaneous bladder surgery" [15]. In 1995, the percutaneous approach made a major breakthrough with the publication in the *Lancet* of "percutaneous cystoscopy" in fetal surgery for posterior urethral valves [16]. An experimental video-assisted "percutaneous cystoscopy" was applied to laser prostatectomy in a dog [17]; it is under a "technique of suprapubic percutaneous telescopy" in that bladder control during laparoscopic gynecological surgery was reported in 1997 [18]. Gill et al. [19] published in 2001 a preliminary series of "percutaneous Cohen antireflux". In 2008, Valla et al. reported their 5-year experience of "transvesicoscopic" Cohen antireflux technique [20]. Nerli and Reddy [13] have reported a "transvesicoscopic" Latzko-type repair in four cases of VVF and further complex fistula repair through the transperitoneal transvesical laparoscopic route. The use of "intravesical laparoscopy" or "transvesical laparoscopy" in the literature is confusing; it can cover transperitoneal transvesical laparoscopic procedures like the four cases of mesh erosion presented at the ICS–IUGA meeting [21] or purely vesicoscopic procedures such as bladder diverticulectomy [22], singleport prostatic benign adenomectomy [23], single-port robotically assisted radical prostatectomy [24], and foreign body [25] and urethrorectal fistulae [26]. We like the word vesicoscopy because it is short and fits the purpose.

Supine Retroperitoneoscopy

There have been previous reports of supine position in retroperitoneoscopic vascular surgery [27], extraperitoneal lymph node dissection [28], and hand-assisted laparoscopic bilateral nephrectomy [29]. To our best knowledge at the 2013 American Urological Association meeting, we gave the first video presentation of a retroperitoneoscopic nephrectomy in the supine position on a frail patient unsuitable for other upper tract interventions; we have found since that the supine position approach is particularly good for chasing a difficult pelvic ureter in previously multioperated large patients, for instance, in the repair of a severed ureter after unrecognized initial injury during pelvic surgery. Furthermore, the combination of vesicoscopy and retroperitoneoscopy makes it easily feasible to approach a benign pelvic ureter in a single supine setting without having to reposition the patient, and we find that there is no longer any excuse for leaving in situ a refluxing ureteric stump after laparoscopic or open nephrectomy in an obese patient. In a patient with low BMI, should the peritoneal cavity be free, we would however still prefer a transperitoneal nephroureterectomy.

About Fistula Repair: From Below vs. from Above?

This is a very old discussion [30] to which we have a clear answer: the vaginal approach was, is, and will remain our first choice. It is quick to perform, has excellent results, and is postoperatively uneventful. We won’t replace the Latzko technique or other vaginal repairs by its vesicoscopic equivalent [13,31]. We reserve vesicoscopy for the most challenging and complex cases. We are conscious that we report here a limited series; however, we think that vesicoscopy is of importance as it has entirely replaced in our departments the open approach for the repair of those difficult VVFs. Its principles rely on closing the bladder defect from its lumen under vesicoscopic view, the vaginal defect from its own lumen via the perineal approach, and in one case, the peritoneum from its own cavity via a standard laparoscopic route. In that particular case, the need occurred for an additional transperitoneal laparoscopic step in order to mobilize and close a gigantic peritoneal defect due to a previous open surgical resection of the pouch of Douglas for ovarian cancer. It is also in that case, after chemotherapy, that an omentum interposition would have been much needed and that it had been removed for cancer treatment. Should the need occur again, we would not hesitate to combine vesicoscopic and transperitoneal route in order to mobilize and interpose the omentum. Even if a transperitoneal step is considered, the primary vesicoscopic route remains justified for the bladder appears surprisingly easier to close from the vesicoscopic side than from the peritoneal cavity as shown in our video [32]. Furthermore, in patients with previous multiple abdominal operations, the peritoneal access and dissection may be difficult, dangerous, and time-consuming due to dense adhesions. Should eventually a vaginal access be extremely poor and comprise the closure from its own lumen, vesicoscopy would still allow a decent vaginal closure without claiming the perfection obtained from below.

Should an interposition of the omentum be needed, which has been recently subjected to debate [33], it would then be feasible laparoscopically and compatible with our technique [34]. Finally, vesicoscopy has avoided a urinary diversion in two of our patients, who were given that reasonable option at other centers of excellence of international reputation.

Antireflux Techniques: Open, Endoscopic, or Vesicoscopic?

One could wonder what are antireflux techniques doing in a textbook of urogynecology; the answer is clear—gynecological diseases and techniques flirt dangerously with the ureter, and the experience acquired with antireflux techniques will free the mind of urogynecologists when the time comes to displace or reimplant a ureter. Open antireflux techniques have a high success rate; on the other hand, the endoscopic submucosal injection of foreign material is less invasive, hence its adoption despite a high rate of long-term failure, incremental cost of repeated procedures, and uncertainty regarding the long-term tolerance of foreign particles migrating from their implantation site. Will vesicoscopy, a small technique squeezed between two powerful giants—conservatism and industry—make the difference and those two redundant? In their initial report of three cases, Gill et al. [19] have described a transurethral cystoscopic vision with laparoscopic instrumentation inserted percutaneously into the bladder in the treatment of symptomatic unilateral ureteric reflux. It has since gained popularity; however, its reproducibility by other teams was made difficult by the use of the transurethral cystoscopic visualization, which causes difficulties during the usage of the working instruments because their movement will be “mirror-imaged” on the screen. Yeung et al. [11] used three 5 mm suprapubic ports, allowing percutaneous vision, avoiding this “mirror-image” effect, and reported a series of 23 reimplanted ureters in 16 children with one conversion to open surgery due to a port displacement and a success rate of 96%, which is comparable to conventional techniques. In a comparative to open approach study, Canon et al. reported that in 52 children vesicoscopy was less painful [35]. A recently updated series of 103 children reported a feasibility rate of 98%, and success rate for resolution of the reflux was 94%. Vesicoscopy seems to be an elegant alternative to both open and endoscopic techniques.

Is Fishing Manufactured Foreign Material in Murky Water Still Justified?

On continence and anatomical restoration grounds, a growing number of female pelvic organs are tacked, stapled, taped, and meshed. No one will dispute the fact that as a result a proportionate number of erosions, infections, rejections, incrustations, and migrations do occur. This carefully chosen vocabulary suggests that those manufactured foreign bodies have acquired an unpredictable capacity of misbehaving despite a perfect initial tension-free, atraumatic, meticulous, elegant, and of course clean implantation. When the time comes for the urologist to look after this type of complications, a conservative endoscopic approach eventually prolongs the complication itself, while the bladder becomes increasingly obstructed, overactive, hypertonic, infected, and incrusted. Like a subaquatic cyclops whose single eye is extended with an appendix—claw, loop, or antenna—we, urologists, tear apart, bury, resect, burn, or melt between the bone and bladder just a few millimeter of tape or mesh. We understand that patients and surgeons are reluctant to undergo an open retrieval of the responsible foreign material.

We suggest that vesicoscopy has an earlier role to play, if after a reasonable attempt of conservative management the problem persists. Aiming at completely removing the foreign material is a sound concept that resonates with well-established open surgical principles. Removing transvaginally what can be done from below, following with vesicoscopy for what can be done inside the bladder—which is obviously more than the routine endoscopy—pursuing with laparoscopic extraperitoneal exposure of the cave of Retzius, intraperitoneal laparoscopy, and finally, if needed, open surgery is a logical sequence that we are not hesitant to follow. Vesicoscopy can bridge the gap between repeated cystoscopic maneuvers and open surgery.

Transperitoneal Transvesical Laparoscopy or Vesicoscopy

It does not matter which of the extra- or transperitoneal laparoscopic technique is used; vesicoscopy, which removes the need to open and close a bladder access, is the winner.

Learning Curve

For the advanced laparoscopic surgeon able to suture like an open surgeon, the technique is within easy grasp and will need only minor adjustments. Working in a fairly limited space requires an economy of movements similar to single-site techniques. In and out motions replace the usual lateral motions. For laparoscopic surgeons with lesser suturing practice, this is indubitably a limiting factor that we acknowledge. The extracorporeal Mignot–Grange knot, which is an upside-down version of the fly-fishing knot, easily overcomes the difficulty of intracorporeal knot–tying skills acquisition [36]. Intracorporeal needle handling and intracorporeal suturing skills remain challenging to develop; however, the answer could come from novel methods of mental simulation training, which speeds up and enhances the acquisition of any skill, as demonstrated at our simulation center [37].

CONCLUSION

We suggest using the word vesicoscopy, which is short and convenient. Beyond the encouraging results from our rather small series, we believe vesicoscopy has potentially much more to offer. The few tips presented could be of help to newcomers to the technique. We acknowledge that our results rely on a long laparoscopic and pediatric vesicoscopic experience acquired in France prior to this adult series. We are confident that vesicoscopic skills can be developed successfully with the blended model of simulation training we have designed. We believe that anticipated technological developments should make vesicoscopy even more accessible. A reusable 5 mm port with a noninflatable distal tip stabilization system, narrow head, and translucent pencil-tip trocar is the ideal product we expect to be developed. We have recently used in a vesicoscopic antireflux a 3 mm pre–series kit that is actually stronger than most tools in the commercially available 5 mm range. The digital treatment of the image captured by the HD flexible cystoscope will allow flipping it into an intuitively workable display. This feature available with the last generation of integrated theaters will, for some cases, remove the need for a camera port. However, the soft flexible sheet of the flexiscope should be reinforced to resist the risk of needle puncture or thermal damage from energy devices. There are excellent motorized needle holders available in the 10 mm range. A 5 mm version is anticipated and would make vesicoscopic suturing accessible to all with minimal access training. The ultimate improvement would be a package consisting of a 5 mm motorized stereoscopic videoendoscope, dominant handheld 5 mm motorized needle holder, and 3 mm nondominant handheld instrumentation. That would offer to institutions and countries that cannot consider larger capital investments a decent platform coming at a fraction of the cost, footprint, and skin incisions of those implied with the larger robotic systems. Under the latter perspective, the next generation of multiarm robotic systems follows a size reduction pathway, which is also excellent news for the future of vesicoscopy.

ACKNOWLEDGMENTS

We extend our gratitude to Professor Linda Cardozo, Dudley Robinson, and John Bidmead of Urogynaecology Department at King’s College Hospital, London, United Kingdom, for their ongoing commitment to collaborative working; Professor Margit Fisch and Professor Felix Chun of Universitätsklinikum Hamburg-Eppendorf, Hamburg, Germany, for their consistent support and commitment to surgical education and innovation; Theatre Team at Polykliniki Ygeia, Limassol, Cyprus, for its vesicoscopic enthusiasm; and Charles Everard of King’s College London, United Kingdom, and George Alevizopoulos of European surgical Institute, Hamburg, Germany, for their contribution to mental simulation training.

Cost-Effectiveness in Laparoscopic and Robotic Surgery in Urogynecology

Karen Ward

INTRODUCTION

Over the last two decades, laparoscopic and robotic-assisted surgeries have been used for a number of applications in urogynecology, including colposuspension, paravaginal repair, sacrocolpopexy, and sacrohysteropexy. The majority of the evidence comparing standard, laparoscopic, and robotic approaches relates to sacrocolpopexy. The minimally invasive approach is considered to have advantages, which include a shorter hospital stay, faster recovery, and return to normal activity.

Prolapse is one of the most common indications for surgery in women, with over 200,000 procedures per year for the condition in the United States [1]. The cost associated with prolapse surgery was conservatively estimated as $1.01 billion per year in 1997 [1]. In Europe in 2005, the number of admissions for prolapse surgery was 36,854 in Germany, 36,679 in France, and 28,959 in the United Kingdom. The estimated costs associated with these admissions were €144 million, €83 million, and €81 million in the three countries, respectively [2]. With an aging and active population, the demand for services related to female pelvic floor dysfunction is likely to continue to rise, with an increasing burden on health-care budgets.

The last two decades have seen significant changes in the pattern of prolapse surgery worldwide, with a move toward more minimally invasive treatments. The minimally invasive approach is considered to be advantageous as it is associated with reduced pain, bleeding, hospitalization, and recovery time, with improved cosmetic results.

Sacrocolpopexy, first described via the abdominal route in 1957, is considered to be one of the most effective and durable operations for apical vaginal prolapse [3] with reported long-term success rates of 78%–100% [4]. Despite the advantages of sacrocolpopexy, vaginal vault surgery is more often performed because it is faster, is less painful, allows a rapid recovery, and is cheaper.

Laparoscopic sacrocolpopexy, first described in 1994 [5], has been adopted by pelvic floor surgeons to address concerns about morbidity and to shorten postoperative recovery. Success rates for the open and laparoscopic routes have been shown to be comparable [6] with reduced blood loss and a similar operating time. However, the laparoscopic route requires high levels of laparoscopic skills as it involves extensive dissection and suturing. Laparoscopic instruments have a limited range of movement in the abdominal cavity. Manipulation of the instruments for suturing and knot tying in the pelvis is technically challenging. Adoption has therefore been limited despite the clinical advantages of the laparoscopic route.

Robotic technology has made laparoscopic sacrocolpopexy a more feasible operation for many surgeons as it offers enhanced visualization, an increased range of movement of instruments and improved ergonomics for the surgeon. Some argue that it more closely approximates to the open technique and is therefore easier for the surgeons who do not have advanced laparoscopic skills to learn, with a shorter learning curve. The da Vinci Surgical System (Intuitive Surgical Inc., Sunnyvale, CA) is the only robotic surgery platform currently available.

There has been a rapid adoption of robot-assisted surgery across surgical specialties, particularly in the United States. The number of robotic procedures performed worldwide almost tripled between 2007 and 2010, from approximately 80,0 to 205,000 [7]. By 2014, over 3000 robots had been installed worldwide and over half a million procedures performed (http://www.intuitivesurgical.com/company/profile.html). Uptake has been greatest in urology and gynecology and these specialties perform the majority of robotic surgeries [8].

Enthusiasm for technological innovation by both surgeons and patients often leads to rapid adoption before efficacy and safety is established relative to existing procedures. Rapid increases in cost are often seen with such technology. This may be due to a higher cost of the new procedure or that its introduction results in more patients being treated overall. This is particularly pertinent when the procedure is relatively easy to learn and applicable to a large number of patients. While uptake of laparoscopic sacrocolpopexy has been relatively slow, due to the technical difficulty involved in learning the procedure, robotic surgery is perceived as easier to learn, and uptake of robotic sacrocolpopexy has been rapid in countries with access to the technology.

Concern has been raised regarding the increased financial costs associated with robotic surgery, particularly with regard to acquisition of the system, annual maintenance costs, and disposable robotic instruments. Robotic surgical systems are expensive with prices ranging from $1 million to $2.3 million. The system requires costly maintenance ($100,000–$170,000 per year) and robotic consumables ($700–$3200 per procedure) (http://www.intuitivesurgical.com/company/profile.html). Across all surgical specialties, it is estimated that the additional cost of using a robot-assisted procedure is approximately $1600, about 6% of the cost of the procedure or $3200 when the cost of the robot is included [7]. For many procedures, it is yet to be established whether the increased cost of the technology is offset by improvement in surgical outcomes.

ECONOMIC ANALYSES IN HEALTH CARE

The terms economic evaluation or economic appraisal cover a range of techniques to assess the evidence on expected costs of different procedures or treatments [9]. It involves the systematic identification, measurement, and valuation of all relevant costs and consequences of the options under review.

Effectiveness is a crucial factor in economic evaluation because of the finite nature of resources. With unlimited resources, the most effective treatment would always be selected. Where there is a limited budget, it is important to assess whether the additional costs of adopting a more expensive treatment option are counterbalanced by improved outcomes for patients. Cost-effectiveness is a method of assessing whether the new treatment is good “value for money.” Economic analysis examines the trade-off between a less costly approach and a less-effective approach. Effectiveness is measured in terms of outcomes, e.g., survival, or as utilities such as health-related quality of life.

If there is a reason to believe that the outcomes of procedures under consideration are the same, cost-minimization analysis may be undertaken.

Ideally, economic evaluation should be undertaken alongside a randomized clinical trial, as it is important to include cost comparisons in the evaluation of new treatments. There is an inherent risk of undertaking economic analysis too early in the development of a new technique in that the treatment may not be applied in the most economical fashion when it is first tested. A seemingly high-cost treatment may become less expensive with further refinement. The treatment could also become more cost effective if the refinement also improves efficacy. Thus, the cost-effectiveness of a new procedure is likely to change with time. Studies comparing an existing and a new procedure are also problematic with regard to ensuring that surgeons are sufficiently experienced in both procedures at the beginning of the study.

Perspective of Cost Comparison

The perspective of the cost analysis is key to the understanding of the study. It is possible to view the costs from the point of view of the patient or payer (in health-care systems with direct patient contribution, such as the United States), the hospital, and society as a whole. In health-care systems with universal coverage, such as the United Kingdom, all costs are born by society.

Most analysis is performed from the hospital perspective, and this would appear to be appropriate for surgical procedures such as prolapse surgery as the majority of the costs are associated with hospitalization. This approach is less relevant for conditions managed on a predominantly outpatient basis, such as diabetes. Hospital costs include all of the resources involved in the surgical treatment and inpatient care. There are direct costs, which include equipment, medication, and bed or “hotel” costs and staffing, as well as indirect costs such as hospital administration. The cost of capital equipment can play a significant role in determining cost-effectiveness. In most health-care systems, the hospital does not get additional payment for a robot-assisted procedure but has to pay for the robotic system and its maintenance. These costs may be passed on to patients or payers in other ways by hospitals, to offset the costs of the robot.

The patient perspective will vary according to the type of health-care system due to factors such as employment status, health insurance, and access to health care.

The cost to society should also take account of loss of work productivity of patients and carers during surgery and recovery, together with future morbidity relating to the condition or treatment, e.g., the need for further surgery for recurrent prolapse or incontinence. These costs are difficult to measure but contribute to national productivity. Factors influencing the ergonomics of the procedure and risk of injury to the surgeon, with consequent loss of productivity, may also impact on cost to society.

Costs

Direct Costs

Direct costs of treatment include all inpatient and outpatient costs related to the treatment.

Direct costs may include the following:

- Theater/operating room costs
- Bed or "hotel" cost
- Equipment
- Consumables, e.g., mesh
- Pharmacy
- Anesthesia
- Laboratory tests
- Radiology
- Outpatient or day-case visits

Future costs include the cost of readmission and postoperative resource use. It may also include the cost of repeat surgery or surgery for conditions resulting from treatment, such as urinary stress incontinence. These differences ideally should be identified and accounted for in comparative long-term studies. This will only be relevant for analysis from the patient or society perspective rather than the hospital perspective.

The three biggest contributors toward direct costs for laparoscopic and robotic surgery are operating times, length of stay (LOS), and equipment [10,11]

- Operating room costs, which include staffing, and overheads, such as electricity and heating, are directly related to operating time. When a new procedure is introduced, the operating time will typically be prolonged as the surgeon commences on their learning curve. This initially results in higher costs. In addition, there may be additional steps, such as docking the robot, which contribute to additional theater time in comparison to open or laparoscopic surgery.
- The main financial advantage of laparoscopic surgery is reduced length of postoperative hospital stay. Not only does this result in lower "hotel" costs but a rapid recovery will also incur fewer costs compared with a prolonged recovery such as IV fluids, monitoring, and medication. A reduction in costs associated with hospital stay for minimally invasive surgery can offset the additional equipment costs of the procedure [12].
- The cost of surgical equipment plays a significant role in cost-effectiveness of laparoscopic and robotic procedures. Costs for surgical equipment include capital costs such as the cost of monitors, cameras, laparoscopes, and insufflators as well as consumable costs, which may include mesh as well as disposable laparoscopic or robotic equipment. Equipment that is used for existing procedures, such as that used in laparoscopic surgery, incurs very little additional cost per case. Conversely, the cost associated with acquisition and maintenance of a surgical robot is significant and can add an average of $1600 per case [7]. Since there is currently only one robotic system on the market, there is no price competition and it is unlikely that costs will fall significantly. Consumable costs for robotic surgery may also be significant as instruments have a limited 10 procedure life-span. Cost of capital equipment will also vary according to its utilization. If the cost of the robot is distributed over a large number of patients, the cost per case will be lower. The cost of the robot must be viewed in relation to the institution budget rather than that of a department such as the operating theater suite. The price of surgical equipment can

also vary according to local sales contracts, which are usually related to the volume of equipment purchased.

Interpretation of economic evaluations may be problematic, and the conclusions of a study may not be readily generalizable outside of the context in which the study was undertaken. There are a number of factors to consider:

- The majority of economic analyses of laparoscopic and robotic sacrocolpopexy have been undertaken in the United States and may not be generalizable to practice elsewhere in the world. For example, there may be differences in LOS in Europe where there is a different health-care funding model.
- Costs may not only vary between institutions and different health-care systems but also between different countries.
- Studies undertaken from the hospital perspective often utilize charging data from the hospital billing system, rather than measuring costs directly. While these data are easier to obtain accurately, the charge not only includes direct and indirect costs but also includes a profit margin. The cost to charge ratio needs to be established to establish the underlying cost. This may vary between hospitals as well as within different departments in a single institution.

Indirect Costs

Indirect costs of surgery are difficult to establish but may have a significant effect on the cost to society. If patients recover more rapidly and return to work earlier following laparoscopic rather than open surgery, there may be significant benefits to the economy. It has been estimated that a 15-day difference in return to work has a value to society of just over $2000 (2001 prices), which would reduce or negate the additional cost of robotic or laparoscopic surgery [13].

The physical challenges of performing laparoscopic surgery are well recognized with over 85% of laparoscopic surgeons reporting physical discomfort, which is persistent in up to 50% [14,15]. The potential effects of work-related injury on the surgeon’s productivity and career longevity are difficult to quantify. Surgeons who perform minimal access surgery are reported to be two to three times more likely to become unfit for work compared to medical doctors not performing such surgery [16]. Neck, back, and shoulder pain are rarely reported in surgeons performing robotic surgery but occur commonly in laparoscopic surgeons [17]. A correlation has been observed between raised patient BMI and risk of strain symptoms in surgeons performing laparoscopic but not robotic surgery. Given the global obesity crisis, surgeon ergonomics are more likely to become a consideration in the choice of operative modality in the future [14].

LAPAROSCOPIC AND ROBOTIC SACROCOLPOPEXY

Outcomes

A number of cohort studies have been published with short- to medium-term outcomes of laparoscopic and robotic-assisted sacrocolpopexy. Long-term series are lacking and there have been few randomized studies.

Freeman et al. [6] compared abdominal sacrocolpopexy with laparoscopic sacrocolpopexy in a multicenter randomized trial with follow-up at 1 year. Based on objective and subjective outcomes, they found the procedures to be equivalent, with reduced blood loss and shorter LOS in the laparoscopic group. Operation times were not significantly different.

In a randomized trial comparing robotic and laparoscopic sacrocolpopexy, Paraiso et al. found no differences in vaginal support and functional outcomes between the two procedures at 1 year [18]. Operating time was significantly longer in the robotic group and participants in this group also had greater postoperative pain. Anger et al. [19] reported similar findings in their randomized trial of laparoscopic and robotic sacrocolpopexy designed to compare costs and outcomes. They found the procedures to have equivalent short-term outcomes and complication rates. They also found higher postoperative pain following robotic surgery, together with longer operating time. Data from cohort studies of laparoscopic and robotic surgery support these findings [20–22]. Despite the relative lack of data on long-term outcomes, complications and need for reoperation of both procedures have similar outcomes in terms of subjective and objective measures.

Cost Comparisons

A number of U.S. studies have attempted to quantify costs associated with laparoscopic and robotic surgery. There have been no full cost-effectiveness studies comparing sacrocolpopexy route, and the majority of studies are cost-minimization studies, which assume no difference in outcome between the procedures.

Open versus Robotic Sacrocolpopexy

Elliott et al. [23] undertook a cost-minimization analysis in a retrospective cohort of patients comparing costs for 40 robotic and 19 open sacrocolpopexies between 2006 and 2010. An estimate of the cost of robot purchase and maintenance per case was included in the analysis. They found operation times to be similar between the groups with a shorter LOS in the robotic group. They demonstrated cost savings of the robotic procedure over open sacrocolpopexy. Further analysis of their data suggested that the biggest factor in the cost of the robotic procedure is the number of cases performed at the institution. Other significant drivers of cost were cost per day of hospital stay, LOS, operating room time, and disposable equipment costs.

A retrospective review of 73 robotic and 91 open sacrocolpopexies also found the robotic procedure to be less costly than open [24]. The authors of this study considered themselves to be past the learning curve for both procedures, with the senior author having performed more than 300 open and 100 robotic procedures prior to starting the study. They found operative times to be longer by 30–45 minutes in the robotic group but LOS was shorter. They also factored in robot purchase and maintenance and found the total direct hospital costs to be $1136 cheaper for the robotic approach.

Li et al. [25] analyzed data from the 2009 to the 2010 U.S. Nationwide Inpatient Sample database. They reported trends in utilization and outcomes of both robot-assisted sacrocolpopexy and “open” vaginal vault surgery. These were identified using ICD-9 codes and do not distinguish between vaginal or abdominal approaches to vaginal vault suspension. They identified 2,381 robotic procedures and 11,080 “open” procedures. An increase in the proportion of robotic procedures was seen over the time period, from 14.1% in the first quarter of 2010 to 21.8% in the fourth quarter. Blood transfusion and prolonged hospital stay were less likely following robotic surgery, and although intraoperative complications were higher, there was no difference in postoperative complications. Hospital charges were significantly lower in the open surgery population compared with robotic surgery patients.

Robotic versus Laparoscopic Sacrocolpopexy

Two randomized trials, and a retrospective cohort study comparing clinical outcomes and costs of robotic and laparoscopic sacrocolpopexy, have found robotic surgery costs to be higher than those of laparoscopic surgery [18,19,26].

Paraiso et al. reported a prospective randomized study with 38 laparoscopic and 40 robotic procedures. They found no significant differences in complications, clinical outcomes at 1 year and LOS. Operating time was longer by 67 minutes, 14 minutes of which was robot docking time, in the robotic group. The differences in the two procedures, such as intracorporeal knot tying in the robotic group and extracorporeal in the laparoscopic group, may also have contributed to longer robotic operating time. Postoperative pain was greater at 3–5 weeks in the robotic group. It was postulated that differences in pain might be due to the greater number and size of ports in the robotic arm. Robotic surgery was more expensive than laparoscopic by a mean of $1936 (95% CI $417–$3454). This is a conservative estimate as robot acquisition and maintenance costs were not included in the analysis. The difference in costs was accounted for by the operating room costs since costs associated with hospital stay and postoperative care were similar.

The other randomized trial of robotic and laparoscopic sacrocolpopexy reported surgical costs and costs associated with rehospitalization up to 6 weeks, as well as outcomes at 6 months [19]. Costs were derived from applying a cost-to-charge ratio to the hospital charges rather than from accounting for individual costs of items used. In this multicenter study, no difference was demonstrated in LOS, blood loss, and complications. Operating time was longer in the robotic group and short-term pain was greater in this group. It was felt that the increase in pain might be related to the operating time and the increased tension on the robotic ports due to a lack of tactile feedback from robotic surgery; i.e., the surgeon is unable to sense the pressure on the ports. Over 6 weeks, costs were higher for robotic surgery

($19,616 versus $11,573) but when purchase and maintenance costs were excluded, the cost difference decreased to only $1,000. They concluded that the higher costs were as a result of the robot purchase and maintenance, rather than surgical costs.

Both of these studies stipulated that surgeons should have performed at least 10 of procedures of each type prior to starting the study. It is possible that the surgeons, who were experienced laparoscopists, were still at the start of the learning curve of robotic surgery after 10 cases. Surgeons with greater robotic experience may have obtained different results.

In the retrospective cohort study of 104 subjects, Tan-Kim also found that costs were higher for robotic surgery. The increase in costs was attributed to increased surgical time [26]. Differences in surgical technique between the procedures may have contributed to this. Titanium tacks were used to fix the mesh to the sacrum in the laparoscopic group whereas suturing with intracorporeal knot tying was the method in the robotic group. Robot docking time accounted for only 9 of the 72 minutes difference in operating times. They also acknowledge that the study covered a period when some of their surgeons were at the start of their learning curve for the procedures.

Cost Comparisons of Open, Laparoscopic, and Robotic Sacrocolpopexy

A cost-minimization analysis by Judd [27] concluded that robotic was more expensive than laparoscopic or open sacrocolpopexy under baseline assumptions. They derived parameter estimates from a review of the literature and applied a decision-analysis model to compare costs (US $2008). They used two models; one based on current hospital ownership of a robotic system and one including the purchase and maintenance costs. Sensitivity analyses were performed to assess the effect of varying the parameters. They found robotic sacrocolpopexy to be the most expensive, with an incremental cost of $1155 over laparoscopic and $2716 over open sacrocolpopexy. Robotic and laparoscopic surgery costs only became equivalent when robotic operating time is reduced to 149 minutes, robotic disposable costs reduced to $2132, or laparoscopic disposable costs increased to $3413. The additional costs associated with the robot purchase model were between $581 and $1724 per procedure, depending on robotic throughput. The cost differences reflect higher disposable equipment costs and longer operating time. Despite these findings, the authors suggest that continued robotic innovation might lead to future cost savings in terms of reduced operating time and cheaper equipment.

Patel et al. [11] retrospectively looked at hospital records for five open, five laparoscopic, and five robotic sacrocolpopexy procedures and performed a cost-minimization analysis, assuming that outcomes were equivalent. Operation times in this study were significantly greater than other referenced studies (418 minutes for open, 510 for laparoscopic, and 358 for robotic procedures). The estimated direct costs were higher for robotic surgery than open but not significantly different for robotic and laparoscopic approaches. The differences in costs were attributed to operating room time and equipment. It is not clear whether costs associated with robot purchase and maintenance are included in this analysis.

Learning Curve of Laparoscopic and Robotic Sacrocolpopexy

The learning process of laparoscopic sacrocolpopexy presents a challenge to most urogynecologists. Many of them have little experience of advanced laparoscopic surgery and are traditionally trained as predominantly vaginal surgeons. To become proficient in a new surgical technique, surgeons need a sufficient individual caseload. Even though vaginal prolapse is a common indication for surgery, vault prolapse is relatively uncommon. In England in 2005, only 10.3% of prolapse operations involved a vault support procedure [2].

In order to assess the learning process, it is necessary to define an endpoint at which a surgeon is judged to be proficient. Assessment of the learning curve should include measures of quality and efficiency. Quality of surgery can be assessed by functional outcomes or by complication rates. Efficiency is usually assessed by measuring duration of surgery but may also include conversion to open surgery.

A number of studies have attempted to quantify the learning curve of laparoscopic sacrocolpopexy. They focus on the number of cases required to reduce the operating time, largely due to low rates of reported complications associated with the procedure in the studies [28–30]. Mustapha et al. found that duration of surgery reduced after 15 cases but suggested that 30–40 cases are necessary to master the technique [30]. Operating time declined rapidly during the first 30 cases in the study reported by

Claerhout et al. reaching a steady state after 90 cases [29]. Complications were unchanged throughout this series. The same group further analyzed the learning curve in a subsequent study [31]. They divided the procedure into 5 steps and examined the learning curve for each. Dissection of the vault was the most time-consuming step; times comparable with the teacher (the control) were achieved after 31 cases. Duration of suturing fell within the range of the teacher after only 10 cases, but it should be noted that the participants had attended a 15 hour laparoscopic skills lab prior to commencement of the study. There was no learning curve associated with dissection and fixation to the sacral promontory.

The learning curve for robotic sacrocolpopexy has not been extensively studied. Two studies have found operative times to drop significantly after just 10 cases [32,33]. Germain et al. [33] suggest that the short-learning curve may be due to their extensive previous experience with robotic surgery. The learning curve of robotic hysterectomy has found to be significantly longer than these small series suggest. In a study of 325 cases, performed over 3 years, Woelk et al. used cumulative summation analysis to show that proficiency is achieved after approximately 91 cases [34]. This is similar to the number suggested by Claerhout et al. for laparoscopic sacrocolpopexy. This study also found no decrease in complications with experience. The extent to which this study can be extrapolated to robotic sacrocolpopexy is debatable and further studies of the learning process are required for this procedure.

Yohannes et al. [35] evaluated the time taken to perform suturing and dexterity skills on a pelvic model using either laparoscopy or robot assistance. They demonstrated that the robot allowed suturing and dexterity skills to be performed more quickly than with laparoscopic assistance after only five trials. The study is limited by the small number of participants, the lack of standardized dexterity tasks, and the number of times each participant performed the task. It would have been useful to increase the number of trials to determine how many are required for participants to reach their plateau.

From the available evidence, it would appear that proficiency in laparoscopic sacrocolpopexy, based on duration of surgery, is achieved after 30–90 cases. The corresponding figure for the robotic procedure is yet to be determined. There is some evidence to suggest that some of the necessary skills for minimally invasive sacrocolpopexy are acquired more quickly using robot assistance.

CONCLUSIONS

Financial considerations play a major role in health-care systems worldwide. The high cost of robotic surgery needs to be evaluated carefully in terms of evidence-based outcomes. The following conclusions are made from the limited data available:

1. Similar short-term outcomes have been reported for open, laparoscopic, and robotic sacrocolpopexy. Formal cost-effectiveness analysis has not been undertaken for different surgical approaches to sacrocolpopexy; the majority of studies use cost-minimization analysis to estimate costs from the hospital perspective. Longer-term studies, including data on quality of life, long-term outcomes, complications, and the need for further surgery, would allow the cost to society of such surgery to be evaluated. Interpretation of the literature with regard to cost is problematic, and the results of studies comparing robotic surgery costs to other routes are conflicting. Conclusions vary considerably depending on the model used, the assumptions made, and the method of analysis.
2. Operating time is one of the main drivers of cost in robotic surgery. Large variation in operating time is reported and there is a lack of clarity in many studies as to how operating time is defined. Other factors that need to be taken into consideration when assessing operating time in studies include
    a. Surgeon experience when the study was undertaken (learning curve)
    b. The inclusion or exclusion of concomitant procedures from the analysis
    c. Differences in surgical technique between the comparator procedures, e.g., knot-tying method (intra- or extracorporeal), the use of barbed sutures to fix the mesh to the vagina, and method of sacral fixation of mesh (sutured or tacked)
3. LOS is an important cost contributor especially for open sacrocolpopexy. The cost per day of hospital stay may vary considerably between institutions.
4. Equipment costs account for a large part of the difference between open versus laparoscopic or robotic costs. There are differences in the extent to which all possible items are accounted for in different studies as well as the time period over which the study is undertaken. Some studies

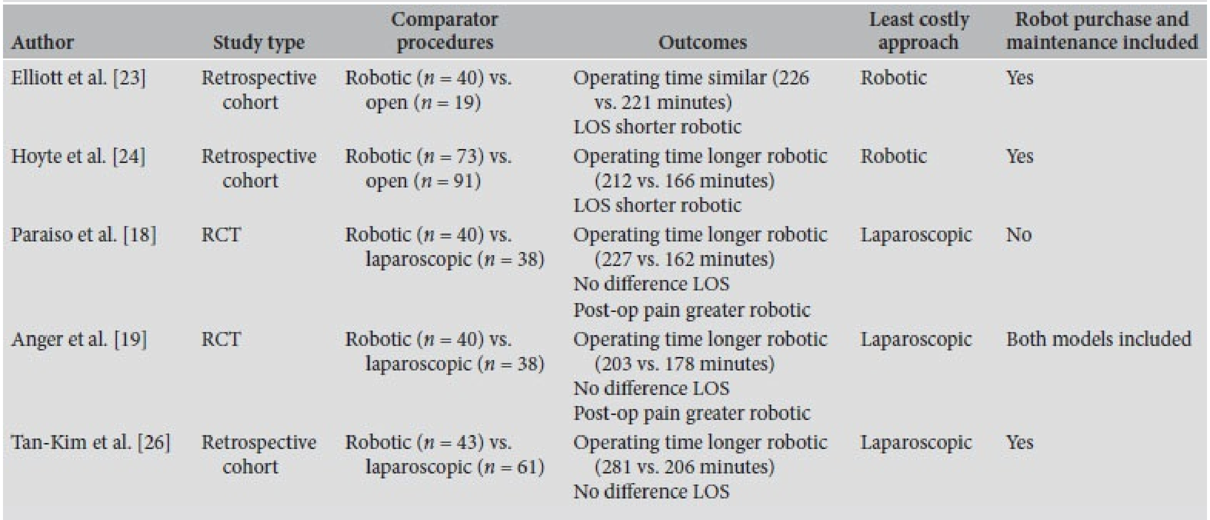
only include inpatient costs, whereas others itemize costs up to 6 weeks postoperatively.

Surgeons outside the United States may struggle to interpret the cost data from existing literature and the extent to which it can be extrapolated to their own health-care systems. There have been no studies of costs associated with robotic sacrocolpopexy in settings outside of the United States.

Robotic technology will continue to develop and is likely to become cheaper as new manufacturers enter the market. There is currently a lack of competition to the da Vinci system, which may, in part, stem from patented technologies as well as acquisition of a competitor by Intuitive Surgical in 2003. Whenever there is minimal or no competition in a market, companies are able to command high premiums for their product and operating margins can be higher compared with other companies within that industry [36]. Until competitors enter the market, the only other option to enable more centers to utilize this technology is the emerging availability of cheaper, preowned systems.

Despite the heterogeneous nature of the cost comparison studies, they appear to demonstrate that robotic sacrocolpopexy is associated with greater direct costs than the laparoscopic approach (Table 105.1). While improvements in the technique and technology, together with future market competition, may drive down costs, robotic sacrocolpopexy does not yet appear to be cost effective compared with the open and laparoscopic approaches.

Table 105.1 Cost Comparison Studies of Open or Laparoscopic Sacrocolpopexy versus Robotic Sacrocolpopexy



Author	Study type	Comparator procedures	Outcomes	Least costly approach	Robot purchase and maintenance included
Elliott et al. [23]	Retrospective cohort	Robotic ($n = 40$) vs. open ($n = 19$)	Operating time similar (226 vs. 221 minutes) LOS shorter robotic	Robotic	Yes
Hoyte et al. [24]	Retrospective cohort	Robotic ($n = 73$) vs. open ($n = 91$)	Operating time longer robotic (212 vs. 166 minutes) LOS shorter robotic	Robotic	Yes
Paraiso et al. [18]	RCT	Robotic ($n = 40$) vs. laparoscopic ($n = 38$)	Operating time longer robotic (227 vs. 162 minutes) No difference LOS Post-op pain greater robotic	Laparoscopic	No
Anger et al. [19]	RCT	Robotic ($n = 40$) vs. laparoscopic ($n = 38$)	Operating time longer robotic (203 vs. 178 minutes) No difference LOS Post-op pain greater robotic	Laparoscopic	Both models included
Tan-Kim et al. [26]	Retrospective cohort	Robotic ($n = 43$) vs. laparoscopic ($n = 61$)	Operating time longer robotic (281 vs. 206 minutes) No difference LOS	Laparoscopic	Yes

Complex Problems

106 Diagnosis of Urogenital Fistula

Ekene A. Enemchukwu and Benjamin M. Brucker

INTRODUCTION

Urogenital fistulas are abnormal connections between an organ of the urinary tract and an adjacent organ of the female genital tract. They can occur in a number of anatomical locations along the urinary tract and the female reproductive system (Table 106.1). The majority of urogenital fistulas worldwide occur in the developing world [1]. Over 90% of these are obstetrical in nature, caused by obstructed labor and poor access to medical care [2]. In contrast, the majority (90%) of urogenital fistulas in the developed world are iatrogenic, occurring after pelvic surgery [3–5].

There are an estimated 500,000 women with untreated urogenital fistulas worldwide [6]. The actual worldwide incidence is unknown. Many women in developing countries never present for treatment due to poor access to care and lack of financial resources. In one study, women who sought treatment presented an average of 5 years after the development of symptoms. Worldwide estimates have largely been collected from hospital data. The incidence of urogenital fistula in the developing world has been estimated to be 30,000–130,000 per year [1]. Garely and Mann evaluated the U.S. 2007 hospital discharge data and found that approximately 5,000 urogenital fistula repairs were performed in the United States each year [7,8]. However, these data are limited by the inability to differentiate between primary repairs, reoperations, and erroneous medical coding. Furthermore, this figure does not account for fistulas that were managed on an outpatient basis or managed conservatively without surgical intervention.

Urogenital fistulas are often devastating. The social isolation, depression, and physical discomfort that can occur as a result of constant urinary leakage can cause significant damage to the woman's physical and psychosocial well-being [9]. Furthermore, it can negatively impact her quality of life. The medicolegal implications and financial impact on the healthcare system are also important considerations [10]. In order to minimize the negative impact of urogenital fistula, accurate and timely diagnosis is critical. Effective management requires accurate diagnosis and avoidance of unnecessary tests and therapies. Finally, the clinician must be certain that any concomitant injuries to the urogenital tract have been ruled out or adequately addressed. This chapter will focus on the epidemiology, etiology, presentation, and diagnosis of female urogenital fistula.

ETIOLOGY AND PATHOPHYSIOLOGY

Common causes of urogenital fistulas include obstetrical trauma, iatrogenic injury during pelvic surgery, infection, pelvic radiation, inflammation, pelvic trauma, foreign bodies, pelvic neoplasms, and complications of pelvic surgery (i.e., postoperative hematoma, leading to breakdown of suture lines) (Table 106.2). Poor nutrition, diabetes, atherosclerosis, steroid use, tobacco use [38], and ischemic states further increase the risk of fistula development in these patients [6].

Obstetrical injury due to obstructed labor is the leading cause of urogenital fistula in the developing world. Arrowsmith et al. characterized the *obstructed labor complex*, which describes the potential multiorgan effect of prolonged labor. These include vesicovaginal fistula (VVF), urethral loss, stress urinary incontinence (SUI), rectovaginal fistula, ureteral obstruction with subsequent hydroureteronephrosis and renal failure, fecal incontinence secondary to anal sphincter incompetence, cervical and vaginal scarring, amenorrhea, secondary infertility, osteitis pubis, and/or foot drop [11]. The exact cause of foot drop is unknown, but it is thought to occur as a result of sacral nerve injury during fetal descent or peroneal nerve injury from prolonged squatting during obstructed labor [1]. The level of injury to the pelvic viscera is determined by the level at which fetal descent stops [12]. Therefore, any combination of urogenital fistulas, including vesicovaginal, urethrovaginal, ureterovaginal, vesicouterine, ureterouterine, and vesicocervical fistula, can develop as a result [9]. Rectovaginal fistulas can also occur after obstructed labor; however, they will not be discussed as they are beyond the scope of this chapter.

Iatrogenic injury during pelvic surgery is the most common of cause of urogenital fistula in the developed world. Ninety percent of urogenital fistula are estimated to occur as a result of inadvertent injury during pelvic surgery [4,5,13–22]. Symmonds reviewed 800 cases in the United States and found that 75% of these injuries occurred during hysterectomy, while only 5% were caused by obstetrical injury [23]. Approximately 600,000 women undergo hysterectomy annually in the United States, and approximately 60% of these are performed for benign disease, including uterine leiomyoma and endometriosis [24]. Studies indicate that the rate of bladder injury during hysterectomy ranges from 1% to 5%, while the rate of ureteral injury ranges from 0.2% to 2.5% [25–27]. Some injuries are identified and repaired intraoperatively [28]. However, a majority of postoperative fistulas are thought to occur as a result of an unrecognized injury [29].

The risk of injury is increased by anatomical distortions caused by intraoperative bleeding, previous pelvic surgery, adhesions, endometriosis, fibroids, ovarian masses, radiation, and malignancy [5,6,19,26,30–33,40]. In 2012, Hilton et al. evaluated the rate of urogenital fistulas after hysterectomy in the British National Health System. They found that the risk of fistula development was the greatest among women who had an abdominal hysterectomy performed for cervical cancer (1.2%) and lowest for those women who had a vaginal hysterectomy for pelvic organ prolapse (0.03%) [34]. Women undergoing total abdominal hysterectomy for benign diseases had a urogenital fistula rate of 0.2%.

Another important cause of urogenital fistula is the pelvic irradiation. Approximately 4%–10% of urogenital fistulas are thought to develop due to pelvic radiation therapy [14,19,23,29]. Previously irradiated tissue undergoes progressive changes secondary to obliterative endarteritis, which can cause fibrosis, necrosis, and subsequent fistula formation [5,35]. The cumulative dose and proportion of external beam or brachytherapy delivered to the genitourinary organ have been shown to be associated with higher rates of fistula formation in some studies [36,37]. Smoking has also been implicated as an added risk factor in patients undergoing pelvic radiation therapy. In one study, current smokers undergoing radiation treatment were more likely to develop VVFs than nonsmokers (73% vs. 23%) [38].

Spontaneous fistulas can develop in patients with a history of malignancy or pelvic irradiation weeks to decades after treatment with a median of 8.7 months [35,38]. Thus, secondary malignancies and oncological recurrences should be ruled out in patients with a history of pelvic malignancy [39]. Examination under anesthesia should be strongly considered in these patients in order to obtain biopsies and evaluate for concomitant pelvic masses prior to planned surgical repair.

UROGENITAL FISTULA TYPES

Urogenital fistulas can occur between a number of structures. A high index of suspicion is needed to ensure that all fistulous communications are identified, including those that communicate with nonurogenital organs or structures. In the next section, we will discuss the most common urogenital fistulas.

Vesicovaginal Fistulas

VVFs are the most common type of urogenital fistula, comprising over half of all urogenital fistulas [31,40–42]. In developing countries, over 90% of VVFs are caused by obstetrical trauma from prolonged labor [2]. This occurs secondary to inadequate emergency obstetrical care during obstructed labor. The consequent prolonged contact between the fetus and a large area of pelvic soft tissue and visceral organs causes an ischemic pressure necrosis [11,15]. Widespread vaginal scarring and fibrosis ensues [6,43]. The level of injury to the lower urinary tract is determined by the level at which fetal descent is halted during labor [11,12]. This often occurs distally, involving the bladder trigone, bladder neck, and urethra, causing large VVFs and urethrovaginal fistulas surrounded by poorly vascular tissue [44]. Although rare, obstetrical VVFs do occur in the developed world [23]. However, these fistulas typically occur in the setting of operative deliveries requiring forceps or vacuum assistance.

Over 75% of VVFs in the developed world occur as a result of unrecognized injury during hysterectomy [19,45]. With an estimated incidence of 0.2%–2%, iatrogenic VVFs often occur as a result of inadvertent bladder injury from aggressive blunt dissection, sharp dissection, electrocautery, or crush injury from a retractor or clamp during pelvic surgery [5,19,23,26,31,32]. A urinoma can form and subsequently drain urine through the vaginal cuff forming an epithelialized tract with subsequent fistula formation. Another potential cause of posthysterectomy urogenital fistula is inadvertent suture incorporation of the posterior bladder wall during the vaginal cuff closure. The ensuing posterior bladder wall ischemia can lead to tissue necrosis and subsequent fistula formation. These injuries are typically supratrigonal and medial to the ureteral orifices [6,19]. The vaginal vault is the most common site of postabdominal hysterectomy VVF. In one series, over 60% of vaginal vault fistulas occurred after total abdominal hysterectomy [3]. It is estimated that only about half (51%) of all bladder injuries are identified and repaired intraoperatively [28].

Radiation is another important cause of VVF. One study found that 0.6%–2% of women irradiated for cervical cancer will eventually develop a VVF [46]. In a 2007 study, the authors observed a 47.8% fistula rate in 23 women who had concurrent chemotherapy and radiation for stage 4 cervical cancer [38]. The risk of fistula development was even higher in smokers. Finally, pelvic organ prolapse surgery and synthetic midurethral slings have also been implicated as causes of VVFs [47,48]. A 2008 meta-analysis noted a 1.3% bladder injury rate during anterior prolapse repair with nonabsorbable mesh, half of which were associated with mesh introducer kits [49]. The percentage of injuries ultimately leading to VVF development was not reported. Unfortunately, the true incidence of urogenital fistula after peer-reviewed data is sparse, largely comprised of case reports.

Ureterovaginal Fistulas

Ureterovaginal fistulas are rare complications that are often caused by unrecognized injury to the ureter during pelvic surgery. Considered one of the most serious complications in pelvic surgery, consequences include paralytic ileus, sepsis, renal failure, and renal loss [13,16]. Although the ureter can be injured during any pelvic surgery, injury occurs most commonly during gynecological operative procedures. Approximately 60%–75% of ureterovaginal fistulas developed as a result of ureteral injuries during abdominal hysterectomy [50,51]. In the literature, the incidence of ureteral injury during hysterectomy ranges from 0.2% to 2.5%, with only one third of injuries recognized at the time of surgery [4,5,11,25]. The incidence of concomitant vesicovaginal and ureterovaginal fistula has been reported to be as high as 12%–25% [6,52,53]. Ureterovaginal fistulas are less common in the developing world but have been described in the *obstructed labor complex* [11].

The ureter is at greatest risk of iatrogenic injury in the distal third centimeters. It is most commonly injured during its course over the pelvic brim, through the cardinal ligament, near the uterosacral ligament, and at the level of the vaginal fornix prior to insertion into the bladder [4]. In anatomical studies, the ureter has been noted to pass an average of 1.5–2.5 cm lateral to cervical os at the level of the cardinal ligament [4,54]. The left ureter is at greatest risk of injury due to its course in the pelvis, which places it closer to the cervix than the right ureter [31,55]. However, right-sided injuries are still common and have been reported to occur more frequently in another small series [26]. Ureterovaginal fistulas can occur as a result of partial versus complete ureteral transection, electrocautery, or ischemic injury caused by suture ligation, clamp trauma, or damage to the delicate periureteral blood supply [6,16].

The complex fistulous connections that can develop are often difficult to define due to their tortuosity and proximity to the ureterovesical junction [51]. A missed ureteral injury can be disastrous and should always be ruled out during the diagnostic evaluation of any patient with suspected urogenital fistula. Other rare causes of ureterovaginal fistulas include retained vaginal foreign bodies (i.e., pessaries), which can also present with concomitant VVFs [56–58].

Urethrovaginal Fistulas

Similar to VVF, urethrovaginal fistulas are most commonly iatrogenic in the developed world. Over 70% are associated with anti-incontinence surgery, anterior colporrhaphy, and urethral diverticulectomy [11,12,14,59]. Inadvertent urethral injury during paraurethral dissection and/or trocar passage of urethral slings may cause erosion, tissue loss, and subsequent urethrovaginal fistula [14]. Iatrogenic urethrovaginal fistulas have become more common since the adoption of synthetic midurethral slings and mesh kits [32,60–66]. Pushkar et al. reported their 34-year experience with urethrovaginal fistulas in Russia and found that approximately 30% of urethrovaginal fistulas were associated with anti-incontinence procedures, including autologous slings, periurethral bulking agents, and synthetic slings [59]. Almost 40% were associated with pelvic organ prolapse repair and urethral diverticulectomy. Another 26% were associated with obstetric injury. Concomitant iatrogenic bladder injury can occur. Lee et al. reported and reviewed their 15-year experience and found that 19% of patients presenting with urogenital fistulas had concomitant urethrovaginal and VVFs [5].

In developing countries, much like VVFs, urethrovaginal fistulas are most commonly associated with obstructed labor. These patients often present with concomitant VVFs. Ureterovaginal fistulas can also coexist, so the clinician should make sure to rule out all possible fistulous connections. Other less common but important causes include malignancy, pelvic trauma, pelvic radiation, and chronic indwelling urethral catheters [45,59]. Any patient with a history of malignancy or pelvic irradiation should undergo biopsy to rule out malignancy.

Vesicouterine Fistulas

Vesicouterine fistulas are one of the least common urogenital fistulas, representing 1%–9% of all urogenital fistulas [30,33,41]. They are most commonly associated with lower uterine segment cesarean section [5,19,31–33,40]. Vaginal birth after cesarean, manual extraction of the placenta, induced abortion, misplaced intrauterine device (IUD), brachytherapy, dilation and curettage, pelvic tuberculosis, and congenital anomalies are other known causes [6,19,40,67,68]. Women with vesicouterine fistulas often present with a constellation of symptoms referred to as *Youssef's syndrome*, characterized by cyclical hematuria (menouria), amenorrhea (absence of vaginal bleeding), first trimester spontaneous abortions, and absence of urinary incontinence [33,69]. Vaginal urinary incontinence can also be present and is most likely caused by retrograde filling of the uterus with urine from the bladder and subsequent leakage from a patent, incompetent cervical os [40]. However, concomitant fistulas, such as VVF, urethrovaginal, and ureterovaginal fistulas, should be ruled out, as these are more common causes of continuous urinary incontinence in patients with suspected fistula. Amenorrhea and menouria (cyclical hematuria) may develop as a result of the fistulous communication between the bladder and uterus. The mixture of menstrual blood from the uterus with urine in the bladder manifests as gross hematuria (menouria) that only occurs during the menstrual cycle. As many as 20%–25% of patients with bladder endometriosis involving the bladder mucosa present with cyclical hematuria [70]. Thus, the clinician must rule out other potential causes of cyclical hematuria, including endometriosis and congenital anomalies [68,69]. Ureterouterine fistulas and vesicoure-terovaginal fistulas are also rare. Similar to vesicouterine fistulas, they have been described in patients after cesarean section [71,72], underscoring the importance of ruling out concomitant fistulas.

Ureterofallopian Fistulas

Ureterofallopian fistulas are exceedingly rare urogenital fistulas [18]. Only six have ever been described in the literature, all of which were iatrogenic, attributed to pelvic gynecological surgery for endometriosis [13,15–17], malignancy [73], and urological endoscopic treatment of ureteral stones [5,20,21].

EVALUATION AND DIAGNOSIS

Diagnosis of urogenital fistula requires a high index of suspicion. The evaluation must begin with basic diagnostic principles of a thorough history and physical examination. This may confirm the clinician's suspicion, but additional testing is most often required to confirm the diagnosis, understand the fistula anatomy, and rule out concomitant injuries (Figure 106.1). The information gained is critical to staging appropriate corrective interventions, which will be discussed in the next chapter. In this section, we will discuss the presentation and diagnostic tools that are available to the clinician for the workup of a patient with suspected urogenital fistula.

History

In any patient with a suspected urogenital fistula, the evaluation should begin with a detailed medical, surgical, obstetrical, gynecological, oncological, and social history. Most women will present with complaints of urinary incontinence. The clinician must characterize the urinary leakage and differentiate it from other potential causes of urinary incontinence. The patient should be asked to describe the fluid character, color, volume, onset of leakage, and the position during which leakage typically occurs. Other conditions of the lower urinary tract, including urgency incontinence, stress incontinence, mixed urinary incontinence, vaginal voiding, and overflow incontinence, can mimic the classic presenting symptoms of urogenital fistulas. Also important, some of these conditions can coexist with urogenital fistulas. However, if a fistula is suspected based on the presence of patient risk factors, it must be ruled out.

The patient's past surgical history should be reviewed, including prior pelvic trauma or radiation. In cases of prior abdominal and pelvic surgery, the surgeon's operative notes should be obtained. This can help guide further evaluation and operative planning. The obstetrical history, including number of pregnancies, deliveries, and mode of deliveries (vaginal, vacuum assisted, forceps, cesarean) should be reviewed. The gynecological history including history of endometriosis, abnormal uterine bleeding, IUDs, pelvic inflammatory disease, abnormal pap smears, pessary use, or chronic indwelling urethral catheters should be documented. Any history of gynecological, urological, or colorectal malignancies and subsequent treatments should also be noted. Pathology reports and surgical and/or radiation treatment reports should be obtained. Smoking cessation should be strongly encouraged in order to improve the chances of surgical success.

As the clinician completes this detailed history, the differential diagnosis for continuous vaginal fluid drainage should be kept in mind. This includes VVF, urethrovaginal fistula, ureterovaginal fistula, vesicouterine fistula, vesicocervical fistula [74], ureterouterine, ureterofallopian fistulas [15], vaginal infection/discharge, lymphatic fistula [43], pelvic abscess, leakage of peritoneal fluid from the vaginal cuff [6], vaginal voiding, overflow urinary incontinence, SUI, urgency urinary incontinence, mixed urinary incontinence, and a combination of these conditions (Table 106.3 and Figure 106.2). A careful history will help differentiate some of these conditions; however, additional diagnostic tools should be used when appropriate, to rule out concomitant anatomical causes of urinary leakage (Table 106.4).

Symptoms

The timing, pattern, and severity of the patient’s presenting symptoms can provide useful diagnostic information. This information coupled with the patient’s past medical, surgical, obstetrical, gynecological, and oncological histories can help the clinician determine the potential mechanisms of tissue injury, identify the pelvic organs at greatest risk of involvement, and determine which tests will be needed to rule out concomitant conditions.

The most common presenting symptom of a urogenital fistula is continuous urinary leakage from the vagina [4,14]. This classic presentation includes urinary leakage both day and night, which may notably be present during sleep. However, the pattern of urinary incontinence can be continuous, intermittent, or positional. Gross hematuria, irritative voiding symptoms (i.e., frequency, urgency, dysuria) and recurrent urinary tract infections are also early signs of urogenital fistula [29]. Patients with urinary incontinence from urogenital fistulas will often complain of urine odor, skin irritation, perineal candida infections, and vaginal infections.

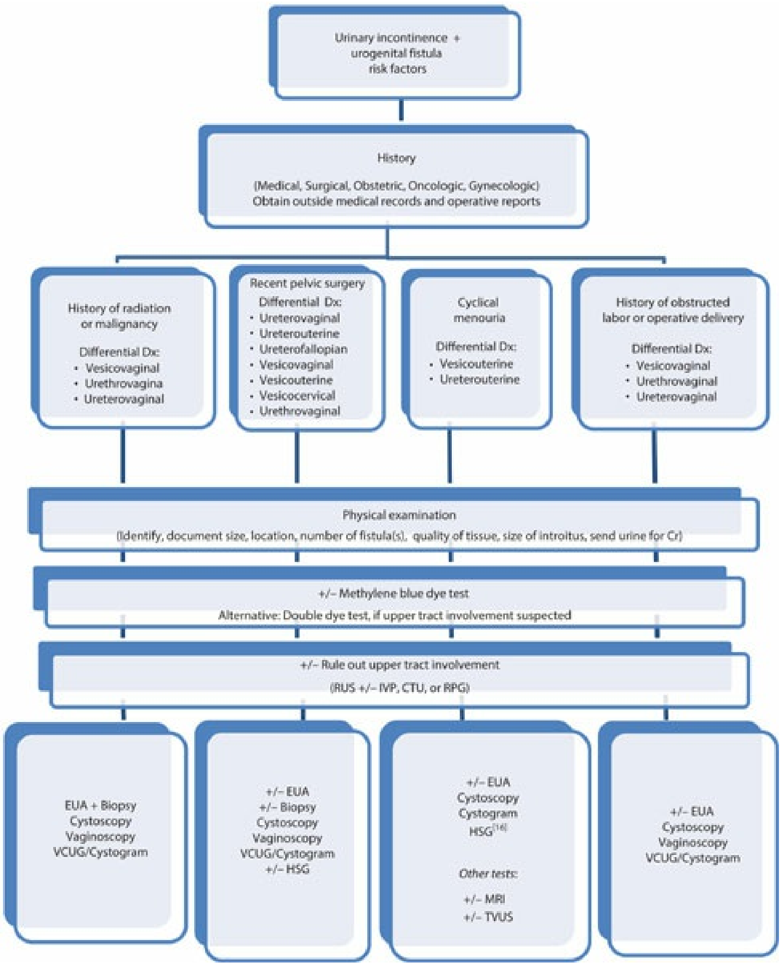

Figure 106.1 Diagnostic algorithm: computed tomography urogram, examination under anesthesia, hysterosalpingogram, intravenous pyelogram, magnetic resonance imaging, transvaginal ultrasound, retrograde pyelogram, renal ultrasound, voiding cystourethrogram.

Presenting symptoms can vary, depending on the etiology, size, location, and presence of coexisting urogenital fistulas. VVFs typically present with the classic continuous urinary incontinence. Vesicouterine fistulas can present with amenorrhea and cyclical gross hematuria (menouria) with or without urinary incontinence. The presenting symptoms for urethrovaginal fistulas are dependent upon the fistula location and its relation to the external urinary sphincter. The symptoms can range from continuous urinary incontinence to postvoid dribbling [40]. If the fistula is distal to the external sphincter, the patient may be spared of continuous leakage. Ureterovaginal and ureterofallopian fistulas may present with paralytic ileus, abdominal distension, pelvic pain, fever, nausea, and flank pain. Urogenital fistulas can coexist and they can also present with any combination of these nonspecific symptoms; thus, the clinician must rule out all potential fistulas.

Table 106.3 Differential Diagnosis
Vesicovaginal fistula
Urethrovaginal fistula
Ureterovaginal fistula
Vesicouterine fistula
Vesicocervical fistula
Ureterouterine fistula [62]
Ureterofallopian fistula [15]
Vaginal infection
Vaginal discharge

Pelvic abscess
Leakage of peritoneal fluid from the vaginal cuff
Urgency urinary incontinence
Stress urinary incontinence
Mixed urinary incontinence
Vaginal voiding
Overflow urinary incontinence

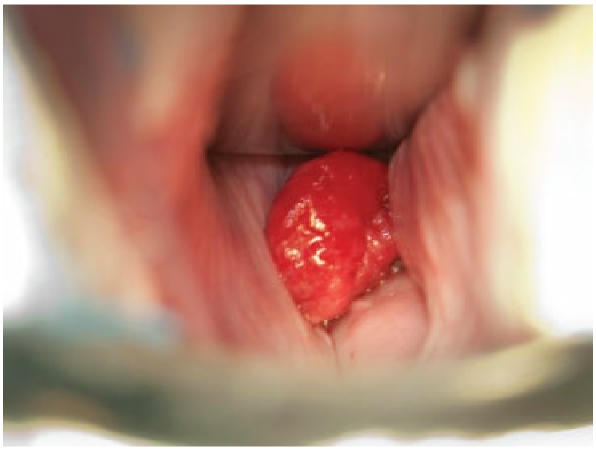

Figure 106.2 Vaginal leakage can be from numerous sources. Here, a fallopian tube prolapse after hysterectomy created a conduit for peritoneal leakage of fluid. (From Ingber M, Vasavada S, Rackley R, Urogenital fistula, in *Textbook of Urology and Urogynecology*, 3rd edn, London: 2010, pp. 951–953, with permission.)

Timing

The onset of symptoms and its relation to a potentially inciting event can provide valuable information. Immediate urinary leakage is suggestive of an unrecognized injury or failed repair of a recognized injury. Electrocautery-related injuries and ischemic trauma caused by clamps, sutures, or ureteral devascularization often have delayed presentations, typically 7–10 days after surgery [14]. Patients undergoing pelvic surgery in previously irradiated field can present weeks to years after their surgery [35,38]. Patients with ureterovaginal fistulas may not experience any urinary incontinence for 7–14 days after surgery, at which point a mucosa lined tract has had the opportunity to develop between the ureter and vagina [51]. These patients may, however, initially present with nonspecific symptoms such as low-grade fever, nausea, paralytic ileus, and flank pain, due to the developing urinoma and obstruction [5]. Although some vesicouterine fistulas present with both cyclical hematuria and vaginal urinary incontinence, other patients without urinary incontinence may not have any symptoms until they develop gross hematuria (menouria) during their menstrual cycle rather than the expected vaginal bleeding [40].

Table 106.4 Diagnostic Tests

Fistula type	Tests	Comments
Vesicovaginal	*Blue dye test* ±EUA Cystoscopy Vaginoscopy VCUG/cystogram Upper tract imaging[a] (IVP, CTU, or RPG)	Biopsy any suspicious lesions in patients with risk factors for malignancy.
Ureterovaginal	*Double-dye test* Upper tract imaging (IVP, CTU, or RPG)	EUA recommended to allow for stent placement, if needed.

	EUA + cystoscopy + vaginoscopy	
Urethrovaginal	*Blue dye test* Cystoscopy VCUG/cystogram ±Upper tract imaging (IVP, CTU, or RPG)	Obtain cystogram to rule out concomitant vesicovaginal fistula.
Vesicouterine Ureterouterine	Cystoscopy HSG Upper tract imaging (IVP, CTU, or RPG)	Methylene blue dye test can be instilled in the bladder and the cervical os observed for blue fluid [78].
Ureterofallopian	HSG Upper tract imaging (IVP, CTU, or RPG)	

Abbreviations:CTU, CT urogram; EUA, examination under anesthesia; HSG, hysterosalpingogram; IVP, IV pyelogram; RPG, retrograde pyelogram; VCUG, voiding cystourethrogram.

[a] Rule out upper tract involvement.

Physical Examination

A thorough physical examination should be performed to evaluate for any signs or sequela of urogenital fistula. Prior to pelvic examination, a careful abdominal examination should be performed to evaluate for abdominal distension, tenderness, and flank pain. In all postsurgical patients, abdominal incisions should be inspected for signs of infection, drainage, or dehiscence. For a variety of reasons, patients often fail to provide accurate surgical histories. The physical examination is an excellent opportunity to review the abdominal and pelvic surgical history.

Inspection of the perineum may reveal signs of skin irritation. The pelvic examination should assess for fluid in the vaginal canal, which can be collected and sent for creatinine levels [29]. The patient can also be asked to provide tampons or pads for creatinine evaluation. A urine specimen should be sent for urinalysis and culture to allow treatment of urinary tract infections prior to surgical repair. A careful speculum examination with appropriate lighting is needed to help identify and determine the size, character, number, and location of the fistula(s) (Figure 106.3). Special attention should be given to the vaginal cuff, anterior vaginal wall, and the cervical os. Irradiated patients may have friable lesions that present months and even years after their treatment. These lesions should be documented and subsequently biopsied to rule out the recurrence of malignancy [35,75].

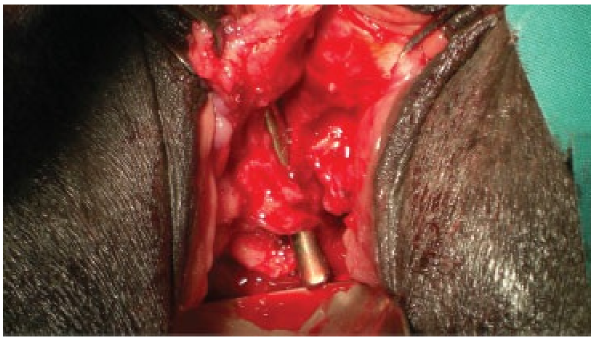

Figure 106.3 The examiner must always evaluate the patient for the presence of multiple fistulas. This patient had both a urethrovaginal and vesicovaginal fistula. (From Ingber M, Vasavada S, Rackley R, Urogenital fistula, in *Textbook of Urology and Urogynecology*, 3rd edn, London: 2010, pp. 951–953, with permission.)

Some urogenital fistulas may be difficult to identify due to the location of the fistula, patient discomfort, and vaginal stenosis. Larger fistulas are usually visible and can often be palpated [59]. However, smaller fistulas can be difficult to identify on physical exam and often require further investigation with examination under anesthesia, endoscopic evaluation, and imaging. If vaginal atrophy is present on exam, it should be treated preoperatively with topical vaginal estrogen to improve the quality of the vaginal epithelium to aid in surgical repair. Finally, the patient’s body habitus, genital anatomy, vaginal tissue quality, and the extent of tissue loss should be documented to aid in presurgical planning. A narrow introitus may warrant relaxing incisions at the time of repair to provide adequate access to the fistula [6].

Dye Test

The *dye test* is a valuable office-based diagnostic test. Although the dye test is considered a routine diagnostic test for urogenital fistula, there are no large series to our knowledge that report the sensitivity or specificity of this test. In one small series, all 12 (100%) patients with VVFs had positive methylene blue dye tests [76].

The dye test is performed by filling the bladder with dilute methylene blue [77] or indigo carmine [39] solution (up to 300 mL). A vaginal exam can be performed at the time of instillation. Often, the fistula is easily identified. If the fistula is not seen, a tampon can be placed into the vagina, and the patient is asked to ambulate, and the vaginal packing is evaluated. If blue staining is noted, the pattern of staining can provide useful information about the possible location of the fistula. Blue staining toward the distal end of the packing or tampon suggests the presence of SUI or urethrovaginal fistula, whereas apical staining suggests the presence of a VVF [45]. The blue dye test has been used in the literature to diagnose vesicouterine fistulas. Setubal et al. instilled methylene blue into the bladder using a Foley catheter and observed leakage of blue fluid from the cervical os [78].

A *modified double-dye test* can be performed if coexisting VVF and ureterovaginal fistulas are suspected [79]. The patient is given Pyridium (phenazopyridine) 200 mg orally. Once the urine is noted to be orange, the bladder is emptied and filled with 300 mL of blue dye diluted in normal saline solution. A tampon or vaginal packing is placed and after ambulation, the packing is evaluated. Orange apical staining is suggestive of ureterovesical fistula. Blue staining is suggestive of a concomitant vesicovaginal and/or urethrovaginal fistula. Upper tract imaging should always be used to confirm ureteral involvement.

Endoscopic Evaluation

Cystoscopy is a valuable diagnostic tool and should be performed in any patient presenting with suspected urogenital fistulas. Cystoscopy has been shown to be a sensitive test identifying 92%–93% of genitourinary fistulas in two small series [42,76]. Mature fistula tracts typically have smooth, epithelialized margins and are often easier to identify [44] (Figure 106.4). Smaller, less-mature fistula tracts can be more difficult to identify. A guidewire or a 5 French open-ended ureteral catheter can be passed through the working port of the cystoscope and used to probe any suspicious appearing erythematous patches, areas of bullous edema, or granulation tissue. Cannulation of the fistulous tract can help the clinician determine the course of the urogenital fistulas. Fistula involvement of the bladder neck, external sphincter, and bladder trigone should be documented. Proximity to these vital structures may warrant concomitant bladder neck reconstruction, autologous pubovaginal sling, or ureteral reimplant, respectively. Cystoscopy under anesthesia should be performed when obstruction is present on ultrasound and upper tract involvement is suspected [23]. This allows the clinician to perform retrograde urography and place a ureteral stent in the same setting, if needed (see in the following text).

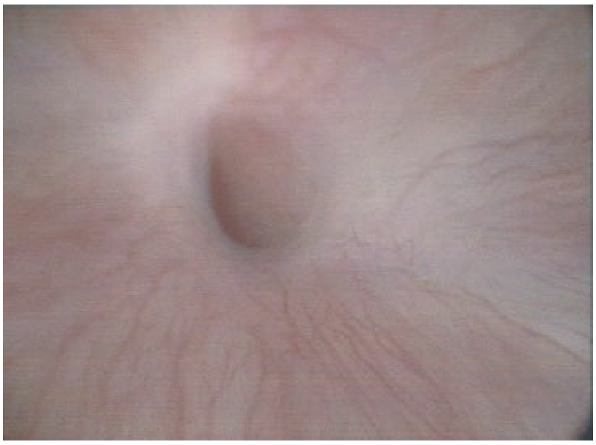

Figure 106.4 Cystoscopic evaluation often will demonstrate the fistula. If vaginal inspection does not demonstrate an obvious connection, placement of a guidewire through the cystoscope port through the fistula can identify the tract. (From Ingber M, Vasavada S, Rackley R, Urogenital fistula, in *Textbook of Urology and Urogynecology*, 3rd edn, London: 2010, pp. 951–953, with permission.)

Vaginoscopy can be used to visualize the vaginal apex and identify the vaginal side of any suspected fistulous tract(s). Patients with a history of gynecological malignancy or pelvic irradiation should have biopsies of the fistula tract taken prior to repair to rule out recurrences and secondary malignancies [35]. If mesh is noted during endoscopic evaluation, operative notes should be reviewed to provide further information regarding the size and course of the mesh. The simultaneous use of vaginoscopy and cystoscopy has been described in the literature as a method for identifying difficult fistulous tracts [80]. We find this practice using a flexible cystoscopy extremely useful for a complete preoperative assessment of the fistula. In cases of small fistula tracts, dye can be used to fill the bladder (ureter or uterus) while simultaneously performing vaginoscopy to look for dye-stained egress of fluid.

Imaging

Imaging can be used to determine the number and location of the fistulous tracts. Imaging is also helpful when the clinician needs to confirm the diagnosis when it is in doubt. Cystography may be a helpful imaging modality for suspected VVFs; however, it is not mandatory if the fistula is clearly documented on physical exam and/or endoscopy (Figure 106.5). Voiding phase images can be added to evaluate for concomitant urethrovaginal fistulas.

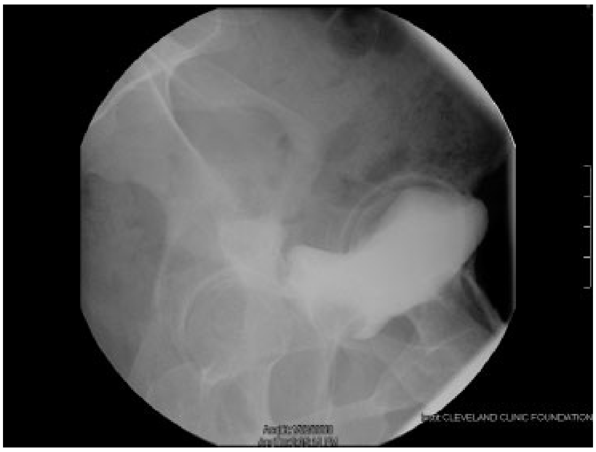

Figure 106.5 Cystogram showing contrast extravasation posteriorly into the vagina. (From Ingber M, Vasavada S, Rackley R, Urogenital fistula, in *Textbook of Urology and Urogynecology*, 3rd edn, London: 2010, pp. 951–953, with permission.)

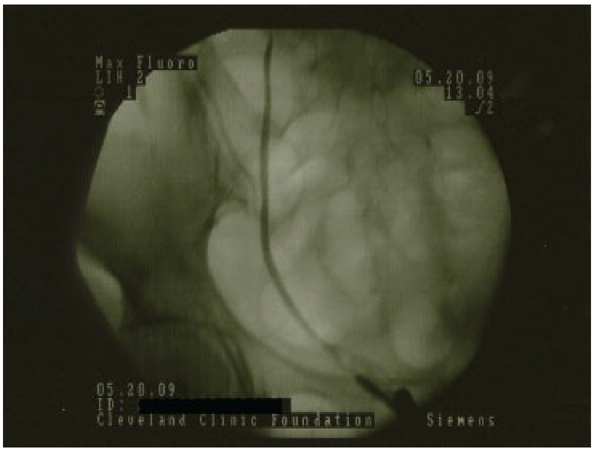

Figure 106.6 Retrograde pyelogram showing a small wisp of contrast tracking medial and posterior into the

vagina. Ureterovaginal fistulas can be present in up to 12% of patients presenting with vesicovaginal fistulas. (From Ingber M, Vasavada S, Rackley R, Urogenital fistula, in *Textbook of Urology and Urogynecology*, 3rd edn, London: 2010, pp. 951–953, with permission.)

Upper tract imaging is also important. Ultrasound can be used to rule out hydronephrosis and signs of obstruction. However, excretory urogram in the form of an intravenous pyelogram (IVP), retrograde pyelogram, or computed tomography urogram (CTU) should always be done to rule out upper tract involvement (Figure 106.6). Normal upper tract imaging essentially rules out ureteral injury, although there have been reports of false negatives with IVP. In one study, only 76 of 84 (90%) patients with ureterovaginal fistulas demonstrated an abnormality on I VP [81]. Partial ureteral obstruction in a patient with a suspected fistula is suggestive of an ureterovaginal fistula until proven otherwise [77]. If the IVP and/or CTU findings are unclear, retrograde pyelography should be performed in the operating room. If examination under anesthesia is planned or if obstruction is noted on initial imaging, intraoperative retrograde pyelography can be performed instead of IVP or CTU. This allows the clinician to place a ureteral stent in the same setting. If ureteral stents cannot be passed beyond the site of obstruction, a percutaneous nephrostomy tube should be placed to maximally drain the urinary system prior to operative repair. An antegrade nephrostogram can be performed to evaluate the remaining upper tract for other injuries, malignancy, and congenital anomalies.

For a patient who presents with cyclical hematuria and amenorrhea, symptoms concerning for vesicouterine fistula, a hysterogram with a short-tipped cannula can be performed [40] if the diagnosis cannot be made with other imaging techniques such as a CT cystogram. As described by Tancer, the uterus is filled with dye, and cystoscopy is performed to evaluate for the presence of dye and identify the fistulous tract, if present [3]. Hysterography and cystography have been used successfully to identify vesicoureterine fistulas [40]. In one series, hysterography was 100% sensitive in patients with suspected vesicouterine fistulas [81]. Upper tract imaging should also be performed in conjunction with these imaging tests to rule out concomitant ureteral involvement (i.e., ureterouterine, ureterovaginal, and ureterofallopian fistulas) [40,71,72]. In the literature, the use of magnetic resonance imaging, transvaginal Doppler ultrasound, and hysterosalpingography for vesicouterine and vesicofallopian fistulas have been described [76,82]. These imaging modalities provide additional useful information in select patients; however, these tests are not usually necessary [83].

Urodynamics

Urodynamics is not considered a routine test in the urogenital fistula workup. However, videourodynamics (VUD) may be considered in any patient with confirmed or suspected urogenital fistula and concomitant lower urinary tract symptoms. Video images can help differentiate lower urinary tract symptoms, such as urgency incontinence, SUI, and mixed urinary incontinence from other causes of incontinence, including vaginal voiding, urethral diverticula, and fistulas.

Preoperative VUD testing can help establish baseline bladder dysfunction and evaluate urethral function for preoperative counseling and planning. Lower urinary tract symptoms, such as urinary frequency and urgency can coexist with urogenital fistulas. Urodynamics can identify the presence of detrusor overactivity and/or concomitant intrinsic sphincter deficiency. Similarly, bladder outlet obstruction can coexist with urethrovaginal fistulas due to scarring, stricture formation, bladder neck disruption, and/or the presence of foreign material (i.e., mesh, urethral bulking agents, stones). If obstruction is suspected, this can be evaluated with a postvoid residual (PVR) and cystoscopy. However, if these tests are unclear, VUD can be used to evaluate for other causes of elevated PVR, including detrusor underactivity.

Approximately 10%–15% of patients with urogenital fistula have concomitant SUI [84]. Coexisting SUI may necessitate concomitant anti-incontinence surgery. Up to 52% of patients develop SUI after successful urethrovaginal fistula repair [59]. The clinician may choose to offer concomitant antiincontinence procedures (i.e., autologous sling) to patients at high risk for postoperative SUI or as an extra layer in patients at high risk of failure due to a history of radiation.

Urodynamics can also identify small capacity or poorly compliant bladders in patients with a history of pelvic irradiation and other risk factors for poor compliance [85], thereby identifying patients that may require a concomitant augmentation cystoplasty procedure [75] or alternatively require a urinary diversion [63,86]. Bladder capacity should be established in any patient who may require ureteral reimplantation, in the event a psoas hitch is needed [44]. Furthermore, VUD can potentially help distinguish urogenital fistulas from other causes of insensible urinary loss, especially when the fistula has yet to be identified [85].

Performing urodynamics in a patient with a large fistula can be challenging. There are a variety of strategies that can be employed to allow adequate bladder filling during the test. First, vaginal packing can be placed at the beginning of the study, during catheter placement to slow the leakage of fluid per vagina. Second, the patient can be placed in the supine position, rather than sitting or standing. If these maneuvers fail, the clinician can attempt to place an 8 French Foley catheter through the large fistula tract. If the fistula is distal, the urodynamics catheter can be placed alongside a small urethrally placed Foley catheter. The Foley balloon will, in some cases, sufficiently obstruct the fistulous tract to allow bladder filling.

CONCLUSION

Urogenital fistulas can be devastating, taking a significant emotional toll on the patient and the treating clinicians. Whether iatrogenic or obstetrical in origin, the clinician must maintain a high index of suspicion in any patient with continuous leakage of urine per vagina. A thorough history and physical examination will often identify the location and mechanism of fistula formation. Appropriate imaging and endoscopic evaluation can provide valuable information needed to determine the size, number, and location of the fistulous tract. Upper tract imaging is mandatory. A missed ureteral injury can be disastrous and should always be ruled out. Urodynamics can help establish baseline capacity, compliance, as well as bladder and urethral function if the fistula is small enough to occlude. Careful presurgical planning is critical for successful surgical repair. A high index of suspicion is needed to ensure that all fistulous communications are identified, including those that communicate with nonurogenital organs or structures.

107 Transvaginal Repair of Urogenital Fistula

Barry G. Hallner, Kristi L. Hebert, and J. Christian Winters

INTRODUCTION

Urogenital fistula is defined as an abnormal communication between the vagina and the bladder, urethra, and/or ureter (vesicovaginal, urethrovaginal, ureterovaginal, respectively). The earliest evidence dates back to 2050 BC in the mummified remains of a female in the court of Mentuhotep II of the Eleventh Dynasty. During the 1935 cadaveric dissection, a large vesicovaginal fistula (VVF) was identified in a significantly contracted pelvis [1]. It is difficult to know the true incidence of urogenital fistula formation; the generally accepted incidence is derived from surgeries to correct these fistulas and approximates 1% or less of all genitourinary operations [2]. In another study, Mattingly et al. reported that urogenital fistulas have an incidence of 0.3%–2% [3]. According to the World Health Organization, it estimates that there are more than 2 million women worldwide affected by obstetric fistula and more than 100,000 new cases of urogenital fistula occurring per year worldwide [4].

CLASSIFICATION

Currently, there is no single accepted standardized method to classify genital tract fistulas. Urogenital fistula may be classified by anatomic communication, size, location, complexity, and extent of involvement (Table 107.1).

ETIOLOGY

A comprehensive list of the various etiologies for urogenital fistulas is shown (Table 107.2). In developed countries, the most common cause of urogenital fistula is hysterectomy [5]. The incidence is 1/1000 with total abdominal hysterectomy, 2.2/1000 with the laparoscopic approach, and 0.2/1000 with vaginal hysterectomies. A database study by Hilton et al. on >350,000 elective hysterectomies performed in England, demonstrated the rate of urogenital fistulas was highest among women who had a hysterectomy for cervical cancer [6]. Mechanisms of fistula development following hysterectomy may include localized ischemia of the bladder by inadvertent dissection into the bladder or thermal injury creating thin and ischemic areas of the bladder prone to subsequent breakdown, unrecognized injury into the bladder with subsequent extravasation or leakage of urine, foreign body (suture) within the bladder, and finally following repair of a recognized bladder injury. If occurring as a result of pelvic operations, the symptoms of the fistula usually appear within 10 days postoperatively. In contrast, radiation-induced fistulas may appear years after radiation therapy.

There are several factors that predispose patients to development of urogenital fistulas, including history of cesarean section, pelvic malignancy, cervical conization, radiation therapy, and endometriosis [7]. In a retrospective analysis by Maier et al., of 10,709 patients who underwent radiation for gynecological malignancy, 35 of them subsequently developed urinary fistulas [8]. Angioli and others reported the incidence of developing a VVF after surgery or radiation for gynecological malignancy at 1% [9]. Radiation promotes aggressive endarteritis obliterans that results in the breakdown of mucosal surfaces by disrupting its blood supply [10]. This promotes impaired vascularization of local tissues, which predisposes this tissue to subsequent necrosis/breakdown that may result in fistula formation—even years after the initial treatment.

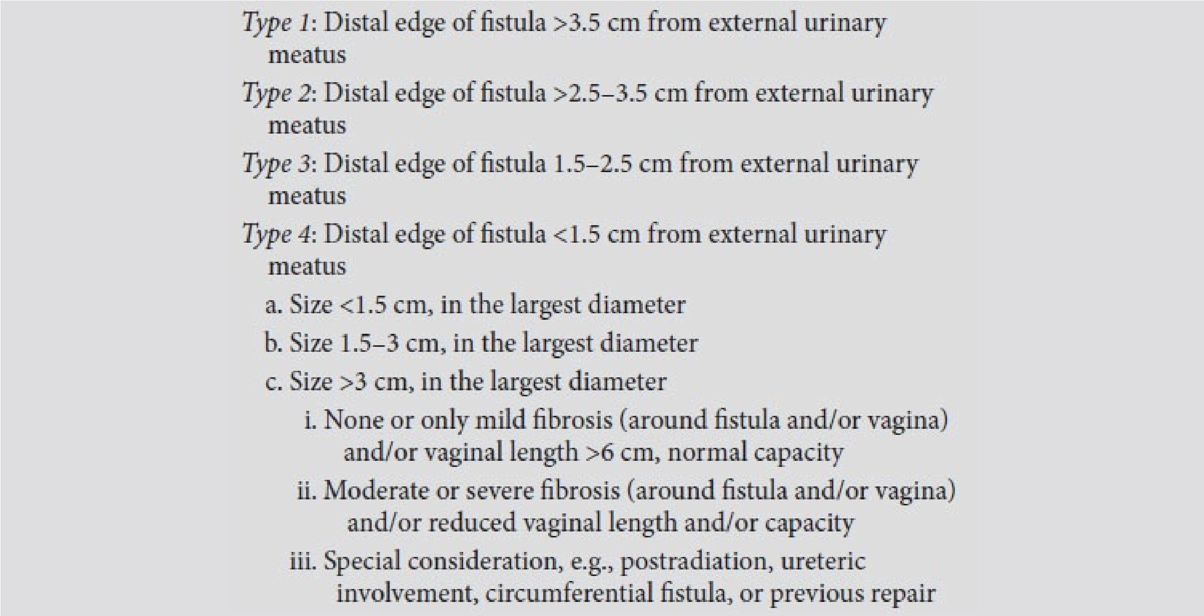
In developing countries, there is a much higher incidence of fistulas being caused by obstetrical complications. A study done by Singh et al. in India reported 59% of urogenital fistulas were caused by obstructed or protracted labor [11]. In many developing countries, cesarean section is not readily available. Women are likely to be in labor for prolonged periods of time, and engagement of the fetal head within the pelvic outlet for this long of a period predisposes the vagina to pressure necrosis and tissue breakdown. As a result, these fistulas tend to be larger and oftentimes more complex with coincidental urethral destruction. Unfortunately, this is a problem with significant social consequence. These women tend to become “outcasts” within many of their communities and have little resources for care. Fortunately, many have recognized this problem, and there are many heroic efforts to improve the access, quality, and continuity of care for these women.

SYMPTOMS

Patients with urogenital fistulas typically present with complaints ranging from vaginal discharge or “drainage” of urinary leakage. If the fistula follows a surgical procedure, the onset of leakage occurring 5–10 days after surgery is most common. Depending on the location of the fistula, this may range from occasional small leakage between normal urethral voids and positional change to total insensate urinary incontinence without normal voids. Some women may present with recurrent incontinence following an antiincontinence procedure. Patients may also experience gross hematuria, recurrent cystitis or pyelonephritis, fever, flank, vaginal, suprapubic pain, and a strong ammonia odor. Patient may also complain of irritation to the vulvar and perineal area from the constant wetness. Essentially, the presentation of fistulas may be quite variable, and it is essential to suspect a fistula in order to achieve the diagnosis in some cases.

Table 107.1 Genitourinary Fistula Classification

	Classification based on structures involved		
	Bladder	Urethra	Ureter
Vagina	Vesicovaginal	Urethrovaginal	Ureterovaginal
Cervix	Vesicocervical	Urethrocervical	
Uterus	Vesicouterine	Not reported	Ureterouterine
Classification based on the complexity and extent of involvement			
Simple	Fistula measures <2–3 cm and is located near the cuff (supratrigonal). Vaginal length is normal. Patient with no prior radiation or malignancy.		
Complex	Fistulas distant from cuff or has trigonal involvement. Fistula measures > 3 cm. Patient with prior radiation therapy. Pelvic malignancy is present. Vaginal length is shortened.		
New classification divides genitourinary fistulas into four main types, then subtypes			



Type 1: Distal edge of fistula >3.5 cm from external urinary meatus

Type 2: Distal edge of fistula >2.5–3.5 cm from external urinary meatus

Type 3: Distal edge of fistula 1.5–2.5 cm from external urinary meatus

Type 4: Distal edge of fistula <1.5 cm from external urinary meatus

- a. Size <1.5 cm, in the largest diameter
- b. Size 1.5–3 cm, in the largest diameter
- c. Size >3 cm, in the largest diameter
  - i. None or only mild fibrosis (around fistula and/or vagina) and/or vaginal length >6 cm, normal capacity
  - ii. Moderate or severe fibrosis (around fistula and/or vagina) and/or reduced vaginal length and/or capacity
  - iii. Special consideration, e.g., postradiation, ureteric involvement, circumferential fistula, or previous repair

PHYSICAL EXAMINATION

speculum vaginal exam should be performed in all patients with suspicion of urogenital fistula. The fistula may appear as an epithelialized luminal tract of various sizes (ranging from small pinpoint hole to large defect) or localized “dimpling,” scarring, or granulation of the vaginal wall. Following anti-incontinence surgery, foreign body materials (suture or graft) may be adjacent to or involving the fistulous tract. The quality of the surrounding vaginal and labial tissue should be noted as well. Areas of infection, suture reaction, or granulation may need to be addressed before repair can be contemplated. Biopsies should be considered in any areas of suspicious tissue and of the fistulous tract in patients with history of malignancy. The size, location, and number of the fistula(s) should be documented (Figure 107.1). The vaginal depth, diameter, and mobility should be noted as these factors can help determine the appropriate method of surgical repair. The bladder may be filled with methylene blue during the vaginal exam to help identify the location of the fistula. If there is still a question of urogenital fistula despite a negative examination, the fluid leaking per vagina may be sent for creatinine. If the fluid is indeed urine, the result will be severalfold times the serum creatinine level.

Table 107.2 Causes of Urogenital Fistula

- I. Congenital
- II. Acquired
  - a. Iatrogenic
    - i. Postoperative
      - 1. Hysterectomy
        - a. Abdominal
        - b. Transvaginal

        - b. Mesh kits
        - c. Sacrospinous/uterosacral fixation
      - 4. Urethral diverticulectomy
      - 5. Endoscopic procedures
      - 6. Bowel and vascular surgeries
    - ii. Radiation injury
  - b. Noniatrogenic
    - i. Pelvic malignancy
    - ii. Obstructed labor
    - iii. Trauma
    - iv. Sexual injury
    - v. Infection
    - vi. Foreign body

DIAGNOSTIC TESTING

A full description of diagnostic procedures including dye tests, endoscopy, and imaging can be found in Chapter 106. If a urogenital fistula is not readily identified or the precise location is not clear from the physical and endoscopic examinations, a “double dye” test may be performed. In this, phenazopyridine is given PO if no leakage is seen on the pad; the bladder is retrofilled with methylene blue; blue dye is then seen staining the most distal part of the pad, indicating leakage from the urethra, whether as a result of bladder overactivity or of intrinsic sphincter deficiency (ISD). With an ureterovaginal fistula, the most proximal pad stains yellow/orange; no blue staining is noted. With a vesicovaginal or urethrovaginal fistula, the pad stains blue in the middle to proximal area of the pad. Reflux of the blue dye to the proximal pad in an ureterovaginal fistula makes true diagnosis difficult [12].

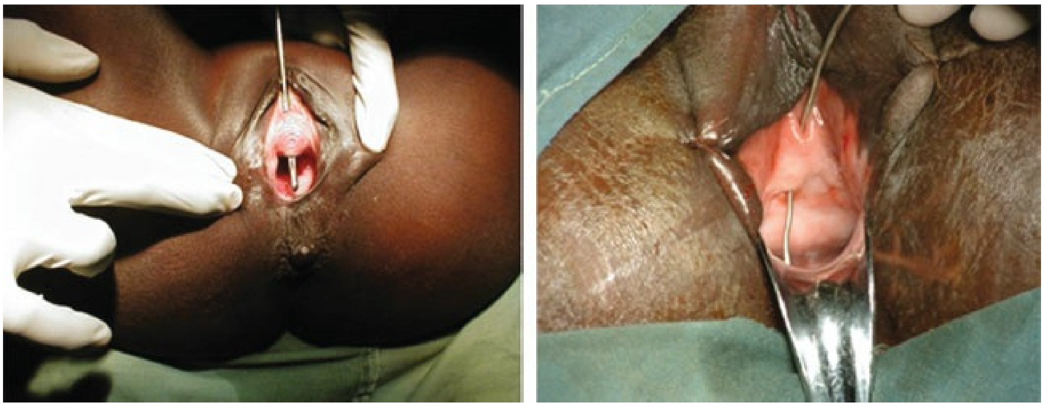

Figure 107.1 Exam performed under anesthesia. Note the probe passed through the fistulous tract. In both cases, a single urethrovaginal fistula was noted.

We believe that cystoscopy should be performed in all patients with suspicion of urogenital fistula (Figure 107.2). The goal of cystoscopy is to identify the location of the fistula, the size of the fistula, and the number of fistulas and to determine the location of the fistula(s) relative to the ureteral orifices. In the absence of an obvious fistulous tract, a fistula may be suspected in an area of dimpling, scarring, or localized edema within the bladder wall. The integrity of the bladder tissues should also be carefully assessed to assist in determining the timing of repair. If there is a history of malignancy, a biopsy of the fistulous tract must be performed. Vaginoscopy can also be performed after cystoscopy, to confirm the location of the fistula within the vagina and assist in assessing the quality of the vaginal tissues for repair. A retrograde pyelogram should be performed at the time of cystoscopy if upper tract imaging has not been performed or if there is high suspicion of ureteral involvement (see Chapter 106). Coexisting ureteral pathology (obstruction/hydronephrosis/fistula) has been reported in approximately 10% of cases of VVF [5]. Partial or complete ureteral obstruction on retrograde pyelography should raise suspicion for the presence of ureterovaginal fistula [13]. CT urogram is our preferred imaging modality for preoperative upper tract imaging. Not only can the ureters be visualized on excretory and delayed phases, but also urinary tract reconstruction images can provide precise anatomical detail preoperatively. Voiding cystourethrography or plain cystograms may be used for diagnosis of VVF; however, they may be suboptimal for identifying exact location of a fistulous tract (see Chapter 106). According to Narayanan et al., MR should be considered when evaluating for urogenital fistula in patients with a history of pelvic malignancy. MR evaluates for fistula as well as recurrence of pelvic malignancy [10]. On T2-weighted images, the fistula will appear as a high-intensity fluid-filled connection. Transvaginal ultrasound is rarely performed as <30% of fistulas are identified sonographically [14].

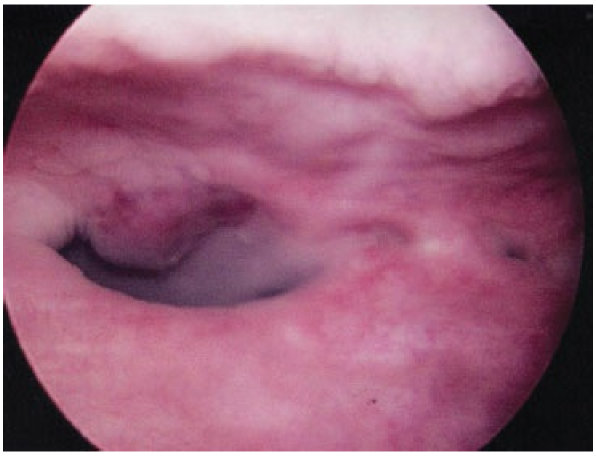

Figure 107.2 Cystoscopic evaluation often will demonstrate the fistula. In this figure, note the abnormal appearing tissue at the edge of the fistula indicated by black arrow. Biopsy noted a recurrence of vaginal squamous cell carcinoma.

MANAGEMENT

Conservative Management and Minimally Invasive Techniques

The psychological and physical distress caused by a VVF can be overwhelming to patients due to the constant wetness, odor, and potential infections. Ideally, the goal of treatment of a VVF is the closure of the fistula and resolution of urinary leakage as quickly as possible. The most conservative treatment option of a VVF is simple continuous bladder drainage. Davitas and Miranda described four patients who underwent successful postoperative VVF closure by simple bladder drainage [15]. Although outcomes have not necessarily been proven and constant, 12%–80% of fistulas that are small (<1 cm) and diagnosed early may spontaneously resolve within 4 weeks with continuous bladder drainage [16]. If, after several weeks of continuous bladder drainage, the fistula persists, alternative therapeutic treatments such as fibrin glue and electrocautery can be considered instead of surgery.

If the fistula is small (<5 mm), fibrin glue may be attempted as a sealant. Fibrin glue, also called as fibrin sealant, can be produced from pooled blood sources or from a single blood donor. The single-donor blood can be allogenic or autologous. The use of pooled blood products such as Tisseel^{TM} (Baxter, Inc., Deerfield, IL) and Beriplast^{TM} (CSL Behring, Inc., King of Prussia, PA) has been more commonly used in VVF treatment in Europe. A primary component of the synthetic fibrin sealant is highly concentrated human fibrinogen [17]. A common mode of application is the double-barreled syringe apparatus, which enables simultaneous application of equal amounts of the fibrinogen and thrombin solutions through a blunt-tipped needle. Bijan and Stoller [17] note a number of studies using fibrin glue to treat VVF with a success rate of approximately 66%–100%. It must be considered that reports of fibrin glue usage in VVF treatment are limited to case reports and small case series only. These reports have not been replicated on a large-scale basis. Although results have been satisfactory, it appears that applying fibrin sealant for fistula closure should be individualized [17]. Fibrin sealant has been used successfully in combination with and without bovine collagen as an additional "plug" [18,19]. Additionally, small VVF may be repaired with electrocoagulation or laser ablation of the fistulous tract [20]. Falk in 1957 and Stovsky in 1994 successfully treated patients with electrocoagulation that had VVF <3.5 mm in diameter, followed by catheter drainage for 10–14 days [21,22]. The fistulous tract is electrocoagulated by endoscopically inserting a Bugbee electrode inside the fistulous tract as far as possible. The electrode is slowly withdrawn from the track with the electrode on coagulation, till the edges of the fistula tract blanch [22]. Care is taken not to overcoagulate as this can cause widespread tissue necrosis, sloughing, and enlargement of the fistula [23]. It is important to mention that in patients with a thin vesicovaginal septum, large VVF, nonoblique fistula tract, or significant inflammation around the fistulous tract, there is an increased risk of failure and the possibility of enlarging the size of the fistula [24]. All patients who choose these options (cautery/fibrin glue) of fistula management must be warned that these procedures may change the adjacent tissue integrity for a subsequent repair, if needed.

In the case of an ureterovaginal fistula, the initial management is ureteral stenting [25]. Stenting tends to be more successful when performed sooner rather than later. In one study, 82% of attempts of ureteral stenting in patients whose fistulas were <1 month old were successful compared with only 33% of attempts with older fistulas (>1 month) [26]. Once a stent has been successfully placed, it should be left in place for 6–8 weeks. Once the stent is removed, sequential follow-up over time with upper tract imaging should follow to rule out ureteral stricture development. If a stent can't be placed by way of a retrograde approach, options of surgical repair versus a percutaneous nephrostomy must be considered. If a percutaneous nephrostomy tube is placed, attempts at antegrade stent placement should follow. If a stent is successfully placed in the bladder, the patient can be followed as in patients who are successfully stented via a retrograde approach—surgery will likely not be needed. If a percutaneous nephrostomy is not done or if a stent cannot be placed via an antegrade approach, surgery will be necessary to correct the problem. Urethrovaginal fistula should be repaired as soon as they are diagnosed unless that tissue is inflamed or infected [27].

SURGICAL REPAIR

When planning for surgical repair, several considerations must be made in order to optimize patient outcomes because the best opportunity to achieve successful repair of the fistula is within the initial operation [28,29]. As the number of attempts increase so does the amount of scar tissue, anatomical distortion, and a decrease in potential reconstructive flaps. Unfortunately, there is no single "best" approach to all patients with VVF, and each case should be individualized based on the fistula characteristics and the surgeons' experience.

TIMING OF REPAIR

In most cases of iatrogenic fistulas identified early, they may be repaired immediately. Early repair of the fistula spares the patient the devastating physical, psychological, and social impact on their quality of life [30]. The emerging consensus is that uncomplicated fistulas may be repaired early, as soon as the tissue quality is deemed suitable for repair. This is unlike radiated, infected, or indurated tissue, where a waiting period of several months is recommended to allow tissue sloughing, necrosis, and inflammation to resolve prior to attempting surgical repair. Typically, a 3–6 month waiting period is recommended in these settings. During this waiting period, vaginal examinations should be done every 3–4 weeks to monitor tissue quality and evaluate for resolution of inflammation and/or infection. Even in complex fistulas, many can be closed in a more timely fashion without a 6-month waiting period, if sequential examinations reveal tissues amenable to repair [16].

PREOPERATIVE CONSIDERATIONS

When the decision to proceed with surgical closure of the fistula is made, it is important that the patient be medically optimized and capable of tolerating the planned surgery. Nutritional status should be optimized to aid healing. Vaginal, oral, or transdermal estrogen should be considered in cases of vaginal atrophy to help improve the vaginal epithelium. We prefer the use of vaginal estrogen due to the lack of systemic effects. In the case of excessive urinary leakage, the use of vaginal estrogen may not be possible. Short-term use of oral or transdermal estrogen therapy may be used even with a history of breast or gynecological cancer [31,32]. Zinc oxide topical ointment and sitz baths may help control ammonia dermatitis [33]. Preoperative antibiotics are recommended, and several studies have shown that various regimes may be equally effective in successful repair and reducing the need for postoperative antibiotics. The American Urological Association and the American College of Obstetrics and Gynecology have set forth guidelines regarding preoperative antibiotics as well as deep venous thrombosis prevention [34–37].

SURGICAL APPROACH

VVF may be repaired transvaginally or transabdominally. Factors such as size, location, and the need for adjunctive procedures should influence the choice of approach. One of the most important factors is the individual surgeons' experience. Transabdominal repair of VVF is discussed in the following chapter. The majority of VVF can be repaired transvaginally [38]. In 1988, Lee et al. reported that 80% of 303 patients were repaired transvaginally, regardless of fistula size, number, or history of previous repairs [39]. There are several advantages to the transvaginal approach when compared to a transabdominal approach such as shorter operating time, shorter hospital stay, less postoperative pain, and less blood loss [40]. Relative disadvantages include vaginal shortening and difficult exposure involving VVF that are high near the vaginal cuff, especially in deep, narrow vaginas or in cases without any apical prolapse [24].

TRANSVAGINAL APPROACH OF VESICOVAGINAL FISTULA

Transvaginal repair of VVF usually includes one of two strategies. One may excise the vaginal epithelium and perform a partial colpocleisis procedure (Latzko repair) or utilize a multilayer flap closure with or without tissue interposition (Figure 107.3).

Latzko Procedure of Vaginal Cuff Fistulas

The Latzko procedure is a partial colpocleisis without excision of the fistula tract [41,42]. It is indicated for VVF at the vaginal apex that area <3 cm [43]. This technique avoids widening of the fistula tract that can be associated with excising it, excessive bleeding, tissue necrosis caused by cautery, and injury to the ureters if close to the repair site. Success rates between 93% and 100% for primary and repeat repairs without significant vaginal shortening have been reported [44].

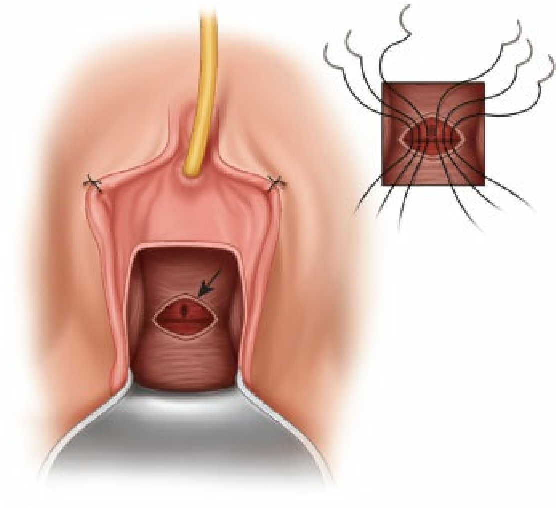

Figure 107.3 The Latzko procedure. The vaginal epithelium is sharply dissected from the anterior and posterior vagina approximately 2–3 cm from the fistula. The fistula tract is not excised. The underlying fibromuscularis is closed in at least two layers with absorbable suture. The vaginal epithelium is then closed with absorbable suture.

Technique of Latzko VVF Repair

The patient should be placed in a high dorsal lithotomy position. Choice of stirrups should be surgeon preference. A self-retaining ring retractor will facilitate exposure. The patient is examined under anesthesia. In the case of a narrow introitus, a midline episiotomy or medial lateral episiotomy may aid in exposure. The ureters should be catheterized at this time if the fistula opening is close to the ureteral orifices [45]. Several techniques may be used in order to pull the fistula toward the introitus for better access. In one method, a pediatric Foley catheter or Fogarty catheter can be placed through the fistulous tract and placed on traction after the balloon is inflated. If the fistula is too small to accommodate the pediatric Foley, the fistula tract can be gently dilated to allow insertion of the catheter. Another method is to place stay sutures at least 2 cm away from the fistula margin. This helps keep orientation and aids in traction. We prefer to use the self-retaining ring retractor with the sharp hooks to pull the tissue around the fistula toward the introitus. Next, starting a point at least 2 cm extending from the fistula is marked with a surgical marking pen circumferentially around the fistula. The dissection area may be developed by hydrodissection with either injectable saline or a dilute solution of a vasoconstrictive agent or simply sharp dissection. In either situation, a 2 cm margin of vaginal epithelium is sharply dissected from the underlying fibromuscularis circumferentially. Once the vaginal epithelium has been sharply removed, the fibromuscular layer can be imbricated in an anterior to posterior fashion using a # 3-0 delayed absorbable suture in an interrupted fashion. A second-layer closure should be performed to ensure a watertight seal. The bladder can be tested for watertightness either at this point or once the vaginal epithelium is closed. Test for watertightness by retrofilling the bladder with either sterile milk or methylene blue. Cystoscopy is performed to confirm ureteral patency. The remaining vaginal epithelium is closed with # 2-0 delayed absorbable sutures in either a running or interrupted fashion. A transurethral Foley or a suprapubic tube is placed to continuously drain the bladder for 10–14 days.

The Latzko procedure is optimal for cuff or very proximal fistulas near the cuff. In the case of more distal or complex VVF, urethrovaginal fistula, or urethrovesicovaginal fistula, the Latzko procedure is more likely to result in increased loss of vaginal length and a multilayer flap closure with or without tissue interposition is indicated [33].

Transvaginal Multilayer Flap Repair

A transvaginal multiple layer flap repair is among the most common surgical approaches to repair VVF. The advantages include lack of an abdominal incision, elimination of cystotomy, easy incorporation of interposition material, and the ability to repair fistulas at any location in the vagina. The essential components of procedure include creation of full-thickness well-vascularized vaginal flaps, excision of the fistula tract, closure of the fistula defect, multilayer closure, avoidance of overlapping suture lines, and adequate drainage. Tissue interposition may be incorporated as needed. Success rates of 72%–90% have been reported, and most authors advocate early repair of VVF using some modification of this approach.

Technique of Transvaginal Multilayer Flap Repair

To begin, the patient is placed in a high dorsal lithotomy position. A self-retaining ring retractor may be used to facilitate exposure. Stay sutures may be placed to help expose the fistula. The layered technique involves circumscribing the vaginal epithelium around the fistula (Figure 107.4). Hydrodissection can be used to help develop the plane or simply sharp dissecting the vaginal epithelium from the fibromuscularis. Depending on the size, shape, or location of the fistula, the initial vaginal epithelium incision can be a U-shaped, inverted-U, J-shaped, or oval incision. These incisions can be incorporated into the incisions made to circumscribe the fistula. These incisions should be created in order to facilitate an advancement flap over the fistula closure at the time of vaginal closure. After incision, sufficient vaginal epithelium is separated from the underlying fibromuscularis to permit a tension-free closure of the tissue. Usually, this requires a significant amount of tissue mobilization surrounding the fistula. Unlike the Latzko procedure, the fistula tract is excised in the classical approach. Care must be taken not to overexcise the fistula edges, which can enlarge the defect, increase the risk of bleeding from the fistula edge, and decrease bladder volume by removing bladder tissue. If the fistula is large and a tension-free closure is difficult, regular circumferential vaginal relaxing incisions are made at a distance from the fistula and may facilitate mobilization and tension-free closure [45]. Once the tract is excised, a layered closure is performed. The first layer is closed with interrupted # 4-0 delayed absorbable sutures. Ideally, a second layer of the pubocervical fascia is closed over the fistula. Alternating horizontal and vertical suture lines prevent the suture layers from lying directly over one another. The bladder may be tested for watertightness by retrofilling the bladder with sterile milk or methylene blue or by giving indigo carmine via IV. The remaining vaginal epithelium is then advanced over the closure site and closed with # 2-0 delayed absorbable sutures in an interrupted or running fashion. A vaginal pack may be inserted. A transurethral Foley catheter is used to continuously drain the bladder for 2–3 weeks. Alternatively, a suprapubic tube may be used solely or in conjunction with a transurethral Foley catheter.

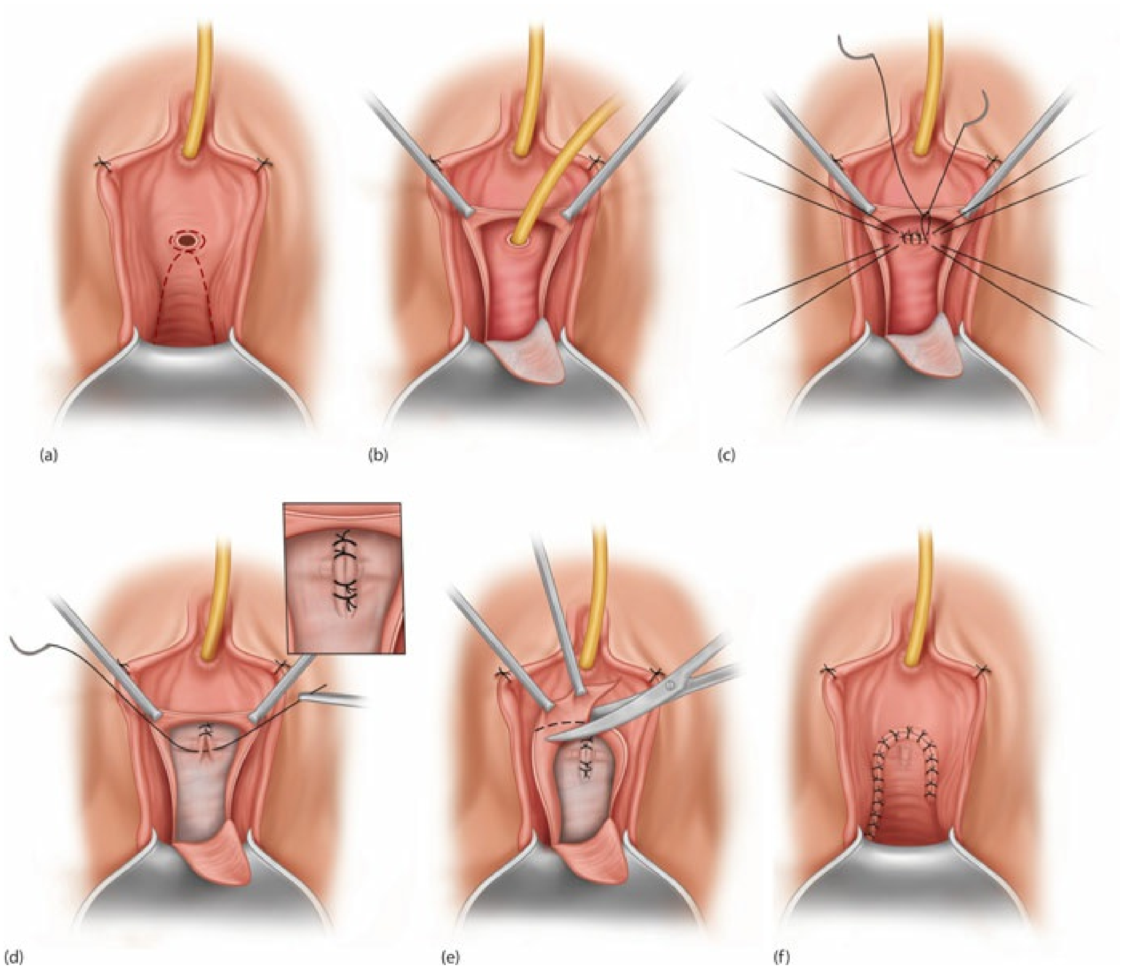

Figure 107.4 Steps in transvaginal vesicovaginal fistula repair. A Foley catheter may be inserted into the fistula for retraction purposes. Incisions should be planned to provide adequate flap mobilization and vaginal closure over the fistula repair, such as an inverted-U (a). A small Foley may be placed within the tract for exposure. The vaginal epithelium is dissected off of the fistula site, until healthy tissue is obtained (b). The fistula is closed with absorbable suture (c). If possible, a second layer of overlying fascia is closed in a perpendicular fashion (d). Excess vaginal mucosa may be trimmed (e). Finally, the vaginal flap is closed after advancing the repair (f).

If the fistula is recurrent, large, or at the surgeon's discretion, tissue interposition flaps may be used as an additional layer and provide a blood supply to the repair [45]. Local vaginal flaps include Martius graft, gluteal skin flaps, gracilis muscle flaps, peritoneal flaps (Figure 107.5), rectus abdominal flaps, labial myocutaneous flaps [24], collagen xenografts, and oxidized cellulose [27]. The most commonly used vaginal flap is the Martius graft, a transposition of a labial fat pad with or without the bulbocavernosus muscle. It was first described in 1928 [46]. It has a high reported success rate in complex fistula repair [47]. Success of the Martius graft is 70%–100% [27]. It is a long band of adipose tissue from the labia majora and has excellent strength and vascularity. The superior and anterior blood supplies come from the external pudendal artery. The lateral border is supplied by the obturator branch, and the inferior aspect of the graft is supplied by the inferior labial artery [45]. Typically, the graft is mobilized on each side and left intact at either the superior or inferior end. The vaginal epithelium is mobilized and a long curved clamp is passed through the vaginal incision to the mobilized fat pad. This will create a tunnel in which the graft will pass through. Grasping the free end of the graft, it is passed medially under the labia minora and attached with delayed absorbable suture to cover the fistula repair. The vaginal and labial incisions are closed without tension. Alternatively, for proximal fistula near the cuff, a peritoneal graft can be utilized by advancing the posterior peritoneum including the preperitoneal fat after mobilization by sharp dissection. The flap is advanced to cover this fistula closure and secured utilizing small absorbable sutures. Following this, the vaginal advancement flap is closed thus completing the repair.

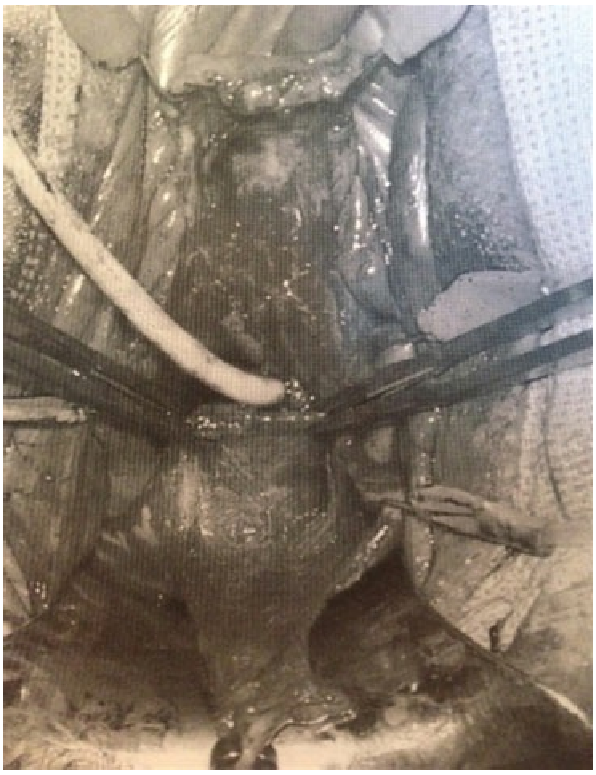

Figure 107.5 A flap of peritoneum is developed and used to buttress the fistula repair. (From Mattingly RF, Harkki-Siren P, Petri E, et al. in: Vasavada SP, ed. *Female Urogynecology, and Voiding Dysfunction*. New York: Marcel Dekker, 2005. 761–764. Print. With permission.)

COMPLICATIONS

As with any surgical case, complications can be divided into early and late complications. Early complications include hemorrhage, bladder spasms, bladder infections, vaginal infections, and intra-abdominal infections. Treatment of these early complications should be initiated as soon as complications present to prevent fistula recurrence. Antimuscarinic agents can be used for bladder spasms. Postoperative antibiotics may be used in the cases of bladder, vaginal, and intraabdominal infections. Delayed complications include fistula recurrence, urinary incontinence, vaginal shortening, vaginal stenosis, and ureteral injury from the repair. It is not uncommon for patients to complain of dyspareunia from vaginal stenosis and/or from the Martius graft site [45]. In patients who have undergone a repair of a VVF, elective cesarean delivery is recommended for all subsequent births in females contemplating future fertility. Patients must have a realistic expectation of possible complications and outcomes related to fistula repair. It is equally important to counsel patients that urinary incontinence after successful repair can be as high as 12%. Waaldijk reported occurrence of urinary incontinence after repair of fistulas in 1% of cases without sphincter involvement, 13% with sphincter involvement with no additional tissue loss, and 16% with both sphincter and tissue loss [48].

CONCLUSION

In developing countries, urogenital fistulas are extensively related to obstructed labor due to limited access to obstetrical care. In developed countries, urogenital fistulas are typically a result of a gynecological procedure, most commonly a hysterectomy. The literature on urogenital fistulas is mainly based on small case series and expert opinion. The tenants of fistula surgery are well established and include adequate exposure and visualization of the fistula tract, careful dissection of the surrounding tissues to allow a tension-free watertight closure, and use of well-vascularized flaps, nonoverlapping suture lines, and appropriate bladder drainage. Timing of repair remains controversial. Prevention is key and good surgical technique is mandatory in any surgical procedure but especially when operating deep in the pelvis. Even when injuries to the bladder do occur during a surgical procedure and are properly and promptly repaired, a fistula may still occur. Proper patient counseling is vitally important and may help mitigate medicolegal action. Success in management is dependent upon multiple factors including the individual patient, the fistula characteristics, and the surgeons' experience. VVF is a devastating outcome physically and emotionally to patients. Each patient should undergo individualized management using the principles outlined throughout this chapter. Patients must undergo extensive counseling regarding what happened, the rationale in identifying the problem, and the appropriate steps to fix the problem as soon as technically feasible. In the vast majority of cases, early intervention via vaginal repair is associated with outstanding success rates. These patients should be reassured at frequent intervals throughout the process, and meticulous follow-up after surgery insuring adequate drainage and absence of other complications is critical to achieving surgical success.

Transabdominal Vesicovaginal and Vesicouterine Fistula Repair

Howard Goldman and Christopher Tenggardjaja

Genitourinary (GU) fistula is a devastating condition that leads to decreased quality of life due to incontinence. The surgeon who can cure someone of their leakage caused by vesicovaginal/uterine fistula can truly make a difference in the patient's life. The best opportunity for success lies in the initial diagnosing and treating surgeon's hands. GU fistulas are composed of any nonanatomic communication between the urinary tract (ureters, bladder, and urethra) and vagina, cervix, or uterus. While fistula repair can be approached in myriad ways, the most effective way of closure lies with the approach with which the surgeon is most comfortable. In this chapter, the indications and techniques for transabdominal surgical management of vesicovaginal and vesicouterine fistula (VVF, VUF) will be discussed. The reader is directed to other chapters to further learn diagnosis/evaluation and transvaginal techniques for management of GU fistulas.

TRANSABDOMINAL VESICOVAGINAL FISTULA

Open Repair

The traditional reasons for a transabdominal approach to VVF include surgeon's technical expertise, high location of the VVF, need for concomitant abdominal procedures such as augmentation cystoplasty/ureteral reconstruction, and hostile vaginal environment such as scarring from radiation or narrowed introitus due to nulliparity [1,2]. Again, the best approach for the treatment of VVF will be the approach that the surgeon has the most experience with. If there are any concerns about multiple abdominal adhesions due to prior surgeries or radiation, preoperative planning with colorectal surgery may be prudent.

The patient is placed in the low lithotomy position with stirrups. Perioperative antibiotics are administered within 30 minutes to 1 hour of incision time and are chosen to appropriately cover the skin and vaginal flora. If possible, the patient is positioned above the break in the bed to allow for exposure of the pelvis. Pneumatic compression devices are placed on the legs and per our protocol, subcutaneous heparin is administered prior to all our pelvic surgery cases. If there is concern for fistula proximity to the ureters, a cystoscopy can be performed prior to the procedure and ureteral stents placed for localization. During this time, the fistula tract can be cannulated to help with manipulation during the surgery. Cystoscopy can be deferred if a transvesical approach is planned and open-ended catheters or feeding tubes can be placed through the cystotomy under direct visualization of the ureteral orifices.

Transabdominal VVF repair has been described from an intraperitoneal or extraperitoneal approach. The main benefit of an extraperitoneal approach is the avoidance of entering the peritoneum. Depending on the etiology of fistula, the intraperitoneal approach could be less desirable due to multiple adhesions. The drawback of an extraperitoneal approach is the inability to utilize different types of flaps, such as omentum, that are only available intraperitoneally. After a catheter has been inserted into the bladder, a Pfannenstiel or infraumbilical midline incision is made. The dissection is carried into the space of Retzius. The bladder is then entered through a cystotomy. If there is any difficulty locating the bladder due to prior surgical interventions in the retropubic space, the urethral catheter can be backfilled. The classic transvesical approach first described by O'Conor describes bivalving the bladder widely down to the VVF [3]. Furthermore, the bladder should be dissected free from the VVF proximally and distally for a tension-free closure. Proper dissection and mobilization of the surrounding tissue allows for the placement of an interposition flap such as omentum or peritoneum. The benefit of bivalving the bladder is the ability to catheterize the ureteral orifices intraoperatively and increased exposure [4]. The drawback is the possible morbidity associated with a large bladder incision. The alternative to minimize the potential complications of a large cystotomy is a transvesical approach [5]. In this setting, a limited anterior cystotomy is made. The posterior bladder at the area of the fistula is exposed. The fistula tract is circumscribed and can be excised. Another option is to leave the fistula tract in situ and incorporate it into the repair. The vaginal muscularis is dissected free and closed. The bladder detrusor and mucosa are then closed separately using absorbable suture.

An intraperitoneal approach can also be utilized. Once the peritoneal cavity is entered, the bowels are packed cephalad with moist lap sponges and a self-retaining retractor is placed. Slight Trendelenburg can be useful to keep the bowel out of the field. If minimal adhesions are encountered and the VVF is away from the trigone, a dissection plane can be carried between the vagina and the bladder without the need for an O’Conor approach. The bladder and vagina are mobilized apart from each other for several centimeters beyond the fistula tract to enable a tension-free closure. The vaginal muscularis is closed using absorbable suture. If possible, the bladder is closed in two layers. At the surgeon’s discretion and given the patient’s anatomy, an interposition flap can be harvested and may be placed between the bladder and the vagina to keep the suture lines apart (Figures 108.1 through 108.3). A traditional O’Conor approach with wide bladder exposure can be useful in many cases and may be preferred by many. An intraperitoneal approach can be useful for easy mobilization of an omental interposition flap. Also, numerous other flaps have been described including peritoneum, bladder mucosa autograft, urachus, perisigmoid fat, and epiploica. An abdominus rectus myofascial flap has also been described [6–8]. The intraperitoneal approach also allows for concomitant procedures such as ureteral reconstruction and augmentation cystoplasty. After the cystotomy and fistula are closed, the repair is evaluated by low-pressure retrograde filling of the bladder. Postsurgical drainage is achieved with large-bore urethral catheterization with the addition of a suprapubic cystotomy being an option. It is our preference to leave a urethral and suprapubic catheter and remove the urethral catheter within a few days once the urine has cleared. Cystotomy closure is achieved using a two-layer closure with absorbable sutures. A drain is left postoperatively and discontinued when the output is low. Postoperative care is similar to any abdominal case with appropriate pain control, early ambulation, and advancing diet when the patient is tolerating clears. Anticholinergic medication during recovery is also an integral part of the postoperative regimen.

Minimally Invasive Transabdominal Approaches

Conventional Laparoscopy

Transabdominal VVF repair is subject to the morbidity associated with a laparotomy incision, bowel manipulation, and an open abdomen. Laparoscopy affords the convenience of a transabdominal approach with improved visualization in the pelvis while being minimally invasive. The main drawback of laparoscopy is the steep learning curve associated with its adoption [9]. Since the first description of laparoscopic VVF repair in 1994, multiple large series have described good results with conventional laparoscopic VVF repair [10]. Most series describe ureteral and fistula catheterization with cystoscopic assistance at the start of the case. Access to the peritoneum is performed with a Veress needle and trocar placement with a visual obturator or with an open Hassan technique. Laparoscopic ports are placed in a standard configuration utilizing a midline infraumbilical 10–12 mm port for the laparoscope, an additional 10 mm port on the left side in the midclavicular line midway between the umbilicus and the anterior superior iliac spine, an additional port at the right midclavicular line mirroring the left side, and 5 mm ports as needed. Dissection has been described with either a transvesical or an extravesical approach. Pneumoperitoneum is sustained by inserting a Vaseline soaked gauze pack in the vagina and a clamped catheter in the bladder. Principles regarding VVF repair remain the same with wide mobilization of the area around the fistula tract, closure of the vaginal muscularis and bladder with separate suture lines utilizing absorbable suture, and placement of an interposition flap when available. Again, placement of a drain at the end of the case and prolonged catheter drainage post-op are mainstays of VVF repair.

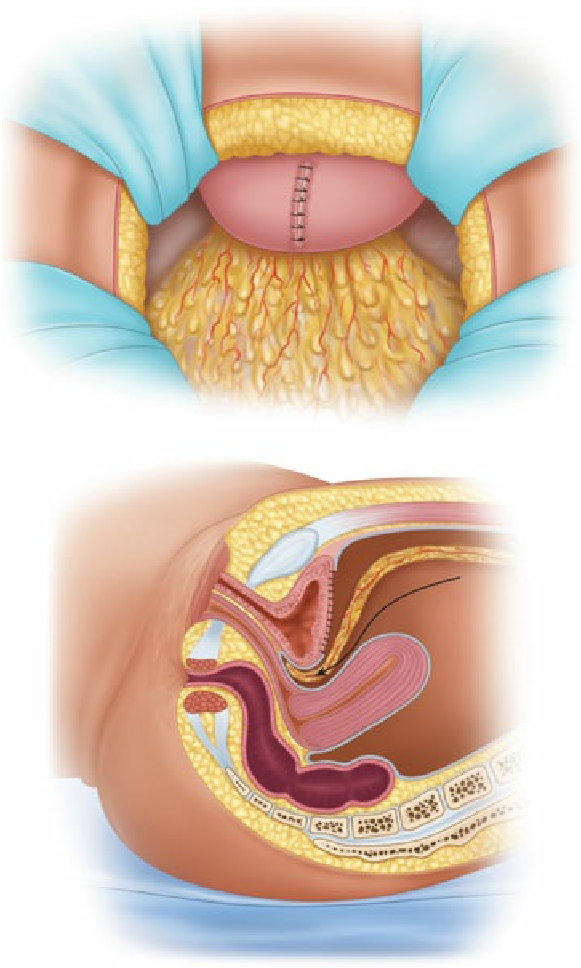

Figure 108.3 Transabdominal vesicovaginal fistula repair. Interposition omental flap placed between the bladder and the vaginal closure, which can also be used in vesicouterine fistula repair. (Courtesy of Cleveland Clinic, Cleveland, OH.)

Robot-Assisted Laparoscopic Repair

The advantage of robot-assisted laparoscopy in the repair of VVF is the ability to perform a minimally invasive procedure without the learning curve associated with conventional laparoscopy. This advantage must be weighed against longer operative times involved with docking the robot in addition to the added expense compared to conventional laparoscopy [11]. Robot-assisted laparoscopy has been described with port placement similar to that of a standard “W” configuration with a 10–12 mm port placed periumbilically, 8 mm robotic arm ports placed at least 9 cm apart to prevent external collisions, and an assistant port on the patient’s right lateral side (Figure 108.4). A parallel or side docking of the robotic arms is helpful to allow for access to the vagina. Instruments typically utilized include monopolar shears, bipolar grasping forceps, and needle drivers. Dissection then proceeds in an extravesical or transvesical manner in the same way described for conventional laparoscopy.

VESICOUTERINE FISTULA REPAIR

Open Repair

Given the high location of VUF, most case series discuss a transabdominal approach although transvaginal repair has been successfully reported [12]. The decision to perform a hysterectomy at the time of VUF repair depends on the patient. If the patient has had multiple children or does not desire any more pregnancies, then concomitant hysterectomy can be performed at the time of VUF repair. If the patient is of childbearing age, uterine sparing would be the more logical approach if technically feasible [13]. For subsequent pregnancies, the patient and their obstetrician should discuss the risks and benefits of delivery by elective cesarean versus vaginal delivery.

● 10–12 mm robotic port

Figure 108.4 Minimally invasive vesicovaginal fistula/vesicouterine fistula repair. Port placement for robot-assisted laparoscopic fistula repair. (Courtesy of Cleveland Clinic, Cleveland, OH.)

The transabdominal approach for VUF repair begins much as that for a VVF. Placement of ureteral stents is based on the preference of the surgeon and the location of the fistula. The patient is placed in a low lithotomy position and either the previous Pfannenstiel incision or an infraumbilical midline incision is made. While an extraperitoneal transvesical approach can be utilized, a transabdominal intraperitoneal approach is straightforward and may often be necessary. The bladder is opened to the site of the fistula at which time the bladder is separated from the uterus. The uterus is then closed that usually just requires a few sutures on the outer surface, and the bladder is closed in a multilayer fashion. Typically, an omental or peritoneal flap is placed between the uterus and the bladder, utilizing a long-acting absorbable suture to parachute the flap past the repair to prevent overlapping suture lines.

If a hysterectomy is to be performed instead of a uterine-sparing procedure, the usual method of transabdominal hysterectomy is performed. We typically perform cystoscopy with evaluation for bilateral ureteral efflux after the hysterectomy prior to closure of the fistula. After the closure of the bladder and vaginal cuff, an interposition flap can be placed to decrease the chance of a VVF. Finally, the postoperative course and recovery are similar to that of a VVF repair.

Minimally Invasive Transabdominal Approaches

Both conventional laparoscopy and robot-assisted laparoscopic techniques have been described for VUF repair. Both are limited to case series in the literature with both transvesical and extravesical techniques being described. For conventional laparoscopy, a traditional five-port approach is used. A laparoendoscopic single-site (LESS) approach has also been described but is hampered by the difficulty of suturing and may necessitate the placement of additional 5 mm ports [14].

After pneumoperitoneum is achieved with a Veress or Hassan technique and all ports are placed, dissection is carried down to the vesicouterine plane. The bladder can be entered above the fistula tract and a limited cystotomy is performed down to the previously cannulated fistula tract. Cautery is used minimally in this area to avoid tissue necrosis/devascularization. If an extravesical approach is utilized, the dissection is continued between the uterus and the bladder until the cannulated fistula tract is reached. This dissection can be more arduous if the plane is densely adherent/fibrotic. The tract can be excised or incorporated into the repair and the uterus and bladder are repaired using absorbable suture. An interposition flap can then be mobilized and placed between the repaired areas.

Given the technical skill needed for intracorporeal knot tying with conventional laparoscopy and the reliance on a familiar assistant, robot-assisted laparoscopic surgery has become more popular. Multiple case series have also described VUF repair via a robot-assisted laparoscopic approach. Docking of the robot proceeds as mentioned previously for VVF repair. The fistula tract is cannulated prior to cystoscopy and if there is any concern regarding proximity to the ureters, they are stented. Dissection can then be performed transvesically or extravesically and continues much like that during conventional laparoscopy. Specific to VUF repair, if a hysterectomy is anticipated, then the assistant port can be utilized for either application of a hemostatic clip applier or vessel-sealing device. After completion of the hysterectomy, the uterus can be delivered through the vaginal cuff or if small enough through the camera port with the help of a laparoscopic specimen bag.

OUTCOMES

Vesicovaginal Fistula

Regardless of the approach for VVF repair, the highest possibility of success lies with the technique the surgeon is more familiar with. Series with transabdominal VVF repair report success rates of 80%–90%. The postoperative continence rate is known to be discordant with closure rate due to the complex nature of incontinence after both obstetric and postsurgical fistula repair including de novo urgency or stress incontinence [15,16]. In a retrospective series on postobstetric fistulas, success of repair has been linked to other characteristics such as primary versus secondary attempt at closure, amount of fibrosis, fistula size, location, and patient parity [16]. While there is a theoretical risk of increased bladder dysfunction with a transvesical repair, no prospective study has been performed to actually document postoperative functional changes utilizing urodynamics.

In regards to minimally invasive techniques for GU fistula repair, most series demonstrate a success rate of 86%–100% [17–21]. Morbidity is limited to those inherent to minimally invasive procedures including conversion to open surgery and enterotomy. All minimally invasive studies are limited to small case series with no prospective trials to analyze outcomes compared to transvaginal or transabdominal approaches. In a retrospective case-matched fashion, robot-assisted laparoscopic cases have been compared to open transabdominal cases with outcomes for minimally invasive cases being significantly shorter in regards to length of hospital stay [22]. Lengths of hospital stay and convalescence have been touted as advantages to minimally invasive approaches when compared to any type of open procedure. Adoption with robot-assisted cases though has been hindered by the prohibitive costs associated with console time and equipment when compared with conventional laparoscopy and open techniques.

Vesicouterine Fistula

Given the lower incidence of VUF compared to VVF, most outcomes in regards to VUF repair are limited by rather small numbers and retrospective reviews [12,23]. Due to the increase in cesarean sections, it is believed that the incidence of VUF will rise. Some of the larger series of VUF repairs are reported in conjunction with VVF repair with closure rates approaching that of VVF repair [15]. Success rates in uterine sparing versus concomitant hysterectomy have never been evaluated in a prospective analysis. Thus, hysterectomy during VUF repair is not mandatory. A frank discussion should be with the patient and surgeon regarding a uterine sparing versus non-uterine-sparing repair. If the patient desires future pregnancy, a uterine-sparing procedure should be attempted. Conversely, if the patient is past reproductive age, then a meaningful discussion regarding VUF repair with hysterectomy should occur.

The success rate with minimally invasive surgery has been described as 100%. This is complicated by the rarity of the condition and that all minimally invasive series, whether it be conventional laparoscopy, robot assisted, or LESS, are all case series formats with typically less than five patients [14,24–26]. All series describe successful repair of the fistula without recurrence but suffer from lack of long-term follow-up. Theoretical risks from minimally invasive surgery are those inherent to the procedure including need for conversion to open, enterotomy, and recurrence. Also, the technical demands of conventional laparoscopy/LESS or the prohibitive costs of robotic surgery are potential drawbacks to minimally invasive approaches. No retrospective or prospective studies have been done specifically comparing minimally invasive techniques to open transabdominal surgeries for VUF.

Flap Coverage

One advantage of transabdominal VVF and VUF repair is the availability of multiple flaps. While multiple flaps have been described (bladder, omental, peritoneal, urachal, rectus, perisigmoid fat, epiploica, and porcine small intestine submucosa), the routine use of flap coverage in a nonradiated primary repair has been debated [6,27–30]. Proponents argue that the placement of a healthy flap of tissue helps to oppose suture lines, interpose a vascular tissue flap that enables healing, and also gives an extra layer of coverage. It can be argued though that in a primary repair in the nonradiated patient, an adequate dissection and a tension-free closure without overlapping suture lines should be adequate enough for a successful repair. No prospective study has been undertaken to evaluate routine flap coverage versus not in transabdominal VVF or VUF repair.

Evans et al., in a retrospective study, evaluated their success rate using interposition flaps in transabdominal VVF repair. They demonstrated 100% successful closure rates in the 10 benign VVF cases that used interposition flaps versus a 63% successful closure rate in the other 19 benign VVF repairs. In the malignant VVF group, the successful rate of closure was 67% in patients who did not have an interposition flap. The study though was limited due to the inherent bias of a retrospective study design [30].

Timing

Conventional teaching regarding timing of VVF/VUF repair is to wait at least 3 months. This allows for tissue quality to improve and the fistula tract to mature. Within this 3-month period, the possibility of spontaneous fistula closure with conservative management exists even if the success rate hovers around 12% at best in a multicenter retrospective study of vesicovaginal fistula management [31]. During conservative management with catheter drainage, other minimally invasive approaches are at a surgeon’s disposal. Endoscopic fulguration of the tract or injection of hemostatic agents has been described with limited success [32]. For vesicouterine fistula, hormonal induction of amenorrhea with subsequent spontaneous closure has also been described in the early period. Rates for closure with hormonal induction vary widely though with the literature dominated by case series due to the relative rarity of VUF [23,33–35]. Thought should also be given to the etiology of the fistula. If the VVF/VUF is due to radiotherapy, it is unlikely to heal with conservative management due to the underlying poor tissue quality. The opponents of waiting suggest that the limited gain in success is countered by the detriment to patient’s quality of life, while the fistula tract is open. The data for timing of fistula closure are limited to small case series reported in the literature with no large-scale randomized studies having been performed [36–38]. That being said, patients with a GU fistula should be followed with serial exams and proceed to surgical correction when the tissue is robust.

CONCLUSION

VVF and VUF are detrimental to a patient’s quality of life. Transabdominal repair can be performed through a traditional open approach or minimally invasive conventional or robot-assisted laparoscopy. At select centers, single-site surgery has also been performed successfully. The transabdominal approach is most commonly performed in cases with a high supratrigonal fistula, complex fistula repair, vagina not conducive to transvaginal repair, surgeon’s preference, or concomitant procedures such as hysterectomy or ureteroneocystostomy. Success rates depend on a variety of factors including number of previous repairs, history of radiation, size of the fistula, and degree of scarring. Flap coverage and timing of repair are often debated with many suggesting the use of an interposition flap if readily available and waiting a minimum of 3 months prior to closure. Regardless of approach utilized for repair, the greatest opportunity for success lies in the approach the surgeon is most comfortable with.

109 Management of Obstetric Urogenital Fistula

Andrew Browning

INTRODUCTION

The last decade and a half has seen great efforts to reduce maternal mortality and morbidity rates across the world. Despite this, many women in the developing world still do not have access to medical attention for the delivery of their child. Maternal mortality is still unacceptably high in these areas, and paralleling this are high rates of maternal morbidity. One of the most feared consequences of a morbid delivery is the obstetric fistula—reducing a woman to a life of shame, isolation, and misery and a life that sometimes ends in suicide or at least the victim wishing she had died during that frightful labor.

ETIOLOGY AND EPIDEMIOLOGY

The etiology of obstetric fistula is ischemic necrosis from a long unrelieved obstructed labor. The impacted presenting part compresses the pelvic tissues against the mothers' bony pelvis. This connection was made 1000 years ago. The early medical text *Al Kanoun* by Avicenna, who died in 1037, gave the warning of labor causing a hole in the bladder—a condition "incurable and remains so until death" [1]. This accounts for the vast number of obstetric vesicovaginal fistula seen throughout the world.

There are also an increasing number of fistulae occurring after cesarean section, up to 24.5% in one series [2]. These may or may not be iatrogenic. Often, the cesarean operations are performed in difficult circumstances with difficult pathology, with little or no lighting, poor equipment, and the surgeon having little or poor training and experience. But the fistula may have been present by the time the patient reached the health facility having labored too long at home before the patient's family decided to get help.

Fistula can also occur after forceps delivery or manipulations and cuttings from poorly trained health attendants. They have been recorded after almost every pelvic surgery. Less common causes include advanced pelvic cancer; sexual trauma, particularly in young undeveloped girls; infections, such as tuberculosis of the bladder; schistosoma; and lymphogranuloma venereum.

There have been numerous epidemiological studies of obstetric fistula patients from various parts of the globe. Typically, the patient is primiparous 43%–62.7% [3,4] but a significant number are multiparous (up to 20%–25% having had four or more deliveries) [3,5], the obstructed labor presumably due to delivering larger children or secondary to malpresentations. Interestingly, a number of studies have shown these women to be short, often less than 150 cm in Nigeria [5], India [6], Ethiopia [7], and Niger [8]. Ampofo showed them to be 7 cm shorter than the general female population [9]. The women are largely uneducated, more than 92% having had no formal education [4,10,11]. A recent study showed that women suffering fistula in Tanzania and Sierra Leone have a much narrower intertuberous space as compared to those women delivering normally and also reconfirmed a short stature among fistula sufferers, but the latter was a weak predictor of fistula formation [12].

Fistula patients are often young. Although it is difficult to get a true estimate of their age, as it is often unknown, it is evident from their appearance that many are in their teens. If their age is asked and the answer relied upon, a 42% are aged less than 20, with 65% being less than 25 years old [4]. Other studies confirm this trend [10,11,13,14]. The majority have had home deliveries with no skilled attendant present and typically more than 50% have been divorced by their husbands due to their offenses [4]. It has been noted in Nigeria that if the woman is childless, she is more likely to be divorced, whereas those women who have live children are more likely to be attending those children and the husband has remained with her [11]. What is unclear is the association of obstetric fistula and female genital mutilation (FGM) or cutting. The opinion of many fistula surgeons is that the obstructed labor occurs against the mothers' bony pelvis and not against the scarred tissues resulting from a circumcision at the outlet. This was confirmed in a study comparing fistula patients with and without circumcision in northern Ethiopia. There was no difference between the presentation, type of injury, and outcomes when comparing 255 obstetric fistula patients with type 1 and 2 circumcision and 237 obstetric fistula patients without circumcision. It was concluded that FGM was not a variable in fistula formation [15]. From further experience in Ethiopia, fistula can indirectly result from type III circumcision or infundibulation. During labor, a traditional health attendant may cut the circumcision open, cutting anteriorly, damaging the urethra, bladder neck, and bladder base.

The other factor that leads to some controversy is early or child marriage. It seems reasonable to assume that because adult height and sexual maturity are reached before the completion of pelvic growth, early marriage and, hence, pregnancy may lead to an increase in obstructed labor and, hence, obstetric fistula [16]. On the other hand, a younger patient may have more flexible ligaments when young, and indeed, in a recent unpublished series of 1000 consecutive fistula patients from Ethiopia in an area with a high prevalence of early marriage, 55% of fistula sufferers received their injury in their second or higher delivery, that is, when they were older. Just less than half received their injury in their first delivery. The ratio of primiparous to multiparous is similar in areas not so renowned for early marriage. The correlation of early marriage and fistula formation has been theorized and probably does contribute slightly to fistula formation, but it certainly would not be a major contributing factor, but this has not been concretely confirmed by studies in the field. Unfortunately, early marriage can result in traumatic fistula, if the husband needs to enlarge the vagina of a young girl to enable intercourse to take place. This is sometimes done, again by a traditional healer cutting open the vaginal tissues anteriorly and sometimes damaging the urethra and/or bladder in the process. This is similar to a “gishiri” cut performed in some areas as a traditional treatment in some areas for a variety of gynecological ills [10].

PREVALENCE

There are no accurate figures for the true prevalence of obstetric fistula. There have been few population-based studies to determine the scope of the problem [17]. A large hospital-based study of over 22,000 patients gave the incidence of obstetric fistula as 0.35% of deliveries [18]. Knowing the majority of women in the developing world deliver in their villages and not in a hospital, the true incidence was thought to be higher. That having been said, the World Health Organization (WHO) often quotes the incidence as 0.3%. Using this figure, there are probably between 50,000 to 100,000 new cases of obstetric fistula occurring across the world each year and about 2 million women suffering from this condition throughout the world [19]. Others have taken further calculations equating the obstetric fistula rate with maternal mortality. Danso, knowing that for every maternal death, there are at least 30 women suffering from morbidity, considered one of which may be an obstetric fistula. This would make about 500,000 new cases of obstetric fistula worldwide each year [3]. Recent studies hint that this might be overestimated, and a meta-analysis done in 2013 suggests that the prevalence is 0.29 per 1000 women of reproductive age and incidence is 0.09 per 1000 recently pregnant women and suggested that there may be 1 million women living with this condition in low- and middle-income countries across the world [20].

SYMPTOMS AND SIGNS

The majority of deliveries are stillborn. The woman is weak and shocked postdelivery and on average, it takes 26.1 days before she is strong enough to be able to walk unaided [4].

The immediate course of the injury is that 3–10 days postdelivery, a necrotic slough is extruded through the vagina, and the vesicovaginal fistula is exposed rendering her completely incontinent of urine, leaking every minute of the day and night (Figure 109.1). Rarely, if the fistula is very small, she can describe symptoms more like stress urinary incontinence, but leaking from the vagina rather than the urethra. If she has sustained similar injuries to the posterior compartment, she is also rendered incontinent of feces and flatus per vagina.

It is easy to think of the obstetric fistula as merely just a hole in the vagina to the bladder and perhaps the rectum. However, unlike iatrogenic surgical fistula that is usually just a discreet injury, the pathology of the obstetric fistula is broader, and the term “field injury” has been coined to refer to the range of injuries. Another term that is used is the “obstructed labor injury complex” [21]. The ischemic process affects not only the tissues of the genitourinary tracts and bowel but also all the other tissues in the mothers' pelvis, that is, nerves, muscles, and bones. This results in primary conditions, those associated with the etiology of obstetric fistula and the ischemic process within the mothers' pelvis over a broad area, and also secondary conditions—conditions delayed, arising later as a result of the incontinence or scarring within the pelvis.

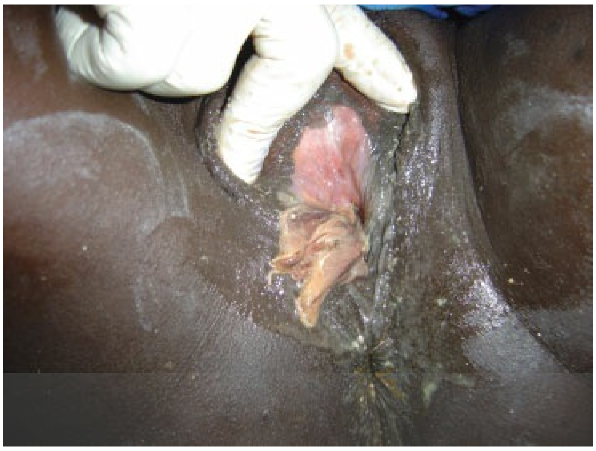

Figure 109.1 Necrotic tissue extruding from the vagina.

Primary Conditions

Vesicovaginal Fistula

The level of impaction during labor determines the site of injury. If the impaction occurs at the pelvic inlet, the vesicovaginal fistula may be juxta- or even intracervical [22] (Figures 109.2 and 109.3). If impaction occurs lower, the urethra may be involved. The urethra is injured in 28% of cases with 5% of patients in Ethiopia having the urethra completely destroyed [21]. This has prognostic indications as the mechanisms for continence in the female have been destroyed [17,23,24].

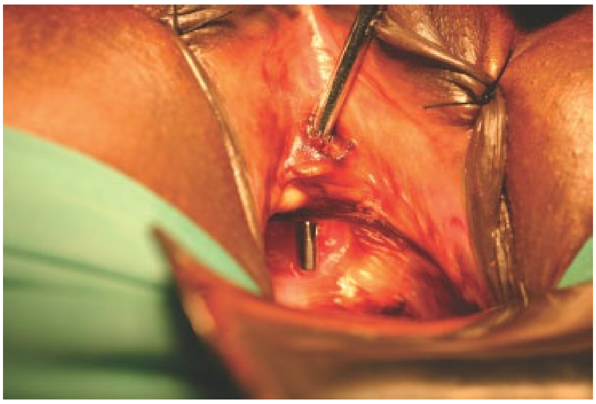

Figure 109.2 Fistula located lower, or more distally in the vagina, involving the urethra.

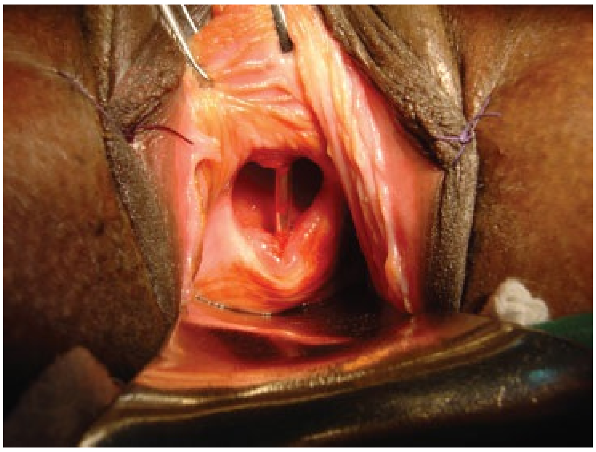

Figure 109.3 Midvaginal fistula, more proximal in the vagina, involving the trigone.

Ureteric Injury

In a small number of obstetric fistula cases, the lower part of the ureter can be involved. The whole ureterovesical junction is necrosed and sloughed away, leaving the vesicovaginal fistula with the ureter draining outside of the bladder straight into the vagina. It is becoming more common to see isolated ureterovaginal fistulae after cesarean section or cesarean hysterectomy, more commonly on the left, and these are iatrogenic, occurring at the time of operative delivery [2,25].

Rectovaginal Injuries

A rectovaginal fistula occurs if the presenting part is impacted against the sacrum during labor, causing ischemic necrosis of the rectovaginal septum. It has various reported prevalence and seems to vary geographically, ranging between 6% (B. Hancock, personal communication, Uganda) and 22% in Ethiopia [4]. If present, it usually occurs in conjunction with a vesicovaginal fistula, rarely presenting in isolation [4]. The status of the anal sphincter should always be noted as there may be residual flatal or fecal incontinence even after repair [26]. Neglected fourth-degree tears are also common (Figure 109.4).

Reproductive Tract

The tissues of the vagina are obviously injured, but in some cases, the whole vagina has necrosed, leaving little or no identifiable remaining vaginal epithelium (Figure 109.5). Overall, about 28% of patients will need some form of vaginoplasty [21]. The cervix is often torn or partly necrosed and fistula surgeons testify that it is rarely that one will see an uninjured cervix. Vesicouterine fistulae, although more uncommon, do occur and the uterus affected.

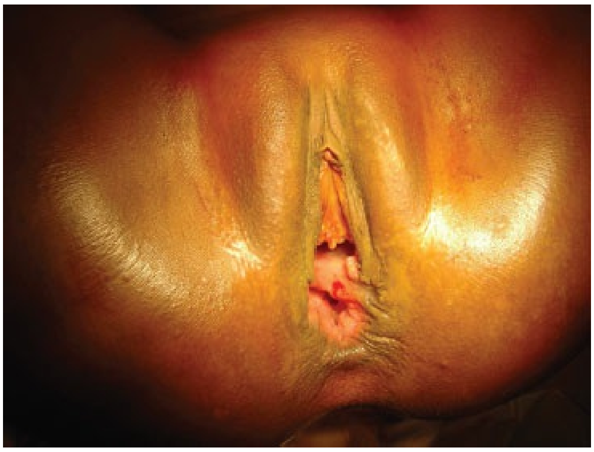

Figure 109.4 Concurrent fourth-degree tear. A reasonably common finding.

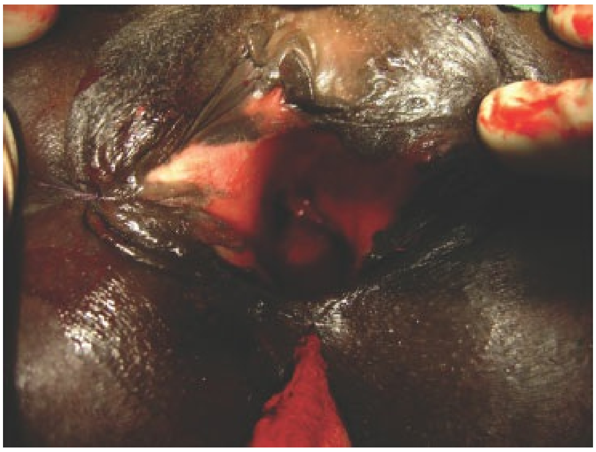

Figure 109.5 Severe injury with no urethra, no bladder, and no vagina remaining.

Muscles

The muscles of the pelvic basin are often affected by a neuropathy, directly weakened by the ischemic process or even completely destroyed. A recent ultrasound study of the levator muscle complex in obstetric fistula patients showed little muscle loss and little denervation [27], but certainly in extensive injuries, an “empty pelvis” is all that remains.

Bones

A series by Cockshott performed x-rays on 312 women with obstetric fistula and found that 32% had some x-ray abnormality, ranging from bony resorption, bony spurs, obliteration or separation of the symphysis pubis [28].

Nerves

It has been quoted that between 20% and 65% of obstetric fistula, patients will have some form of peroneal neuropathy manifesting as bilateral or unilateral foot drop [21,29]. There are currently three theories as to its etiology: a prolapsed intervertebral disc, direct compression of the fetus on the lumbosacral trunk during labor, or impingement of the common peroneal nerve as it transverses the head of fibula while the patient squats for prolonged periods during labor [30,31]. Waaldjik and Elkins commented that most patients do improve with time with 13% still showing some signs at 2 years [29].

Secondary Conditions

Social Consequences

The consequences of complete incontinence for a woman in the developing world, where the status of women is usually low, are far reaching. Over half are divorced by their husbands who feel that the affected woman is now unable to fulfill her marital duties and unable to bare children [4]. Her incontinence has other consequences as she is now in urine-soaked clothes, unable to clean herself or her attire. She is unable to interact socially; others find her presence unacceptable. She cannot go to church or mosque to worship, to the market, or to the well to draw water. She lives in isolation stripped of her dignity and place in society.

Mental Health

It is becoming more apparent that mental health issues in obstetric fistula patients are a significant disease burden [32–36]. The GHQ-28 shortened form of mental health questionnaire revealed a 93% positive screening for potential psychological disorder, and 100% of those patients interviewed in Ethiopia screened positive [32]. Similarly, in Kenya, 17% of patients had suicidal ideations before receiving treatment, 73% were depressed, and 26% severely depressed [35]. If, however, the patient is cured completely by the operation and has no residual incontinence, the percentage screening positive returns to the background positive rate from the general population [33,36].

Limb Contractures

There are often stories of patients being shut away in huts for months if not years. It is thought with time, disuse can cause limb contractures. This is seen in roughly 1%–2% of patients in Ethiopia. It is occasionally so severe that her legs are locked in the fetal position.

Malnutrition

Malnutrition results from isolation as the patient may be fed and cared for inadequately by a relative in a small room or hut. The average BMI from a small unpublished series from Ethiopia was 19 (A. Browning, unpublished work). Cases of severe malnutrition with hypoproteinemia are not uncommon.

Upper Renal Tract Damage

One study from Nigeria looking at intravenous pyelograms in women with fistula revealed 49% of patients sustained upper renal tract damage. The most common consequence is hydronephrosis (34% of women), but the damage may progress all the way to nonfunctioning kidneys [37]. This is presumably due to scarring partially or totally occluding the lower ureter causing obstructive uropathy and partly due to repeated ascending infections.

Bladder Stones

The constant leakage of urine leads many women to drink less water and, hence, produce less urine. The concentrated urine might collect in pockets of scar, vagina, or bladder and, with time, form calculi, causing pain, infection, and increased odor. Occasionally, the woman herself or perhaps a local healer will insert foreign bodies into the vagina to try and stem the flow. Such foreign bodies have included stones, rags, or plant material, acting as a nidus for calculi formation.

Urine Dermatitis

The leakage of urine, often concentrated, affects the skin. The ammonias and phosphates can encrust on the skin, causing excoriations, secondary infections, and areas of tender hyperkeratosis. Much thought has gone into treating this condition coined the “urine dermatitis,” but the most expedient way to just to ensure that the urine is not in contact with the skin is by applying barrier ointments such as Vaseline or better by closing the fistula, making the patient continent (Figure 109.6).

Reproductive Outcomes

After fistula occurrence, up to 44%–63% may suffer from amenorrhea [21,38,39]. This has a multifactorial causality most of which are not clearly delineated. Surely, some are due to stresses of the delivery and the resulting social isolation. Some patients do have their menses return following repair [38,39]. A low BMI is often be the cause. It is thought that some will have focal anterior pituitary necrosis from shock during the long labor [40]. A small unpublished series by Dosu Ojengbede from Nigeria looking at hysteroscopy showed intrauterine scarring is common, Asherman’s syndrome (L.L. Wall, personal communication). Others will have a cryptomenorrhea from an obstructed outflow tract with time causing a hematometra. If the patient does receive treatment, remarries, or returns to her husband, the subsequent fertility rates are quite desponding. A number of studies have shown that as few as 19% achieve a pregnancy [38,41,42] with perhaps a higher prematurity rate and infant mortality in those that do [43]. Subsequent deliveries are hazardous. One small series following the pregnancies in women delivering post–fistula repair showed an alarming 27% recurrence rate of fistula with a supervised vaginal delivery [41]. It is commonly recommended that any further deliveries should be performed by cesarean section. A series from Barhirdar, Ethiopia, confirmed that 49 deliveries after fistula repair with the delivery of 50 infants (1 woman delivered twins). All but three patients delivered by cesarean section, three infants died, two from premature delivery and one from an obstetric complication. There were no recurrences of the fistula. All of these patients presented to the fistula hospital and used the hospital as a maternal waiting area so a timely cesarean could be implemented. During the time period of the study, 24 women represented after trying to deliver a subsequent child at home, some of them reaching a health facility, but after a prolonged period of labor. All women delivered a stillborn child and all reopened their fistula. There were verbal reports of women dying trying to deliver at home and likely more. Likewise, there could have been some women who did deliver successfully at home, and there are many anecdotal reports of this occurring, but it seems a considerable risk [44].

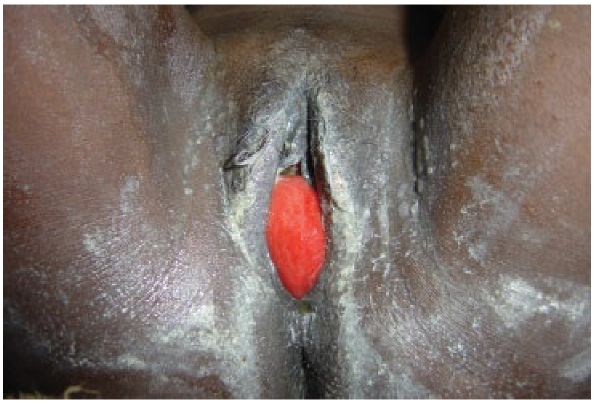

Figure 109.6 Urine dermatitis, note the bladder fundus prolapsing through the fistula and out through the introitus.

INVESTIGATION

The investigations of the fistula are kept simple, merely because most patients with obstetric fistulae present in areas where resources are limited.

The majority of obstetric fistula patients can be confidently diagnosed by history and examination alone—a history of a long labor (more than 1 day) with a stillborn child and complete incontinence of urine is the rule. Most obstetric fistulae can be diagnosed on simple digital vaginal examination—noting the site, size, and amount of scarring.

If the fistula is very small, it may not be palpable and a dye test must be performed. The classical teaching for this is to place three clean swabs into the vagina and insert 50–100 mL of dilute gentian violet via a catheter into the bladder. The swabs are left in the vagina for some minutes and then removed. A fistula is confirmed by the presence of dye on the gauze, and depending on which of the three gauzes are stained reveals the approximate site of the fistula. However, it is common in many centers to directly visualize the fistula by examining the patient with the aid of a Sims speculum, retracting on the posterior vaginal wall to expose the anterior wall, instilling the dye, and seeing where the dye leaks into the vagina. In some very small fistulae and some vesicouterine or vesicocervical fistula, the dye may take some minutes to find its way into the vagina. In these circumstances, it is best to insert a gauze swab into the vagina, instill 50–100 mL of dilute dye into the bladder, remove the catheter, and ask the patient to walk about for 15–30 minutes. It is surprising how many gauzes are stained with dye at the end of this time when the initial examination showed a negative test.

The posterior vaginal wall is examined digitally again noting the site, size, and any scarring associated with a rectovaginal fistula. The state of the anal sphincter is noted as is the distance of the fistula margin to the sphincter. A small number of patients will complain of flatal incontinence with or without incontinence of diarrhea through the vagina hinting that a small fistula is present, unrecognizable to the physicians’ digital examination. A dye test can also be performed by the installation of dilute dye into the rectum via a Foley catheter.

Routine urine tests, renal function tests, and intravenous urography are not warranted as the results do not often influence management, and these tests are expensive and are simply unavailable in most units where fistula surgery is usually performed.

PROGNOSTIC FACTORS AND CLASSIFICATION

There are several factors to the fistula injury that influence the outcome to surgery, both with being able to successfully close the fistula at operation and also the rate of ongoing urethral incontinence despite a closed fistula. These include (1) urethral involvement, which makes the repair more complex as the urethra needs to be reconstructed and continence maintained despite the loss of the continence mechanisms, (2) severe vaginal scarring, making access to the fistula for repair difficult or impossible without relaxing incision and increases the likelihood of ongoing incontinence, (3) the size of the fistula, and (4) finally, the amount of bladder tissue loss, reflected in a small remaining bladder capacity [23,45,46].

There is no universally agreed classification for obstetric fistula. There are two classification systems currently in use, the Waaldjik and the Goh. The Goh system has been validated and seems predictive of outcome [45,47,48]. It looks at the site of the fistula in relation to the external urethral meatus, its size, and the amount of scarring. This is based on three of the four known predictive factors for outcome (above). It is difficult to measure bladder volume before repair so site, size, and scarring are examined. The measurements of site and size are objective, but the measurement of scarring tends to be more subjective (site size scarring, Goh classification Table 109.1). The Waaldjik system concentrates more on the urethra and if it is a circumferential defect or not [49]. There has been one study comparing the prognostic value of both systems and concluded that the Goh system had significantly better predictive value of obstetrics fistula closure [50].

TIMING OF REPAIR

It has been commonly taught that a surgeon should wait for roughly 3 months after the injury before attempting repair [51]. The rationale behind this is to allow the necrotic tissue to slough away and the often suboptimal tissue that remains to recover before attempting to operate. There has been one compelling paper advocating earlier repair, to repair as soon as the dead tissue has come away, with active debridement while waiting. This affords a good success rate and enables the woman to regain health more quickly, before she is made an outcast [52]. However, the tissues are much more difficult to handle at this stage, with the tissues tearing and sutures cutting out. This series was done by an extremely experienced fistula surgeon and the results are yet to be replicated in other units and with more inexperienced surgeons. It would be prudent for the inexperience fistula surgeon to rely on the traditional teaching of waiting for 3 months.

Table 109.1 Classification for Cardozo Text

		Breakdown of repair (n = 987) (%)	**Ongoing incontinence despite repaired fistula (n = 987) (%)**
	Classification of genitourinary fistula with comparative outcomes		
Site			
Type 1	Distal edge of fistula >3.5 cm from the external urinary meatus	2	3
Type 2	Distal edge of fistula 2.5–3.5 cm from the external urinary meatus	1.6	20
Type 3	Distal edge of fistula 1.5 to <2.5 cm from the external urinary meatus	3	32
Type 4	Distal edge of fistula <1.5 cm from the external urinary meatus	3	46
Size			
a	Size <1.5 cm in the largest diameter	2	10
b	Size 1.5–3 cm in the largest diameter	0.5	22
c	Size >3 cm in the largest diameter	4	30
Scarring			
i	None or only mild fibrosis (around fistula and/or vagina) and/or vaginal length >6 cm, normal capacity	2	7
ii	Moderate or severe fibrosis (around fistula and/or vagina) and/or reduced vaginal length and/or normal capacity	2	24
iii	Special consideration, e.g., postradiation, ureteric involvement, circumferential fistula, previous repair	4	41
Overall results		2.7	23.2

	Classification of genitoanorectal fistulas
Site	
Type 1	Distal edge of fistula >3 cm from the hymen
Type 2	Distal edge of fistula 2.5–3 cm from the hymen
Type 3	Distal edge of fistula 1.5 to <2.5 cm from the hymen
Type 4	Distal edge of fistula <1.5 cm from the hymen
Size	
a	Size <1.5 cm in the largest diameter
b	Size 1.5–3 cm in the largest diameter
c	Size >3 cm in the largest diameter
Scarring	
i	None or mild fibrosis around the fistula and/or vagina
ii	Moderate or severe fibrosis
iii	Special consideration, e.g., postradiation, inflammatory disease, malignancy, previous repair

The pathology for iatrogenic fistula is different, being a discreet injury rather than ischemic over a broad area. These can be operated upon as soon as it is practical. If the fistula is iatrogenic in an ischemic operative field, such as a cesarean after 2 days of labor, it could be argued to follow the same guidelines as for obstructed labor fistula.

IMMEDIATE MANAGEMENT

If a patient presents within the first few weeks of injury, while the tissues are still raw, a large gauge catheter should be inserted and kept on free drainage for up to 4 weeks. With this management, up to 20%–40% of smaller vesicovaginal fistulae will heal [52,53].

ROUTE OF REPAIR

The route of repair, vaginal or per abdomen, traditionally depends on the experience and training of the surgeon. Doctors with gynecological training often favor the vaginal route, while doctors with urological training favor the abdominal route. The abdominal route might be found easier with high vault, juxtacervical, or vesicovaginal/vesicouterine fistulae. Even these cases can be confidently managed vaginally with experience, which has obvious benefits postoperatively. A recent publication comparing vaginal to abdominal route of repair showed that the abdominal route seemed to be associated with higher rates of closure. However, of the cohort, only 5% of cases underwent an abdominal repair and were more likely to be higher in the birth canal, which have a better outcome than those lower in the birth canal anyway [23,54]. The choice of route of repair seems to be reflected more on the surgeon’s training and experience.

TREATMENT

Many surgical techniques have been described, including the open transvesical and transperitoneal or combined techniques, fibrin glue, laparoscopic techniques, partial colpocleisis, and cauterization. The most popular “flap-splitting” technique will be described here.

At a meeting of “fistula surgery experts” hosted by the WHO in 2002, it was agreed that the flap-splitting technique should follow the principles of

1. Exposure of the fistula and protection of the ureters
2. Wide mobilization of the bladder off the vagina/cervix/uterus and surrounding tissues
3. Tension-free closure of the bladder
4. Dye test to confirm watertight closure of the bladder

Exposure of the Fistula and Protection of the Ureter

The patient is placed in the exaggerated lithotomy position with the patients’ buttocks over the end of the operating table. The table is placed in steep Trendelenburg, which will bring the anterior vaginal wall perpendicular to the surgeons gaze.

In up to 28% of patients, there is significant vaginal scarring that renders it impossible to insert a speculum [21]. Lateral relaxing incisions are necessary to release the scar, expose the fistula, and then be able to insert the speculum for adequate exposure.

In all trigonal and supratrigonal fistulae, except the very small, the ureters should be identified and catheterized (Figure 109.7). This can be done through the fistula and the catheter ends advanced through the urethra. This is to prevent inadvertent injury during dissection and inadvertent suturing of the ureter during repair.

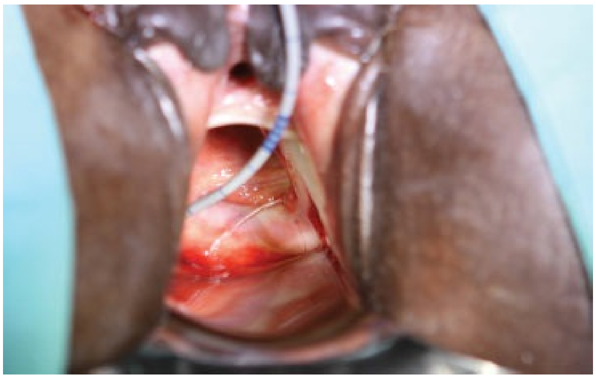

Figure 109.7 Right ureter catheterized, left ureter spurting urine at the edge of the fistula.

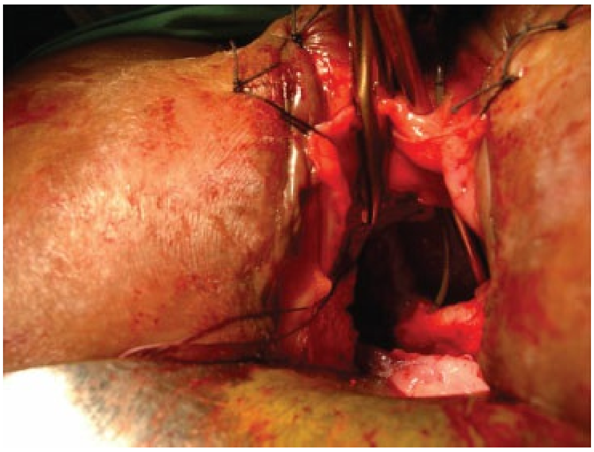

Figure 109.8 Wide mobilization of the bladder. Note mobilization along right lateral pelvis.

Wide Mobilization of the Bladder off the Vagina/Cervix/Uterus and Surrounding Tissues

The hallmark of successful vesicovaginal fistula surgery is wide mobilization of the bladder, releasing it from scarred attachments to the surrounding structures and excision of the scar tissue from the bladder and surrounds, so good viable tissue is approximated in the repair. Almost all mobilization IS obtained proximally, laterally and at times anteriorly into the cave of Retzius. The distal margin of the fistula usually involves the urethra WHICH is more fixed, so mobilization of the vaginal tissues off the urethra is merely enough to be able to place a suture in the urethra/bladder. (Figure 109.8).

Tension-Free Closure of the Bladder

Once the bladder has been successfully mobilized, the bladder is sutured together under no tension. If tension remains on the suture line, it runs the risk of disrupting. The initial sutures secure the angles of the fistula. The bladder is closed with interrupted sutures (2-0 polyglycolic acid) approximately 4 mm apart. Usually, this is done in a single layer to the bladder muscle.

Dye Test to Ensure a Watertight Closure

To ensure that a watertight closure has been achieved, 50–100 mL of dilute colored fluid (dilute gentian violet is often used) is instilled into the bladder (Figure 109.9).

To Graft

A contentious issue in fistula surgery is whether to use an interpositional graft. It has been traditionally taught this aids healing by bringing a fresh blood supply to the compromised tissues surrounding the fistula. It may also plug any undetected microleaks along the repair. The most common graft used is the Martius fibrofatty graft harvested from the labia majora. Other grafts have been described, being of the gracilis muscle, peritoneum, omentum, and broad ligament. One small study did show an increased success rate with using the Martius graft [55]. However, based on a large study done in Ethiopia [56], many fistula surgeons no longer use grafts routinely and note similar success rates to graft interposition. There are instances when a graft may be advantageous, such as for a patient who has had multiple unsuccessful operations or when the tissues are very thin and fragile, say with the complete reconstruction of a neourethra.

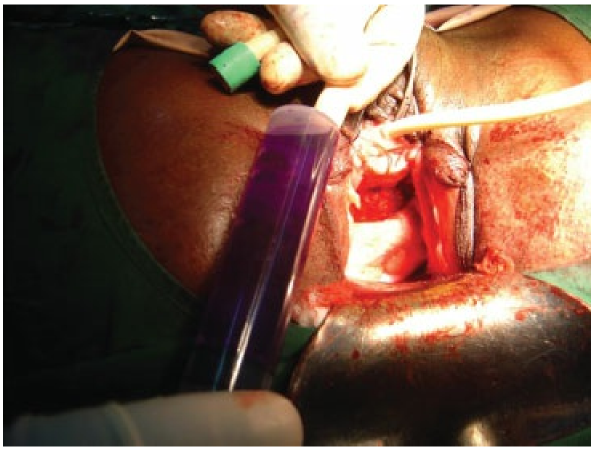

Figure 109.9 Tension-free bladder closure and testing the integrity of the closure with a dye test.

To form a Martius graft, an incision is made longitudinally along the bulge of the labia majora. The fat underneath is exposed and a flap of fat developed from anterior to posterior with the pedicle still being attached posteriorly. A tunnel is created into the vagina superficial to the inferior pubic ramus, beneath the bulbocavernosus and vaginal skin. The fat is introduced into the vagina and placed over the fistula repair with anchoring sutures (Figure 109.10).

The vaginal and labial skins are repaired, taking precaution to prevent hematoma formation.

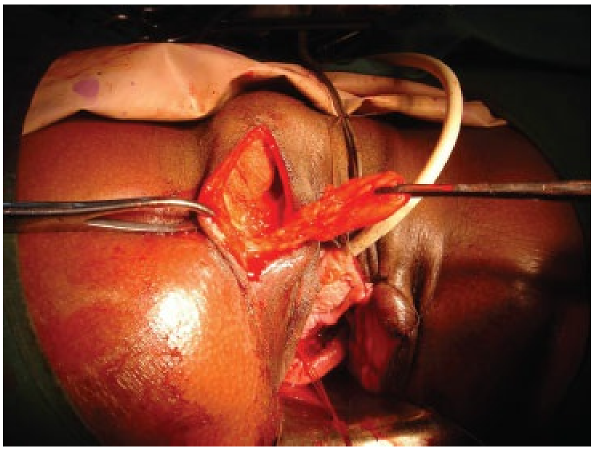

Figure 109.10 Martius graft/flap, harvested from the right labia majora, before tunnel formation and introduction into the vagina.

PARTICULAR SURGICAL PROBLEMS

Absent Urethra

Up to 5% of obstetric fistulae have the entire urethra sloughed, which poses one of the most difficult problems for the fistula surgeon [21,57]. An anatomical closure may be quite possible, but a functioning closure is very difficult. There are two ways commonly used. First, a new urethra may be created from the remaining paraurethral tissues. Initial incisions are made about 2.5–3 cm apart either side of where the new urethra will lie (Figures 109.11 and 109.12). Flaps are then created and sewn over a Foley catheter and this delicate structure is anastomosed to the bladder. A graft is sometimes placed to help support and nourish this frail construction, a gracilis graft has been described [58], but if a graft is used, the Martius graft is the common choice (as mentioned earlier). The vaginal epithelium is drawn over the repair.

Second, a new urethra may be created from an anterior flap of the bladder tissue. A longitudinal flap is created after dissecting the bladder off the symphysis pubis and then advancing this toward the urethral meatus. The flap sewn into a tube over a Foley catheter, a graft placed, and the vagina repaired [59]. This is often not possible with obstetric fistulae as these types of fistulae often result in much loss of the bladder tissue; this procedure will thus decrease the size of an already small bladder.

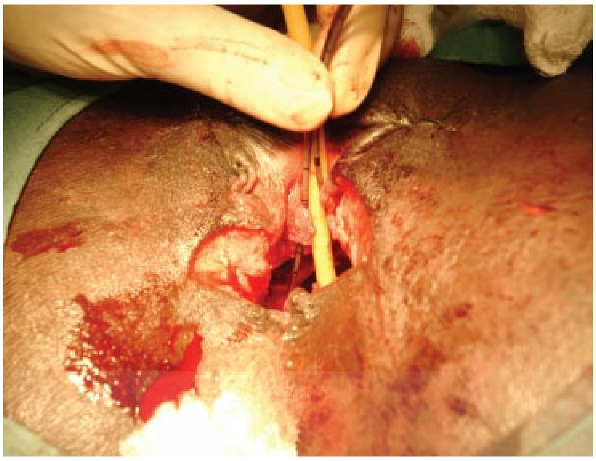

Figure 109.11 A patient with absent urethra. Mobilization of the remaining tissues to roll over a Foley catheter.

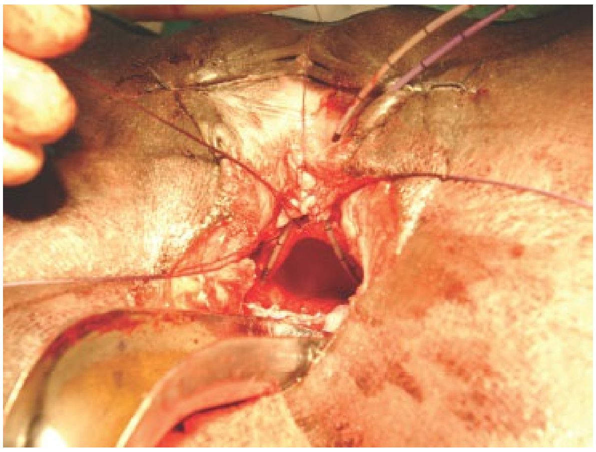

Figure 109.12 Neourethra in the same patient as Figure 109.11. She was able to be continent using a urethral plug.

When a new urethra is made from remaining paraurethral tissues, urethral strictures may form in the long term resulting in urinary retention and voiding disorders. There is also a high rate of residual incontinence after repair. This is presumably stress urinary incontinence. To help reduce this, a sling of levator muscle can be used to support the repair, taking a flap of levator from the right and left (or scar tissue, if there is no other tissue remaining), and sewn in the midline [60].

Circumferential Fistulae

A circumferential fistula occurs against the posterior pubic symphysis. In these cases, the bladder is completely detached from the remaining urethra (Figures 109.13 and 109.14) The bladder needs to be mobilized not only off the vagina and surrounding structures, but also off the pubic symphysis, dissecting high into the cave of Retzius. The bladder is then advanced on mass to the urethra and anastomosed to it.

Again, there is a high rate of residual urinary incontinence, presumably stress urinary incontinence. This may be improved by the use of a levator muscle sling employed at the time of repair [60,61] (Figure 109.15).

Rectovaginal Fistula

The techniques for repair are similar to that of the vesicovaginal fistula: flap splitting with wide mobilization, excision of scar tissue, repair of the fistula under no tension, and repair of vaginal epithelia. Grafts are rarely used for rectovaginal fistula, but the Martius graft may be employed if a long enough pedicle is developed for it to reach the operative site. Rectovaginal fistulae can be comfortably repaired per vaginum, but some surgeons may prefer to use the abdominal route for the high fistula adhered to the sacral promontory. Diverting colostomies were used liberally, but in more recent times, fistula surgeons have largely stopped using these with no appreciable difference in outcomes and saving the patient two extra procedures—opening and closing the colostomy. A diverting colostomy would still be advised for very large (>5 cm in diameter), high, and circumferential bowel fistulae, where a breakdown of repair could leak into the peritoneal cavity. Low, large rectovaginal fistulae can still be safely repaired without a colostomy. If there is a diverting colostomy, there is no need for the bowel to be prepared adequately before the operation.

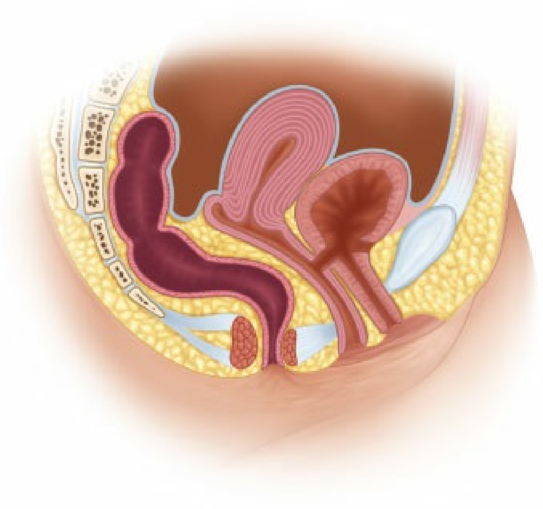

Figure 109.13 Circumferential fistula. There is complete detachment of the bladder from the urethra.

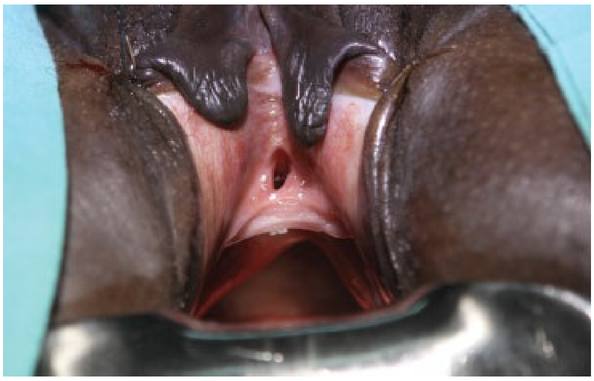

Figure 109.14 Circumferential fistula. Note small remaining “tag” of the urethra, then the anterior lip of the bladder, and some 4–5 cm proximally attached to the pubic bone.

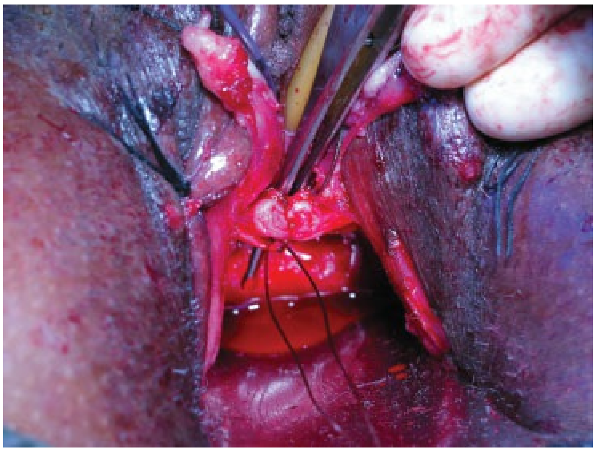

Figure 109.15 Supportive sling for urethral injuries. Made from the levator complex or if there is no levator remaining, from scar remnants.

No Vaginal Tissue Remaining

About 28% of cases will need some form of vaginoplasty due to vaginal skin loss and after repair, dyspareunia and apareunia can result [39,41]. Vaginoplasty may be anything from a simple Fenton-type procedure to release vaginal scarring to reconstruction of a new vagina from tissue flaps, anteriorly from the labia minora and majora and posteriorly with rotational flaps of the gluteal skin. This does result in a scarred vagina. Other options are a neurovascular flap of the tissue from the groin crease or a sigmoid neovagina [62]. Some have used a modified Martius graft with the overlying skin being swung in with the flap. However, this skin is hair bearing and can cause considerable discomfort.

POSTOPERATIVE CARE

The ureteric catheters can be removed upon completion of the operation if the ureteric orifices were far from the fistula margin. If they were close to <1.5 cm, or on the margin, they remain for 5–7 days to ensure that the ureters do not obstruct with postsurgical swelling. Occasionally, the ureters will need reimplanting; if so, the catheters remain in place for 10–14 days.

The Foley catheter remains on free drainage for 10–14 days postoperatively. For most injuries, the Foley catheter can be safely removed after 10 days. A small randomized controlled trial showed this to be as effective when compared to 14 days [63,64]. If a breakdown occurs due to poor surgical technique, it usually occurs soon after the operation, in the first few days. If it occurs from poor healing or infection, it usually breaks down on day 7–9. Hence, it seems wise to leave the Foley catheter in place at least until this later danger time has passed. This takes meticulous nursing as a full bladder will put pressure on the repair site and may even disrupt it. The patient should be educated that if their catheter is not draining or they experience bladder pain (indicating a full bladder), they should notify the nurse immediately and have the catheter either irrigated carefully or changed. There has been some cases that break later after the repair, after the patient has returned home, which can occur weeks to months after discharge [39,65].

A vaginal pack is usually placed at the end of the operation. This reduces the operative dead space and is removed the following day.

The patient should mobilize as soon as she is able; however, it is important that the indwelling catheter is secured with either a strong tape or a suture so that the balloon of the catheter does not pull on the fistula repair site while the patient is mobile.

A high fluid intake is encouraged to keep the bladder irrigated.

A normal diet is encouraged. The stools should be kept loose in cases of rectovaginal fistula with a rapid return to a normal diet and use of laxatives.

Spinal headaches are quite common as fine-pencil-point spinal needles are not available. This can be treated with nursing supine, simple analgesia, and caffeine.

RESULTS

The fistula can be closed in up to 94%–97% of cases with their first operation [4,39]. If a fistula is not closed successfully, repeat operations prove difficult. With the second operation, the success rate drops to 79% and with the third, 53% (A. Browning, unpublished work). Successful closure, however, does not necessarily equate to a functional cure. Rates of postoperative incontinence, largely stress urinary incontinence, vary between 5.6% and 33% [4,60].

The postoperative incontinence rate appears to be decreased by using a supportive sling of levator muscle or scar tissue if there is no muscle remaining. This is done at the time of primary repair for all significant urethral injuries [60] (Figure 109.15).

This ongoing incontinence rate of 5.6%–33% is observed at short-term follow-up, within the first few days of catheter removal. With time and bladder retraining and strengthening of pelvic floor muscles, this may improve with time. In northern Nigeria, patients have been followed up over a period of 6 months and 15% of closed fistula patients still have some incontinence at time of final follow-up (K. Waaldjik, personal communication). At the Addis Ababa Fistula Hospital, patients are asked to return in 6 months if they are still experiencing leakage; however, only 8% of patients do [4], probably because the journey is long, difficult, and expensive. In a more rural fistula hospital in Ethiopia, 70% returned for follow-up, and 50% of those patients discharged with mild urethral incontinence (leakage of walking and/or coughing or straining) were cured of their symptoms with 6 months of conservative therapy. Only 18% of patients suffering with more severe urethral incontinence, leaking with walking, sitting, and/or lying, were improved after 6 months of conservative therapy [39]. The latter group were therefore encouraged to use the urethral plug to keep them dry, and all were encouraged to return to hospital for follow-up and a secondary incontinence procedure if it was still needed [39,66].

The rectovaginal fistula seems to have a lower initial success rate at 73% [21]. A more recent but unpublished series of nearly 1000 fistula patients with 111 rectal fistulae put the success rate higher at 98%. However, with subsequent operations, it is almost always possible to get a successful closure although the patient may have some remaining anal flatal and/or stool incontinence from a poorly functioning anal sphincter [26].

POSTOPERATIVE COMPLICATIONS

Ongoing Incontinence

The most concerning complication of fistula surgery is residual incontinence. This is thought mainly to be stress urinary incontinence in type, but detrusor overactivity must also play a role. One study of 22 women with severe incontinence following fistula closure underwent urodynamic assessment and 41% had urodynamic stress incontinence (USUI), 14% had USUI and poor compliance, 41% had USUI and detrusor overactivity, and 4% had voiding disorder and overflow incontinence [67].

There have been several operations described for women suffering urethral incontinence after fistula repair. The pathology is quite different to stress urinary incontinence seen in the west as the pathology usually includes tissue destruction of the urethra, so repairing the fistula can restore the anatomy, but not the function. Operations concentrate on supporting and at times, obstructing the urethra.

The use of synthetic material has been discouraged due to expense, the ethical consideration of placing material that may cause complications later in areas where women cannot easily receive medical help, and when artificial urethral slings have been used in these patients, the results have been discouraging. One trial in Niger compared fascial slings and synthetic slings, outcomes were similar, but there was a significant problem with erosions in the synthetic arm, and for both arms, the success was lower than other series (see the following texts) [68].

A sling operation was described by Carey and Goh in which urodynamically selected patients have a tension-free sling of rectus sheath inserted beneath the midurethra. This is done with open dissection into the space of Retzius and the sling inserted under direct vision. The open step is necessary due to the often dense retropubic scarring and high risk of bladder perforation if done as closed procedure with use of a trocar to pass the sling retropubically. A flap of omentum is inserted between the freed urethra and symphysis pubis to try and prevent further scarring. This procedure has a 66% cure rate at 14 months but in carefully selected and screened patients [66].

Simpler methods include merely vaginal mobilization of the urethra and bladder neck off from the pubic ramus and plication of the lower bladder, bladder neck, and urethra in an attempt to elongate the urethra. Most patients who do return with ongoing incontinence problems have a short urethra of only 1.4 cm. This can elongate the urethra to 3.1 cm. A sling of levator muscle or scar tissue is used if there is no muscle complex remaining. This gives a 70% complete cure rate with no ongoing incontinence and 15% improved in their continence and 15% have no change [69]. This improvement is maintained in a 6-month follow-up but longer-term follow-up is not available. Those not improved or improved slightly but not satisfactorily can use the urethral plug as the urethra is now longer and narrower.

Urinary Retention

After removal of the catheter on day 10 or 14 after fistula repair, up to 8% of patients will have urinary retention with overflow. All patients should have a residual urine volume checked after their catheter is removed. It is usually treated with recatheterization with “bladder training,” that is, clamping the catheter and releasing every 2 hours. After 48 hours, 70% of patients are voiding normally and the remaining will need a time of self-catheterization.

Frequency and Voiding Disorders

It has been noticed that on removing the catheter patients often complain of frequency of micturition and some voiding problems. It was often thought that this may resolve with time and could have been secondary from a prolonged catheterization; however, recent evidence from Ethiopia shows this problem is ongoing in at least some women. Of the 35 women studied with persistent incontinence despite fistula closure, 77% had more than eight episodes of voiding in 24 hours and 51% voiding more than 15 times. This was at 6-month follow-up [70]. A further 13 persistently incontinence women were studied and this revealed a significant number of voiding dysfunctions with low flow rates, prolonged voiding times, and the average voided volume of only 72 mL [71].

Sexual and Reproductive Complications

Other ongoing problems include dyspareunia in 11% of those sexually active (only 35% were sexually active at 6 months follow-up), 30% of women will have ongoing amenorrhea at 6 months, and nearly half of whom do not have an obvious cause, such as being postmenopausal, had a cesarean hysterectomy at the time of delivery, being pregnant, or on a long-acting progesterone contraception [39]. These “less obvious” reasons could be Sheehan’s or Asherman’s syndrome.

Social and Mental Health

Most patients return to their normal living arrangements once they are cured and start to attend social functions and return to work. Several recent studies have shown improvements in social, physical, and mental health once they are cured [33,34,36]. Some, however, do not and still suffer ongoing mental health problems and difficulties with reintegrating back into their communities. Further measures need to be taken to help women return to a normal life.

FAILED REPAIRS

One study examined 71 failed repairs. All of the 71 cases had a fistula described as complicated, meaning that they had one or more of the following: excessive scarring, total destruction of the urethra, ureteric orifices outside the bladder or at the edge of the fistula, a small bladder, both recto- and vesicovaginal fistulae in conjunction, or the presence of bladder stones. Patients were more likely to have a failed repair if they (1) had a ruptured uterus at the time of labor, (2) had a previous failed repair, (3) presented with limb contractures, (4) presented malnourished or in poor health, (5) had a fistula described as complicated, and (6) had blood transfusion [72]. If a patient's repair has broken, it is important to counsel the patient appropriately as there are likely to be discouraged and tearful. It is usually recommended that you should wait for 3 months before attempting another repair. Provisions need to be made for the patient to return to the hospital or if the patient is suffering severely, they can stay within the hospital and wait for their second repair.

IRREPARABLE FISTULA

The term irreparable fistula may be misleading, but some injuries are so severe that no bladder tissue remains to be repaired. The only option for these women to have any quality of life is either to have a bladder augmentation or a urinary diversion operation.

Bladder augmentations are not without their problems. Patients who have such severe injuries often have their urethra affected, so even with a good reservoir, they are still unable to hold their urine. If the urethra is intact, then self-catheterization may be needed to effect full drainage of the bladder as the augmented bladder cannot contract, or mucous secreted from the bowel lining may block the urethra. This may be unmanageable for a woman living in the developing world, far from a supply of catheters and clean equipment.

The diversion operations commonly used are direct ureterosigmoidostomy, Mainz II pouch, or ileal conduit. The former two options require an intact anal sphincter and the woman to agree to pass urine through the anus. The Mainz II shows promise for these women in developing nations as there are perhaps less long-term complications following this procedure as compared to the direct ureterosigmoidostomy [73–75].

The ileal conduit restricts a patient to living near a service that can supply the conduit bags, which are often rare in the developing world. The patient also needs to be close to a health center that knows how to deal with any complications. The ureters and kidneys in these women are often dilated and compromised and ascending infections can be common.

There are anecdotal cases of ileal conduits being performed on patients, and then the patient has been unable to access bags, leaving her in a worse state than she was to start with.

THE FUTURE

Obstetric fistula, like many morbidities suffered by women during labor, is preventable. This should be an attainable dream in the twenty-first century and this suffering is placed in medical texts of yesteryear. The task, however, is immense with up to many thousands of new obstetric units being required for Africa alone to supply adequate maternity care [76]. In tandem with this, roads need to be built, transport systems put in place, and, most importantly, men and women educated. Until all this is achieved, the obstetric fistula patient will still need our caring attention.

Urethral Diverticulum and Fistula

Kathleen C. Kobashi

INTRODUCTION

A urethral diverticulum (UD) is a periurethral cystic structure that may or may not communicate with the urethra [1]. UD presents a diagnostic and therapeutic challenge to the clinician. They may be completely asymptomatic or exceedingly symptomatic. They may be anatomically simple or complex and are associated with a range of conditions that may need to be addressed concomitantly.

Incidence

The incidence of female UD is estimated to be approximately 0.02%–6% [2–5]. However, it is believed that this represents an underestimate and, with increased clinical suspicion and improved diagnostic techniques, the true incidence may prove to be higher [6] at least in symptomatic women. Indeed, UD has historically been an underdiagnosed condition. In 1953, Novak was quoted as saying, “This is a relatively rare condition and no gynecologist will see more than a few in a lifetime” [7]. However, the frequency of diagnosis has increased with more sensitive imaging modalities.

History

The existence of UD has been known since at least the early nineteenth century, when Hey reported the first case in 1805 [8]. In 1938, Hunner reported three cases associated with calculi and commented on the rarity of the condition [9]. In 1956, Davis and Cian reported 50 cases; more than had been reported previously in the entire history of the Johns Hopkins Hospital [10]. They also developed a double-balloon catheter to be used in conjunction with positive-pressure profilometry to facilitate the diagnosis of UD.

BACKGROUND

Etiology and Pathophysiology

Patients typically present in the third to sixth decades of life, with a mean age of 45 years [11]. Rarely, UD has been diagnosed in neonates and children [12,13]. A racial predilection has been suggested, with diagnosis in African-American women being 2–6 times that in white women [14]; however, Ganabathi et al. [11] found no racial differences. A concomitant UD has been incidentally noted in 1.4% of women diagnosed with stress urinary incontinence (SUI) [15,16].

Periurethral glands are tubuloalveolar structures located posterolaterally beneath the periurethral fascia in the proximal two-thirds of the urethra. They drain into the distal third of the urethra [17]. There are two main schools of thought regarding the etiology of UD—acquired and congenital. The most widely accepted theory is UD formation due to infection of the periurethral gland. Infection leads to obstruction of the glands, local abscess formation, and eventual rupture into the urethral lumen, as first described by Routh [18].

Trauma secondary to childbirth or forceps delivery remains a problem in developing countries, possibly contributing to UD formation [19]. However, with current obstetric technology, traumatic delivery is no longer a prevalent factor in developed nations. In fact, 15%–20% of patients diagnosed with UD are nulliparous, thereby refuting this as a sole etiology [13].

Although there has been some evidence supporting a congenital etiology, this theory seems less likely to be the principle etiology given that two large series included no patients younger than 10 years of age [14,20]. Faulty union of primordial folds, genesis from cell rests or Gartner’s duct remnants, and Müllerian remnants causing vaginal cysts have all been suggested as possible etiologies of UD, and it may be possible that a congenital defect, while not a direct cause of UD formation, may place one at risk for developing a UD later in life [4]. The discovery of mesonephric adenoma and adenocarcinoma has implicated Gartner's duct remnants. Paneth cell metaplasia lining a UD also supports a congenital basis [21]. Blindending ureters resulting from an aborted ureteral duplication may rarely lead to an anterior UD [22]. Other suggested etiologies of UD include high-pressure voiding against outlet obstruction, urethral calculi, instrumentation, and complications of previous anterior vaginal surgery [23]. UD has been described following transurethral collagen injection therapy for SUI [24,25]. Clemens et al. [24] hypothesized that the collagen injections resulted in obstruction of the periurethral glands resulting in the gradual accumulation of glandular secretions and subsequent development of noncommunicating diverticula.

Associated Conditions

Symptoms or sequelae associated with UD include incontinence, infection, stones, and malignancy. Urinary incontinence is common in patients with UD. Ganabathi et al. [11] reported a 65% incidence of SUI among patients with UD (57% with SUI as the presenting complaint). These patients may also suffer from urgency incontinence or "paradoxical incontinence," in which urine stored in the UD is lost during stress maneuvers [4].

Approximately 25%–33% of patients with UD present with recurrent urinary tract infections (UTIs), including some who suffer from systemic infections. The most common infecting organisms of UD are *Escherichia coli*, chlamydia, and gonococcus; however, multiple organisms have been cultured [4,26]. Up to 13% of patients present with calculi in the UD, and this can be confirmed by plain radiograph [27,28]. Stones form secondary to stasis, infection, and chronic inflammation in the UD [29] (Wittich, 1987). Stones can be multiple, and in some cases, quite large. A 5 × 6 cm stone was discovered in the UD of an elderly woman during workup for a firm vaginal mass. Urethrovaginal fistula (UVF) secondary to rupture of a UD is also a potential complication [30,31].

Table 110.1 Frequency and Outcome for Treatment Modalities Used for Carcinoma in a Urethral Diverticulum

Treatment	**Patients (*n*)**	**Disease-free (%)**	**Local recurrence (%)**	**Death/metastasis**
Diverticulectomy	27	9 (33)	13 (48)	5 (19)
Radiation	10	2 (20)	5 (50)	2 (20)
Diverticulectomy + radiation	16	8 (50)	5 (31)	3 (19)
Anterior exenteration	26	19 (73)	1 (4)	6 (23)

Source: Shalev M et al., *Urology*, 59, 773iii, 2002.

Although the vast majority of UDs are benign, malignant change has been reported [32]. Approximately 100 cases of neoplasm within a UD have been reported in the world literature [33–37]. There have also been reports of nephrogenic adenoma, a benign metaplastic condition [32,38–44]. Malignancy must be considered whenever a UD is diagnosed, particularly when accompanied by hematuria, induration or firmness of a UD on physical examination, noncalcified filling defects within the UD on radiography, or a visible lesion on cystoscopic examination. Despite the fact that squamous epithelium lines most of the urethra in addition to the fact that squamous carcinomas are the most frequently diagnosed histopathologic malignancy in the female urethra, adenocarcinoma is by far the most common histopathological condition demonstrated within UD, specifically [39,45]. This lends further support to the theory that UDs develop from glandular origins. More than 80% of the diverticular cancers seen are either adenocarcinoma (61%) or transitional cell carcinoma (27%) [45–47]. Squamous cell carcinoma is rare, comprising only 12% of UD malignancies [47]. When identified within a UD, squamous cell carcinoma appears to be very aggressive, with a mortality rate of 78% at 3 years [48]. One case of a high-grade serous carcinoma, a histopathology that typically arises in the uterine corpus or in the Fallopian tubes/ovaries has recently been reported [49].

Treatment of diverticular carcinoma includes wide local excision for localized disease (Seballos et al., 1995). Adjuvant radiation therapy or chemotherapy may also be indicated for extensive malignancy or for nonsurgical candidates [50,51]. Survival is a function of stage [51] and grade [50] of the disease. Squamous cell carcinomas are typically diagnosed at an advanced stage, with all reported cases presenting at stage T2 or higher, and require a more aggressive treatment approach [50,52–55]. Because of the relative rarity of carcinoma in UD, it has been difficult to develop a common definitive treatment strategy (Table 110.1) [56]. Among 79 patients reviewed by one center with follow-up ranging from 6 months to 10 years, anterior pelvic exenteration appeared to offer the highest likelihood of prolonged disease-free survival [48]. Both laparoscopic radical cystectomy and robotic anterior exenteration have reportedly been performed for clear cell adenocarcinoma in a UD [57,58].

PRESENTATION AND DIAGNOSIS

Clinical Symptoms

Patients with UD present with a variety of symptoms ranging from irritative voiding complaints to pelvic pain and dyspareunia (Table 110.2) [4,59]. The classic triad of UD is known as the “3 Ds”—dysuria, dyspareunia, and dribbling. However, few patients with a UD actually have the full triad, [60] and many patients are completely asymptomatic. Urinary urgency, frequency, and hematuria may also occur with UD [61]. Nevertheless, the diagnosis is often not straightforward and UD may mimic other pelvic floor disorders, resulting in diagnostic delay [62].

In a review of 46 consecutive cases of UD, the mean interval between onset of symptoms to diagnosis was 5.2 years [62]. Frequently, patients receive an initial, erroneous diagnosis for which a variety of treatments are considered or attempted (Table 110.3). A high index of suspicion is required in order to diagnose UD because many patients may not be overtly symptomatic upon initial evaluation. In cases of persistent irritative voiding symptoms, pelvic pain, and urinary incontinence unresponsive to therapy, UD should be kept in mind and excluded [62].

Table 110.2 Signs and Symptoms of Urethral Diverticula

Symptoms	Signs
Vaginal or pelvic mass	Recurrent UTI
Pelvic pain	Hematuria
Urethral pain	Vaginal or perineal tenderness
Dysuria	Urinary retention
Urinary frequency	Vaginal mass
Postvoid dribbling	Expression of urethral
Dyspareunia	discharge with stripping of
Urinary urgency	the anterior vaginal wall
Incontinence	
Urinary hesitancy	
vaginal or urethral discharge	
Double voiding	
Sense of incomplete emptying	

Source: Rovner ES, Chapter 78: Bladder and urethral female diverticula, in: Wein AJ et al., eds., *Campbell-Walsh Urology*, 10th ed., Saunders, Philadelphia, PA, 2012, pp. 2262–2289.

Table 110.3 Most Common Initial Diagnoses and Subsequent Treatments Given to Patients before Identification of a Urethral Diverticulum

Diagnosis	Treatment
Chronic cystitis trigonitis	Long- or short-term antibiotics
SUI	Anti-incontinence surgery
Urge incontinence	Anticholinergics
Interstitial cystitis	Hydrodistention
Idiopathic pelvic pain syndrome	DMSO instillation
syndrome	Tricyclic antidepressants
Urethral syndrome	Urethral dilation
Vulvovestibulitis	Vaginal creams—antifungal/antibiotic

Cystocele	Surgery
sensory urgency	Anticholinergics
Psychosomatic disorder	Psychotherapy

Physical Examination

Patients with UD will often have anterior vaginal wall tenderness, with or without a concomitant palpable suburethral mass [62]. Digital pressure along the urethra may demonstrate expressible purulence or blood from the UD that can be seen emanating from the urethral meatus (Figure 110.1) [63]. Firmness of the area may be indicative of a diverticular stone or neoplasm. Rarely, some patients are without any pertinent physical findings, and workup is pursued only on clinical suspicion based on the patient's history. Importantly, the clinician should also evaluate urethral mobility and examine for evidence of SUI, which can be addressed at the time of repair of the UD if deemed necessary.

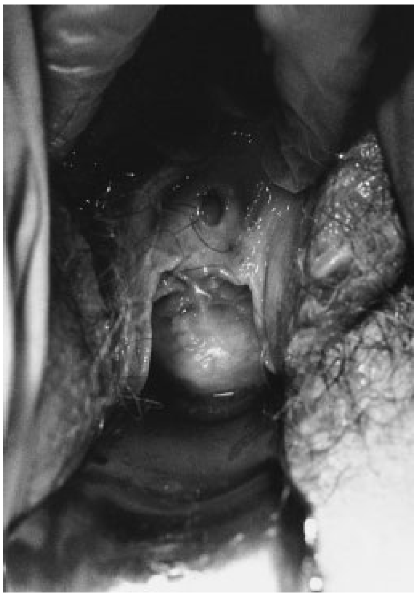

Figure 110.1 Urethral diverticulum presenting as an anterior vaginal mass. (Reproduced from Ganabathi K et al., *J Urol*, 152, 1445, 1994. With permission.)

Differential Diagnosis

The differential diagnosis of urethral and meatal/perimeatal masses (Figures 110.2 and 110.3) is illustrated in Tables 110.4 and 110.5, respectively. Note that Table 110.5 includes conditions that occur in locations distal to the location of the majority of UD; however, they should be considered in the differential diagnosis [64].

Classification System

Leach et al. [65] created a system for classification of female UD known as the L/N/S/C3 system. This acronym represents location, number, size, configuration, communication, and continence. The system aims to facilitate preoperative assessment of UD and standardize the classification, thereby simplifying comparisons between series. Table 110.6 illustrates the classification of 63 patients.

EVALUATION

Endoscopic Examination

A blunt-tip female urethroscope with a short sheath beak and a 0° or 30° lens is used to evaluate the urethra. The anterior vaginal wall is compressed with a finger in the vagina, and the urethral lumen is inspected for any expression of effluent from the floor or the roof of the urethra (Figure 110.4). Fifty percent of patients will have multiple diverticula, and more than half of the UDs will communicate with the urethra in its middle third [3]. Cystoscopy is the only diagnostic tool that allows direct inspection of the urethra and bladder and, in some cases, may facilitate diagnosis of a diverticular neoplasm or calculus; however, the value of cystoscopy as a diagnostic tool has been questioned [66].

The ostium of the diverticular neck can be difficult to visualize between collapsed urethral folds, and noncommunicating diverticula (periurethral cysts) will not have a visible orifice [67,68]. Cystoscopy does not provide any information regarding size, shape, or appearance of the diverticulum or the diverticular wall [69]. Additionally, cystoscopy is invasive and carries the risk of UTI and may cause significant pain in a woman with a diverticulum. Furthermore, a negative finding on cystoscopy does not rule out the absence of a UD. Imaging studies should be considered as cystoscopy will frequently fail to diagnose UD.

Urodynamic Evaluation

Urodynamic studies are not required in the evaluation of all patients with UD but may be useful for patients with symptoms of SUI or bladder dysfunction [70–72]. These symptoms may include urinary leakage with increased intra-abdominal pressure, urgency incontinence, or spontaneous loss of urine that may represent intrinsic sphincter deficiency, paradoxical incontinence (i.e., loss of urine that has “pooled” in the UD), or poor emptying. Identification of these problems is critical in proper surgical planning. In patients with SUI, appropriate correctional surgery can be considered at the time of diverticulectomy. The urodynamic findings in 55 women studied by Leach and Ganabathi [70] are noted in Table 110.7.

Radiological Studies

Careful evaluation of UD can facilitate optimal treatment planning. Proper imaging plays an important role in determining the anatomy of the UD as well as its spatial relationship to its surrounding structures and its position along the length of the urethra. Numerous imaging modalities are available and each has its own strengths and weaknesses [73].

Voiding Cystourethrogram

The *voiding cystourethrogram* (VCUG) is performed under fluoroscopic visualization with the patient standing (Figure 110.5). The assessment of the bladder neck and proximal urethra as well as bladder neck competency is imperative to document incontinence that may be treated at the time of diverticulectomy. Filling defects within a UD may represent tumor or stones (Figure 110.6) [4]. An air–fluid level in the UD may indicate a UD that is much larger than it appears radiographically.

Fifty percent of patients have multiple UDs. Proper and thorough preoperative evaluation is critical to ensure complete excision of all components of the UD. VCUG has historically been considered the study of choice for the diagnosis of UD (Figure 110.5). Some studies have challenged the sensitivity and specificity of a VCUG in the diagnosis of a UD as the study depends upon the patient voiding during the study to provide a complete study. A 3-year experience comparing VCUG to positive-pressure urethrography (PPUG) in the evaluation of UD found that the positive predictive value of VCUG after PPUG was only 60% [68]. Overall, reported sensitivity of VCUG has ranged from 44% to 95% [70,74]. Once considered the gold standard for diagnostic evaluation, VCUG is now used mainly as a screening test. Should it fail to adequately characterize or identify UD and there is still high suspicion that the entity exists, other imaging modalities should be applied [68].

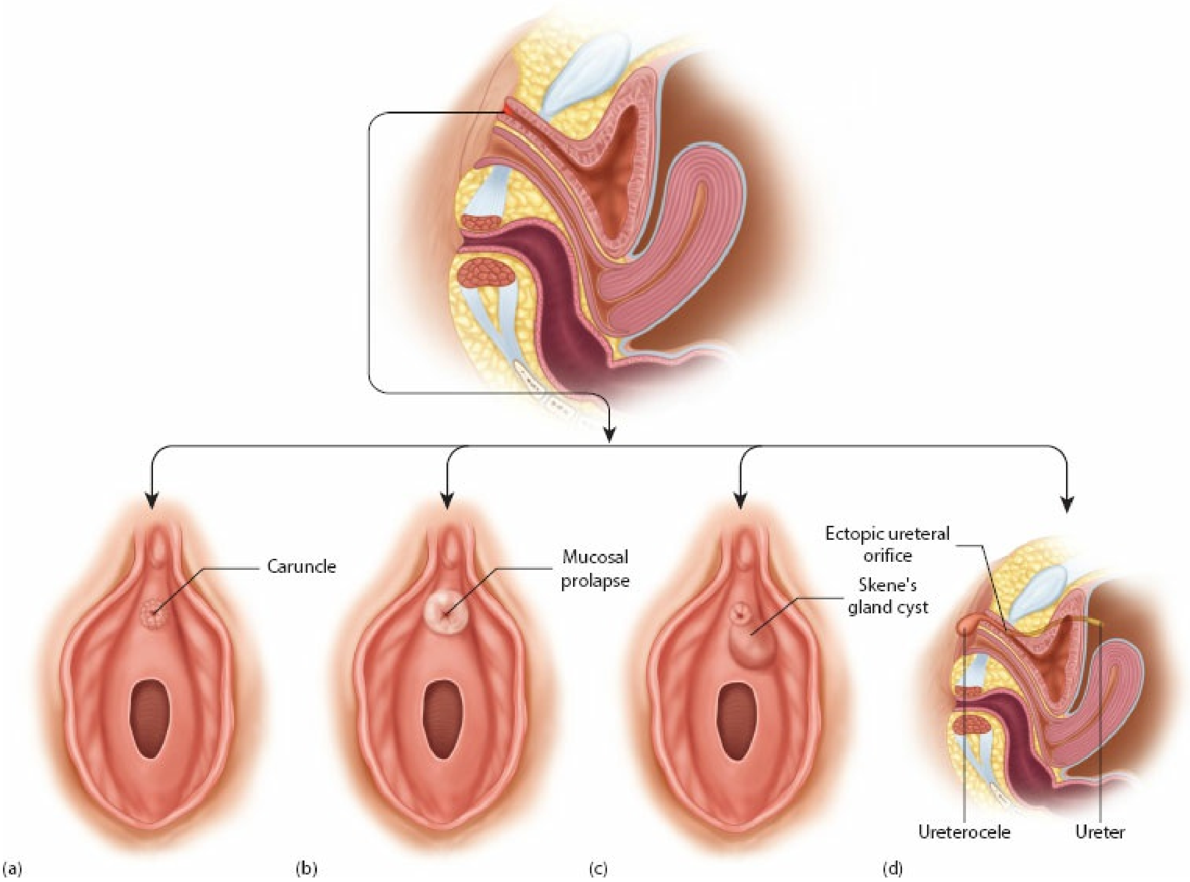

Figure 110.3 Differential diagnosis of meatal and perimeatal lesions: (a) caruncle, (b) mucosal prolapse, (c) Skene’s gland (or duct) cyst, and (d) ureterocele.

Intravenous Pyelography

Intravenous pyelography (IVP) is now a rarely utilized modality and has been replaced in many parts of the word with CT urography. IVP or CT urogram can be useful to evaluate the upper tracts and rule out an ectopic ureterocele [75–78]. An ectopic ureterocele may be considered when there is an abnormal protrusion into the urethra or from the meatus. It is important to obtain a low pelvic view in order to visualize the urethra completely (Figure 110.7).

Retrograde Positive-Pressure Urethrography

Retrograde PPU was once considered the optimal study for the diagnosis of UD. It was reported by Robertson [3] to have a 90% accuracy. Additional studies have reported superior sensitivity of PPU over VCUG for the diagnosis of UD [74,79]. However, this technique is now rarely utilized and is mentioned here primarily for historical purposes. In present-day urological practice, PPU may be employed only as a last resort, when high-quality VCUG or magnetic resonance imaging (MRI) is not available.

PPU is a painful procedure for patients, often necessitating anesthesia. It is also a technically difficult study that requires a special catheter known as the Davis or Trattner catheter [3,80] (Figure 110.8). This catheter has two balloons—one of which is placed just inside the bladder neck and the other at the external meatus. The distal balloon is wedge shaped to fit snuggly into the urethral meatus. Injection of contrast through a separate channel that contains a side port between the occlusive balloons allows for filling of the urethra under slight pressure to facilitate filling of the UD (Figure 110.8).

Table 110.4 Differential Diagnosis of Urethral and Anterior Vaginal Wall Lesions

Lesion	**Location**	**Symptoms/physical exam**	**Cystoscopy/radiography**	**Comments**
Urethral diverticulum	Anterior vaginal wall, midline	UTI, dysuria, dyspareunia, postvoid dribbling, cystic mass	Orifice of diverticulum visible on urethral floor, VCUG opacifies lesion.	May be multilocular
Vaginal wall cyst	Anterior vaginal wall, midline or eccentric	Cystic mass; may be loculated	None or extrinsic compression.	
Gartner's duct cyst	Anterolateral vaginal wall	Cystic mass	None or extrinsic compression; IVP may indicate ectopic ureteral drainage.	Rule out ectopic ureter prior to excision
Müllerian remnant cyst	Midline	Cystic mass	None.	
Ectopic ureterocele	Anywhere in bladder, urethra, vagina (upper third), uterus, fallopian tubes	Cystic mass	May be seen on IVP, US, or cystoscopy.	
Leiomyoma, hamartoma	Vaginal wall	Solid mass	None or extrinsic compression.	Rule out malignancy
Malignant urethral or vaginal neoplasms	Urethral or vaginal wall or hematuria	Solid mass; may have pain, may be seen on cystoscopy	None or extrinsic compression; ± adjuvant therapy erythema, obvious lesion or tumor growing from the diverticulum into the urethral lumen.	Wide local excision, radiation, combination, anterior pelvic exenteration

Abbreviations:DI, detrusor instability (now termed detrusor overactivity); SUI, stress urinary incontinence.

Ultrasonography

Ultrasonography is used in the evaluation of the upper tracts or, occasionally, in conjunction with VCUG to confirm the number and size of diverticula, especially in those cases in which the UD does not completely filled during urethrography [28,81,82] (Figure 110.9). Vargas-Serrano et al. [82] advocated transrectal ultrasonography (TRUS) as the most sensitive tool in the diagnosis of female UD. Keefe et al. [81] support transperineal or transvaginal sonography, reporting 100% sensitivity in their small series and stressing the noninvasive nature of the technique. Wang and colleagues advocate for 2D and 3D transvaginal ultrasound as an accurate and cost-effective imaging modality for the assessment of lower urinary tract perineal masses [83].

Multiple approaches to ultrasonography have been employed, including transvaginal [84,85], translabial [86], suprapubic [80], perineal [81], and TRUS [81]. Dai et al. [87] described a contrast-enhanced transvaginal ultrasound as a technique to facilitate the diagnosis of a female UD. Contrast was injected into the urethra of 14 women suspected of having a UD. Cross-sectional, sagittal, and dynamic images were obtained and color Doppler was applied, and the flow of microbubbles into the UD was tracked. The sonographic findings correlated well with the intraoperative findings, and the authors concluded that this technique provides a tool for the identification of the size, location, configuration, and ostia of the UD.

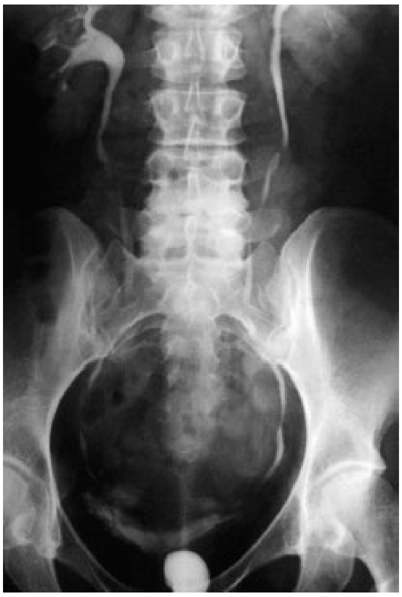

Figure 110.8 Intravenous pyelogram demonstrates the urethral diverticulum and the upper tracts.

Intraoperative endoluminal ultrasonography has been described for localization of the UD [88,89]; however, this is very difficult to perform. One limitation is that the modality is dependent on the technical skills of the operator. Advantages include real-time evaluation and the ability to clarify the spatial relationships between the diverticulum and the urethra [67]. Ultrasound is less expensive compared to other diagnostic tools including VCUG, MRI, and cystoscopy [67].

Magnetic Resonance Imaging

MRI is considered by many to be the most useful diagnostic tool for UD due to its high sensitivity for identifying fluid-filled cavities [38,90–94]. The caveat is that the decompressed UD may not be easily visualized in light for the fact that this study is not performed while voiding, and therefore, the cavity may not be filled to provide for optimal detection. Endorectal and endovaginal coil MRI techniques differ from surface or body coil MRI to that of the former; the coil is placed within the body cavity adjacent to the tissue of interest. This results in improved signal-to-noise ratio and higher-resolution imaging of the urethra [93].

Kim et al. [95] reported 100% sensitivity of MRI in the detection of UD, though others have reported up to a 24% discrepancy between MRI and surgical findings [96]. The signal intensity of fluid is high on T2-weighted images and isointense on T1-weighted images (Figure 110.10). MRI is helpful in defining the extent of a UD and differentiating it from other urethral or vaginal masses, such as malignancy, paraurethral cysts, and Gartner's duct cysts. Endorectal coil MRI can also provide for the diagnosis of periurethral fibrosis and other periurethral pathology [97]. Foster et al. reported on 27 patients with a UD in whom MRI altered the treatment plan in 15% [98]. When compared to VCUG, MRI has been touted to have a higher sensitivity and better characterization of size, location, and complexity of the diverticulum [99]. The superior imaging also may facilitate surgical planning by accurately delineating the extent of the diverticulum.

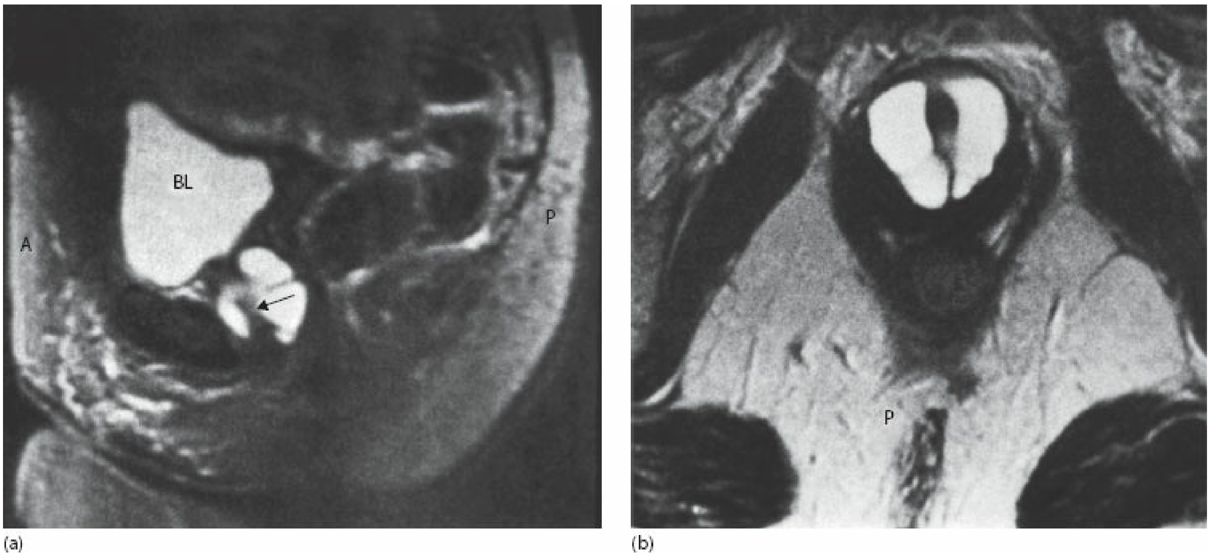

Figure 110.10 T2-weighted magnetic resonance imaging illustrates a multiloculated diverticulum (arrow) posterolateral to the urethra: (a) sagittal view and (b) axial view. (BL, bladder; A, anterior; P, posterior.) (Reproduced from Martensson O and Duchek M, *Scand J Urol Nephrol*, 28, 101, 1994. With permission.)

The high cost of MRI is a detraction compared to other modalities. Endovaginal coil MRI may also be uncomfortable for patients but probably not much more so than VCUG or PPU. Portnoy et al. [100] reported on a retrospective review that showed a high correlation between PPU and MRI in 14 women who underwent both studies. MRI may also provide alternative diagnoses or additional information about surrounding structures that would not be noted on a PPU.

TREATMENT

History

Numerous techniques for the identification and repair of UD have been described. To facilitate identification of a UD, intradiverticular placement of a sound [9,101], a Foley catheter [102], a Fogarty catheter [103], gauze [104], silicone, or blood products [105] have been utilized. Repair has been performed endoscopically and transvaginally by the incision of the urethral floor with layered reconstruction [42], marsupialization [106,107], packing of the UD with various materials to obliterate the cavity [108,109], and transvaginal flap creation with layered closure [70,102,110,111].

Observation

Surgical resection and reconstruction is frequently necessary in the treatment of UD [112]. However, observation is an option in the asymptomatic or very small UD. Marshall reported that UD in young girls may regress spontaneously; therefore, in this rare situation, observation may be a reasonable option [113].

Endoscopic Treatment

Endoscopic treatment should be considered only for distal UD to avoid injury to the proximally located continence mechanism. Transurethral saucerization with incision of the urethral floor [114,115] or of the anterior urethra overlying the UD [116] with a Collins' knife through a pediatric resectoscope can be performed with minimal risk of complication. The major risk is incontinence, which can be minimized by limiting the use of this technique to distal UD [4]. This risk also applies to transvaginal marsupialization (Figure 110.11) of a UD, an outpatient procedure also known as the Spence procedure [3]. One blade of the scissors is placed in the vagina and the other in the urethra; the incision results in marsupialization of the cavity.

Excision with Vaginal Flap Technique

The authors prefer the transvaginal flap technique for all midurethral or proximal UD. This technique allows complete resection of the UD with a three-layer closure and avoidance of overlapping suture lines. An autologous fascial pubovaginal sling can easily be performed concomitantly when deemed necessary (in cases of demonstrable SUI) [117].

Preoperative Preparation

Preoperatively, the risks of a diverticulectomy including bleeding, infection, recurrence, UVF formation, and persistent or worsening urinary incontinence are explained to the patient in detail. It has been recommended that patients have a documented negative urine culture, though many advocate for a short course of oral antibiotics for several days just prior to the day of surgery [4]. All patients receive appropriate perioperative intravenous antibiotics.

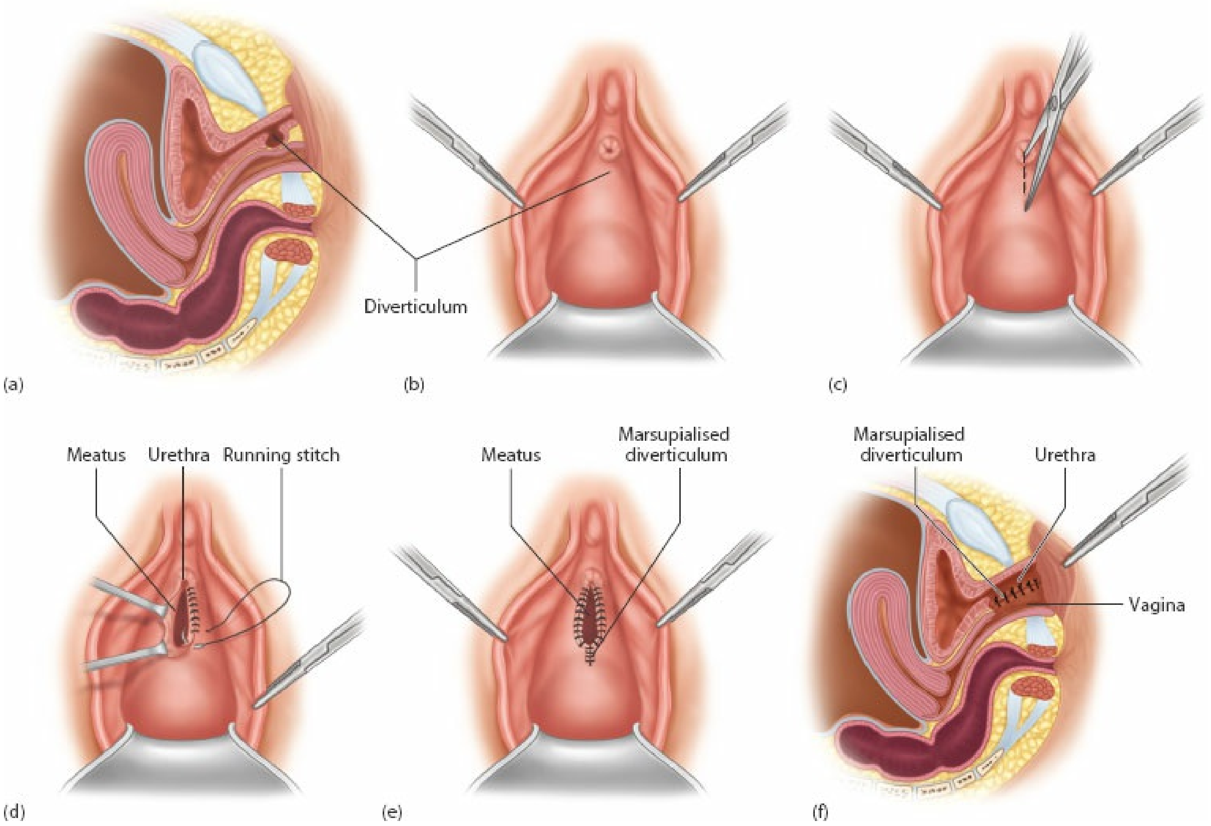

Figure 110.11 The Spence technique for marsupialization of a urethral diverticulum (UD): (a/b) sagittal and vaginal views showing the distal location of the diverticulum and the proximity of the diverticulum to the urethral meatus. (c) One blade of the scissors is inserted into the UD and the other into the vagina. The full thickness of the diverticular septum is incised and (d) a running locking absorbable suture ensures hemostasis. (e/f) This results in a urethral meatus that extends from the diverticulum to the original meatus.

SURGICAL TECHNIQUE

The patient is placed in the low lithotomy position, and prepared and draped, exposing the lower abdomen and perineum. Cystoscopy is performed to examine for the neck of the UD in the urethral lumen. We prefer to place a 12 Fr/5 cc suprapubic tube (SPT), which is secured to the skin and plugged. If a concomitant pubovaginal sling (PVS) is to be performed, the SPT placement is delayed until the harvest and closure of the rectus fascia is complete (see Figure 110.12). A 14 Fr or 16 Fr urethral Foley catheter is passed into the urethra and a weighted vaginal speculum and a Scott ring retractor facilitate exposure. The anterior vaginal wall (Figure 110.12) is infiltrated with saline to facilitate dissection in the proper plane. A U-shaped incision is made with the apex located distal to the UD (Figure 110.13).

In the case of a concomitant PVS, the vaginal dissection is extended laterally to the undersides of the pubic rami bilaterally. The endopelvic fascia is perforated with the bladder completely emptied, and the retropubic space is developed. A strip of rectus fascia is harvested through a Pfannenstiel incision, and the fascia is closed. Helical #0 Vicryl sutures are placed in the ends of the fascial strip, the sling is placed into antibiotic irrigation, and the low abdominal incision is packed with a moist sponge until the sling is placed later in the procedure (see section titled “Concomitant Anti-Incontinence Procedures”).

The diverticulectomy is continued with creation of a vaginal flap via sharp dissection in the white shiny layer of the vaginal wall. *Dissection in the wrong plane can result in significant bleeding or inadvertent entry into the periurethral fascia or the UD, which can render the remainder of the dissection very difficult*. Mobilization of the vaginal flap toward the bladder neck, followed by a transverse incision in the periurethral fascia (Figure 110.14), exposes the UD, which lies directly beneath this layer. The periurethral fascia is then sharply dissected off the UD (Figure 110.15) by developing flaps proximally and distally. The UD is then exposed circumferentially until the diverticular neck is encountered (Figure 110.16). *Difficulty identifying the urethral communication site can result in incomplete resection of the UD and subsequent recurrence. Identification can be facilitated by insertion of a pediatric sound or Fogarty catheter into the UD.*

Complete excision of both the UD and its neck can leave a significant urethral defect (Figure 110.17), while incomplete resection of the diverticulum can lead to recurrence. In cases of a large and/or circumferential UD, the surgeon must be cognizant that extensive dissection beneath the trigone can endanger the ureters and the base of the bladder, sometimes obliging the surgeon to consider leaving the most proximal portion of the UD behind. In these cases, careful cauterization of the inner epithelial surface can be utilized to facilitate obliteration of the cavity. The urethral defect is closed longitudinally without tension over a urethral catheter using a full-thickness #4-0 Vicryl stitch, with care to incorporate the urethral mucosa in each stitch (Figure 110.18).

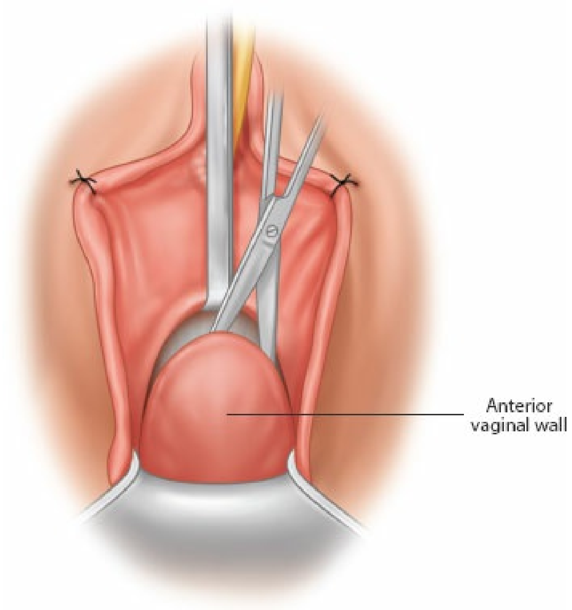

Figure 110.13 An inverted U-incision is made in the anterior vaginal wall, and the vaginal wall is dissected off the underlying periurethral fascia.

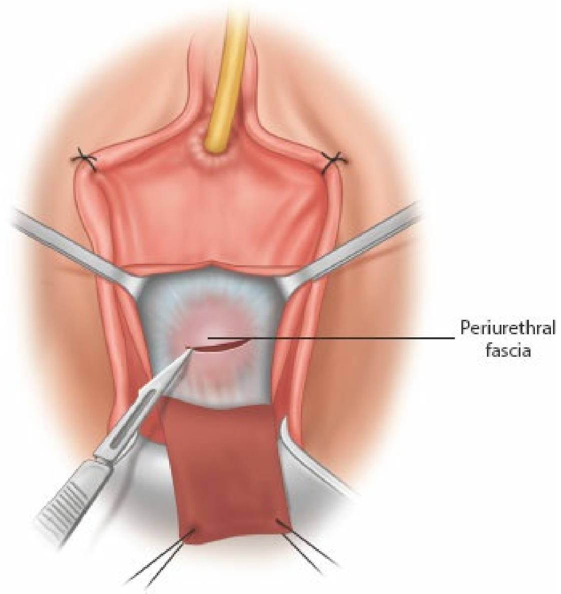

Figure 110.14 The periurethral fascia is incised transversely.

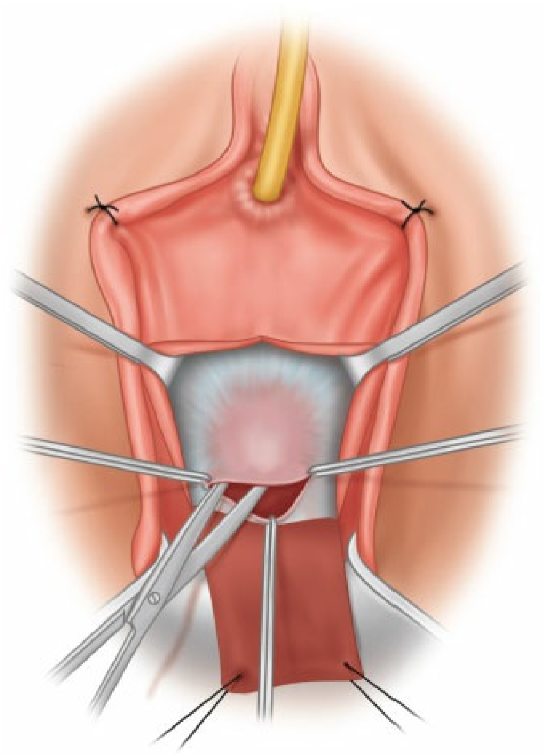

Figure 110.15 The periurethral tissue is dissected from the diverticulum.

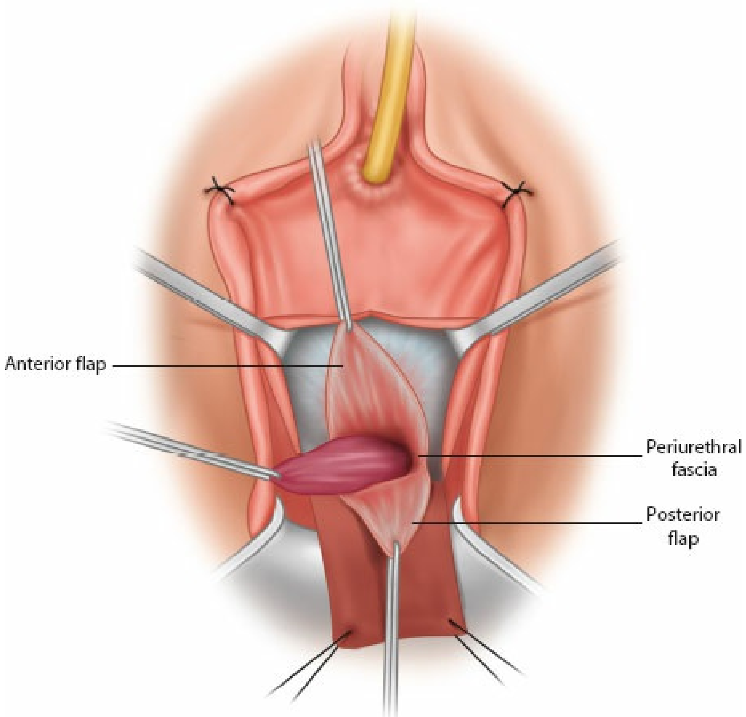

Figure 110.16 The diverticulum is isolated and carefully dissected until the communication is identified.

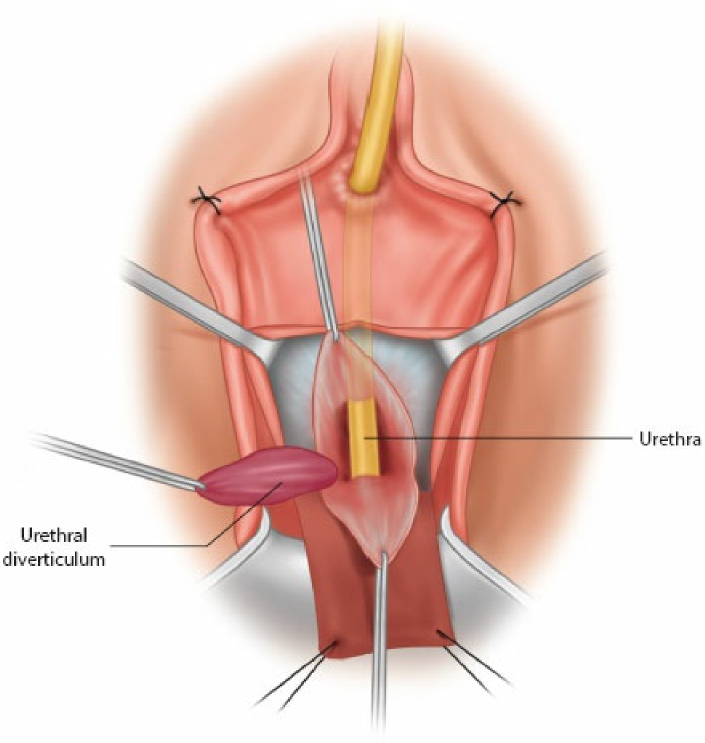

Figure 110.17 The diverticulum is amputated at its communication site, thereby exposing the urethral Foley catheter and leaving a urethral defect.

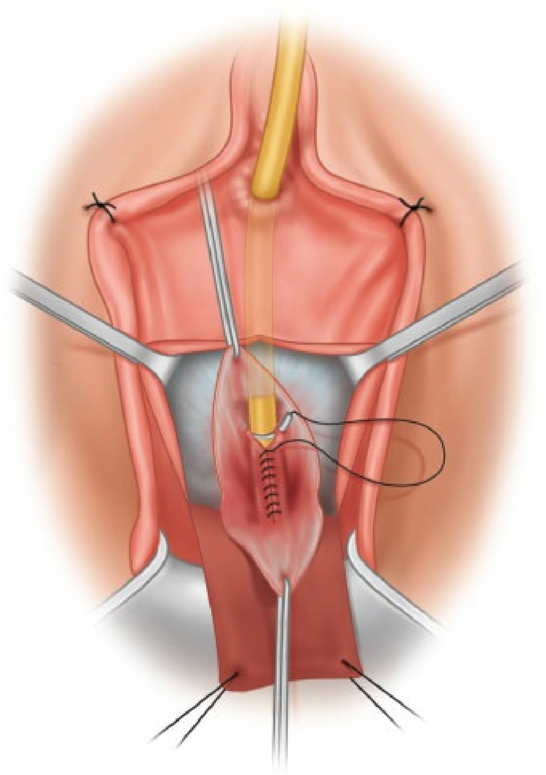

Figure 110.18 The urethra is reapproximated longitudinally with 4-0 absorbable suture.

In cases in which the tissues are tenuous or fibrotic (e.g., due to previous surgery, radiation, or smoking), a well-vascularized 8–12 cm Martius fat pad graft can be placed between the vagina and urethra. The periurethral fascia is closed transversely with running #3-0 Vicryl (Figure 110.19). Dead space should be obliterated beneath this layer. A Martius flap, if utilized, is placed between the periurethral fascia and the vagina. The third and final layer of closure is the inverted U-incision in the vaginal wall, which is closed with #2-0 absorbable suture. The three layers of closure include the urethral wall longitudinally, the periurethral fascia transversely, and the vaginal U-incision. There are no overlapping suture lines (Figures 110.20 and 110.21). Vaginal packing moistened with antibiotic solution or estrogen cream is inserted, the Foley catheter is placed to gravity drainage, and the SPT is plugged.

Complex Diverticula

Anteriorly or dorsally located horseshoe-shaped and circumferential UD presents unique challenges to the pelvic surgeon. Because of their complexity, they frequently present as recurrent diverticula that have been operated on previously. The tissue planes may be obscured complicating the dissection. The anterior location is also challenging to access transvaginally.

Anterior UD can attain large size, leading to difficulty filling the dead space created after excision. The subsequent urethral defect can be quite large (>2 cm). Clyne and Flood [118] described an approach to anterior horseshoe-shaped UD using a suprameatal incision. The authors utilized a double-wrapped porcine xenograft to aid in filling of dead space. Retropubic approaches have also been described [119]. However, for circumferential diverticula, a separate vaginal incision would also be necessary to excise the ventral portion of the diverticulum (Figure 110.22). A parasagittal vaginal incision has been described with detachment of the urethra from the inferior pubic ramus laterally to facilitate anterior dissection [120]. Rovner and Wein [121] introduced a novel technique for excision and reconstruction of dorsal or circumferential UD by dividing the urethra to access the anterior portion of the diverticulum. Once excised, an end-to-end urethroplasty or diverticular sac urethroplasty is performed [121]. Martius flap interposition was performed in nearly all patients in their series to help with closure of dead space (Figures 110.27 and 110.28).

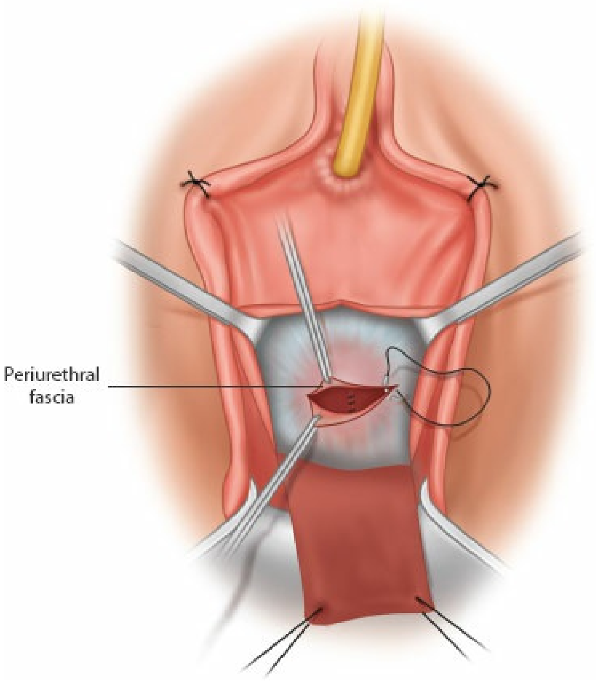

Figure 110.19 The periurethral tissue is closed transversely with 3-0 absorbable suture.

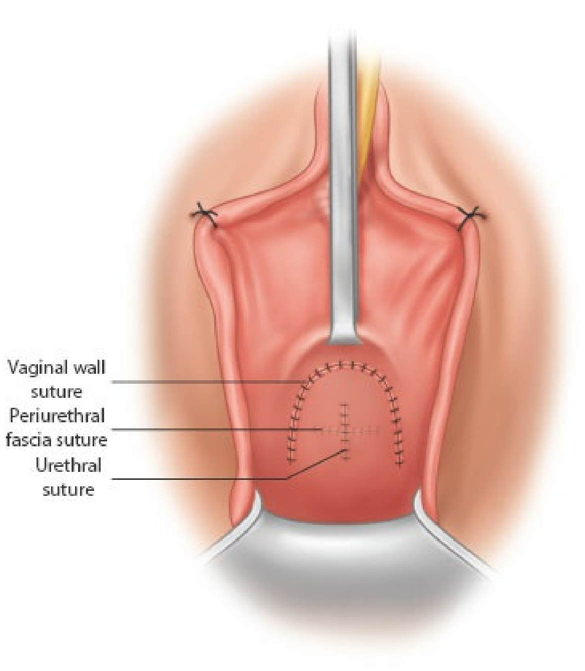

Figure 110.20 The vaginal wall flap is closed, resulting in a three-layer closure with no overlapping suture lines.

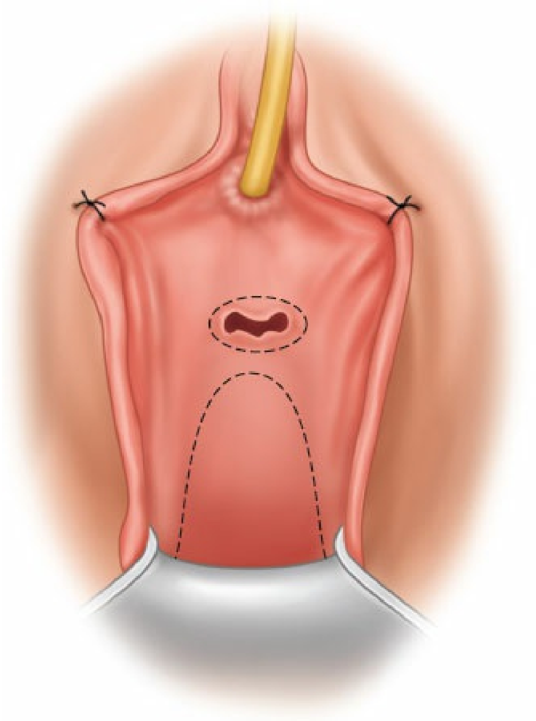

Figure 110.21 An inverted U-incision is made in the vaginal wall with the apex just proximal to the fistula.

Concomitant Anti-Incontinence Procedures

If a PVS is being placed, it is placed over the periurethral fascial layer. If a Martius flap is also being utilized, the sling is generally placed over the Martius fat pad. The dilemma is the need for cystoscopy following retropubic passage of the needles used to deliver the sling sutures from the vaginal to the suprapubic incision to ensure that the sling passers have not entered the bladder or urethra (Figure 110.23).

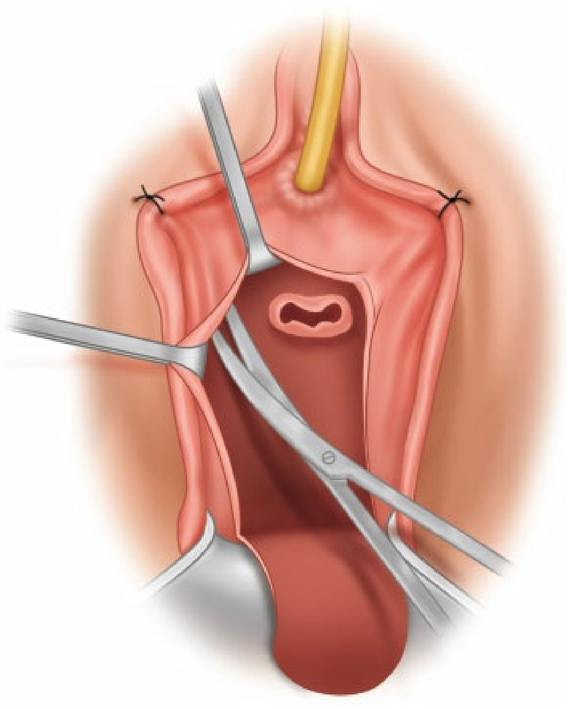

Figure 110.22 The fistula is circumscribed but not excised. The avascular plane beneath the lateral vaginal wall is developed.

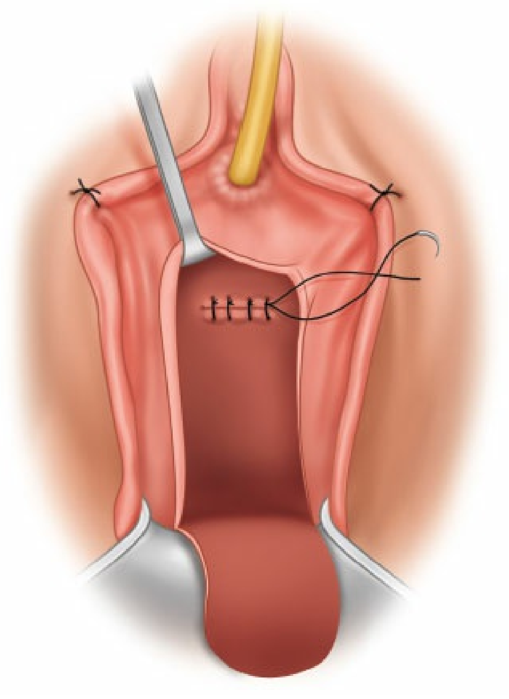

Figure 110.23 The fistula is closed with absorbable suture.

Many advocate for passing the sling prior to the diverticulectomy or following excision of the diverticulum, but prior to the urethral closure. If placed prior to the diverticulectomy, the sling can be carefully packed into the vaginal incision out of harm's way or permitted to hang loosely while the urethra is addressed. In this fashion, gentle cystoscopy can be performed prior to opening the urethra to avoid enlarging the urethral defect or injuring the urethral tissues. The advantage of passing the sling sutures prior to the diverticulectomy is that the cystoscope does not have to be passed over an open urethrotomy or urethral reconstruction; however, the presence of the diverticulum can make the retropubic needle passage difficult. Conversely, while the passage of the needles may be easier if the diverticulectomy has already been completed, cystoscopy with a urethral disruption requires a skilled touch to avoid enlarging the urethral defect. Finally, some will proceed with completion of the diverticulectomy and closure of the first two layers prior to passing the sling, understanding the risk of passing a scope over a fresh urethral closure. While there is no single correct approach, surgeons must be aware of the pros and cons of each alternative.

A synthetic sling should never be utilized in the face of a diverticulectomy due to the risk of urethral erosion, though one group did report placement of a synthetic sling over a biological graft interposed between the urethra and the sling [122]. Consideration of a synthetic sling in patients who have undergone a diverticulectomy in the past and at what interval postdiverticulectomy remains controversial. Historically, bladder neck suspensions (BNSs) could be performed concomitantly with a urethral diverticulectomy [11,123] as there was no suburethral component to the anti-incontinence technique and therefore minimal risk of disruption of the urethral reconstruction by the anti-incontinence procedure. However, BNS are no longer routinely utilized due to the suboptimal outcomes and durability. Consideration of a Burch urethropexy is reasonable in this situation, though it is limited by the necessity to enter the abdomen (Figure 110.24).

Postoperative Management

The vaginal packing is removed no later than the morning of postoperative day 1. All patients receive 24 hours of intravenous antibiotics. Antimuscarinics are used to minimize bladder spasms but are discontinued 24 hours prior to a VCUG that is performed 14–21 days postoperatively. At the time of this first VCUG, approximately 50% of patients have some extravasation from the urethral reconstruction site [4]. When extravasation is evident, the SPT is placed to gravity drainage; the urethral catheter is *not* reinserted. A follow-up VCUG is obtained 7–10 days later. This pattern is repeated with intervals at the discretion of the surgeon until there is no extravasation, at which time the SPT is clamped, and a postvoid residual (PVR) is checked. If it is 100 mL or less, the SPT is removed; if the PVR exceeds 100 mL, the SPT is left in place until this volume decreases (Figure 110.25).

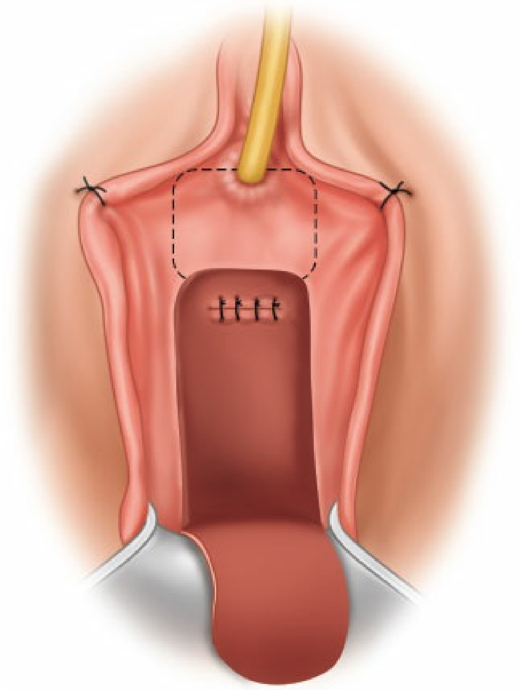

Figure 110.24 Two longitudinal incisions are made to create medially based flaps.

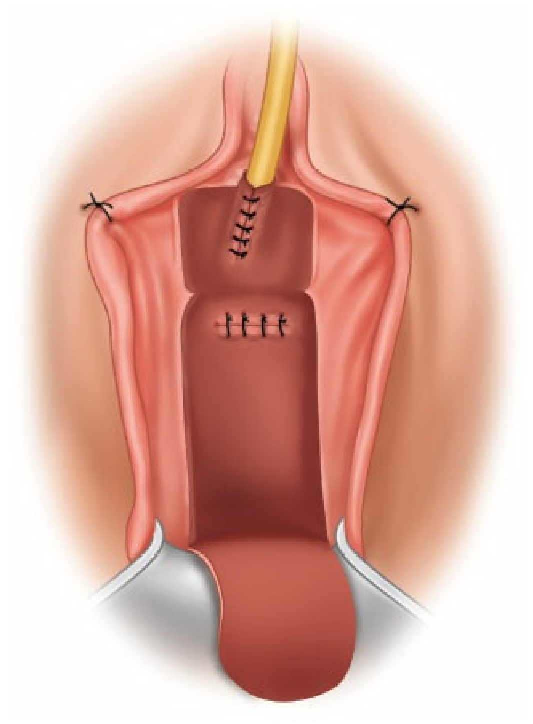

Figure 110.25 The flaps are rolled over a 14-F urethral catheter.

Table 110.8 Complications of Transvaginal Urethral Diverticulectomy

Complications	**% Range of reported incidence**
Urinary incontinence	1.7–16.1
UVF	0.9–8.3
Urethral stricture	0–5.2
Recurrent UD	1–25
Recurrent UTI	0–31.3
Other • Hypospadias/distal urethral necrosis • Bladder or ureteral injury • Vaginal scarring or narrowing, dyspareunia, etc.

Results and Complications

Potential complications following a urethral diverticulectomy include incontinence, UD recurrence, UVF, irritative symptoms, urethral stricture, and general postoperative complications [4] (Table 110.8).

Ganabathi et al. [11] reported on 63 women who had been treated for UD between 1982 and 1992. Fifty-six were treated operatively including 29 who received a diverticulectomy alone and 27 who underwent a concomitant BNs. seven were observed, among whom three declined surgery and four had small asymptomatic diverticula. Complications included recurrent diverticula in two, UVF requiring surgical repair in one, early postoperative UTI in six, and suprapubic tenderness in one who had undergone a concomitant BNs. The two recurrences of the UD occurred distal to the initial repair site. The majority of patients in this series were completely continent with 80.4% dry or requiring no pads and only 1/56 (2.8%) reporting severe incontinence, defined as requiring several pads a day. A greater percentage of the patients who underwent diverticulectomy alone were reported as continent than were those who underwent diverticulectomy with concomitant BNS (Table 110.8). It was reported that incontinence was more frequently secondary to SUI than to detrusor overactivity (i.e., urgency), despite the presumed increase in bladder neck support (Figure 110.26).

Reeves et al. [16] reported a more contemporary series of 89 patients who underwent diverticulectomy by one of two surgeons over an 8-year period with follow-up ranging from 3 to 20 months. Seventy-two percent were continent postoperatively, with 13 (14.6%) experiencing de novo SUI, 3 (3.4%) had recurrent diverticula. Two had abnormal pathology within the diverticulum, including one with leiomyoma and the other with squamous cell carcinoma.

The largest series was reported by Ingber et al. [124]. One hundred and twenty-two patients underwent urethral diverticulectomy over the course of 12 years. Thirteen percent had recurrence of their UD requiring further surgery; a significant number of whom had had previous pelvic surgery excluding diverticulectomy prior the excision of their UD. Other risk factors for recurrent UD were multiple UD or proximal UD. Sixty-one (50%) of the patients responded to a questionnaire at a mean follow-up of 50.4 months. Thirty-nine percent had a UTI within the previous year and 23% had three or more UTIs over the same time period. Twenty-six percent reported persistent pelvic pain or pain with urination.

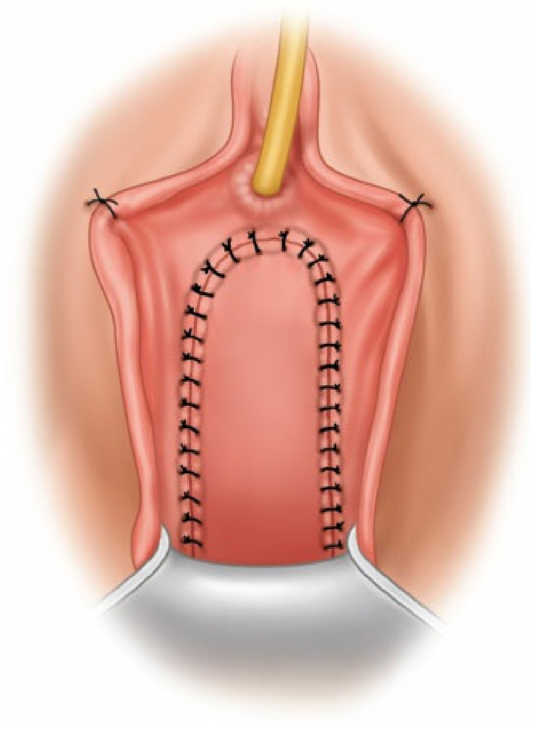

Figure 110.26 The vaginal flap is closed with a running, locking absorbable suture.

Postoperative incontinence may represent persistent SUI that was present preoperatively. De novo SUI has been reported in up to 49% of patients who underwent a urethral diverticulectomy [125,126]. This situation can be avoided by a comprehensive preoperative evaluation such that, if indicated, urinary leakage can be addressed at the time of diverticulectomy [4,11,16]. Incontinence can also result from UVF, recurrent diverticulum with paradoxical loss of urine with stress, infection, persistent or de novo detrusor overactivity, or new onset SUI. The first two conditions may require surgical intervention. New onset SUI may be a result of the urethral dissection, which can compromise urethral support, or secondary to dissection beneath the proximal urethra and bladder neck, which is often necessary when removing a large UD.

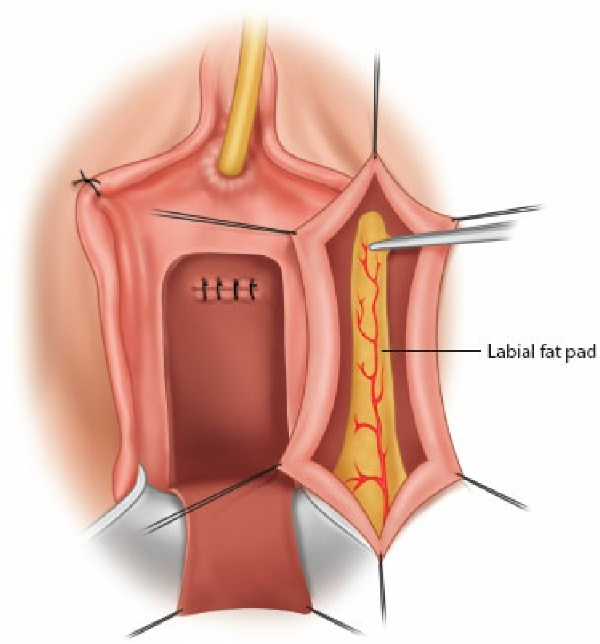

Figure 110.27 The labium majus is incised, and the Martius fat pad graft is mobilized with care to preserve the posteriorly located pudendal vessels.

Though preoperative urinary urgency and frequency symptoms tend to abate in most patients following urethral diverticulectomy, some patients will have persistent symptoms (Stav, 2008). In such cases, the urgency and overactive bladder symptoms should be addressed based upon the American Urological Society/Society of Urodynamics, Female Pelvic Medicine, and Urogential Reconstruction OAB Guidelines [127]. First-line therapy includes behavioral therapy and dietary modification and second-line therapies include antimuscarinic or beta-3 agonist pharmacotherapy (Figure 110.27).

Recurrent UD is often a result of failure to identify multiple UD preoperatively, secondary to lack of either suspicion or proper high-quality studies [11,16]. Incomplete excision of the diverticular neck and faulty closure of the urethral defect are also possible causes. This problem, if anticipated intraoperatively based on tissue quality, can be managed with interposition of a Martius fat pad graft between the vagina and urethra [11]. For small, distal recurrences, endoscopic saucerization or Spence marsupialization may suffice [4]; however, caution must be exercised not to injure the proximally located continence mechanism. UVF formation, another potential complication, is managed in much the same manner and may be prevented by intraoperative Martius flap if tissues appear tenuous or if there is any tension in the urethral closure (Figure 110.28).

Finally, urethral stricture may result from extensive excision of the urethral wall at the time of diverticulectomy and can be prevented by a tension-free urethral closure over a 14 or 16 Fr catheter. If this is not possible, reconstruction using vaginal wall or other pedicalized or free flaps can be contemplated, again with consideration of a Martius labial fat pad graft (Figures 110.29 and 110.30).

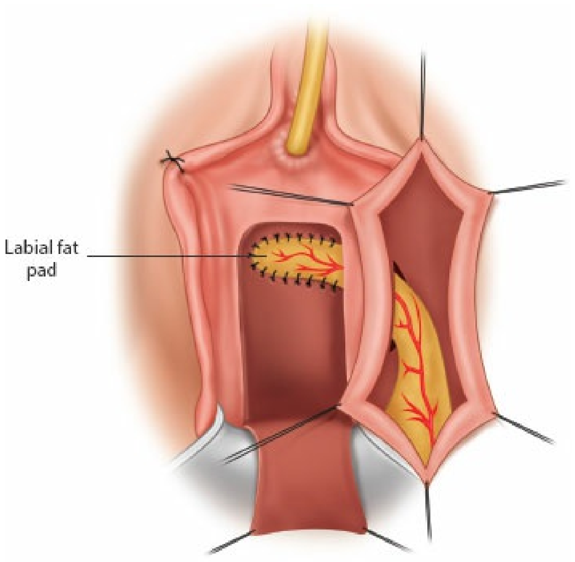

Figure 110.28 The labial fat pad is passed through a medial tunnel and secured over the fistula repair site.

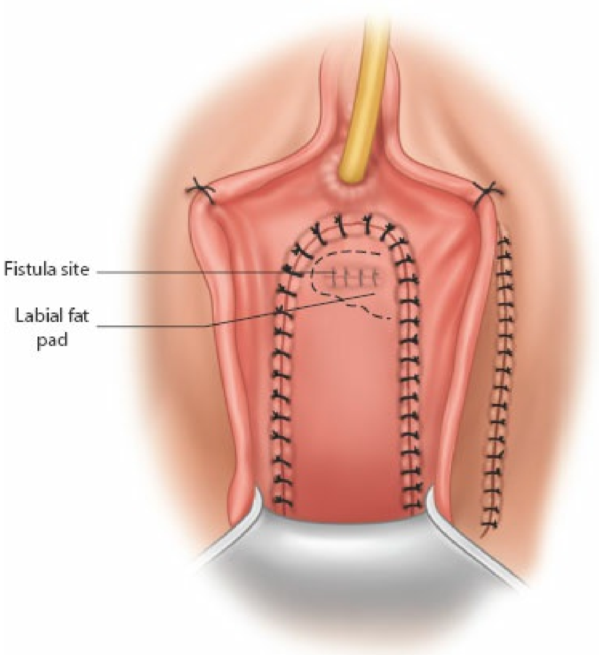

Figure 110.29 The vaginal wall flap is advanced over the fat pad graft, resulting in closure with no overlapping suture lines.

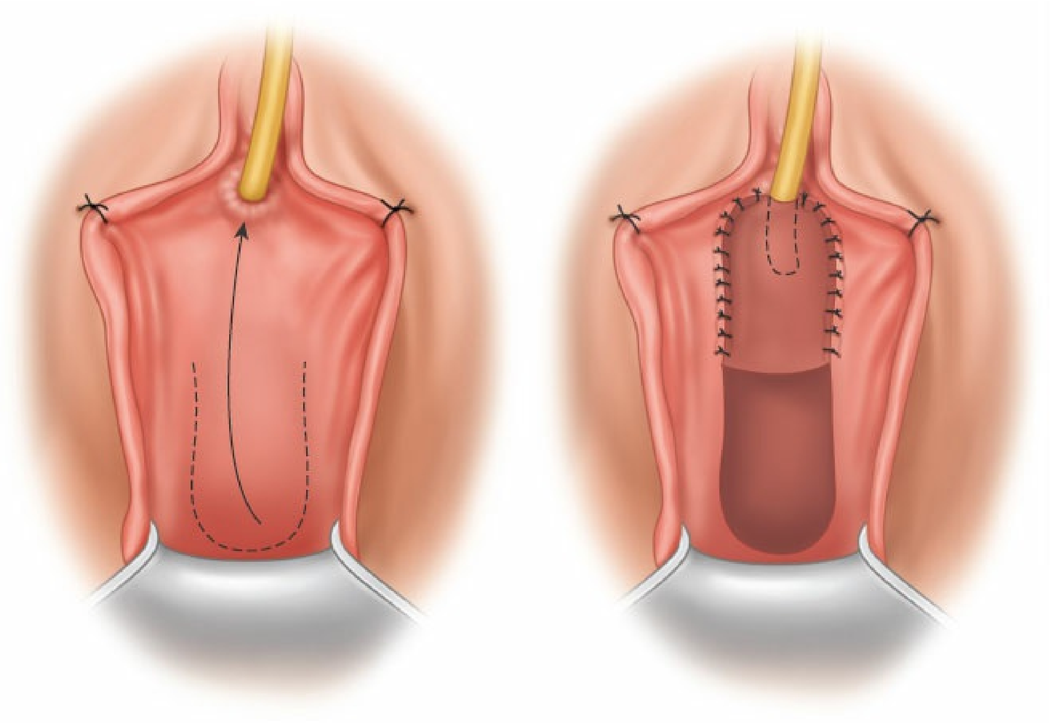

Figure 110.30 A meatus-based vaginal flap is rotated distally.

CONCLUSION

UD is likely an underdiagnosed entity, though improved imaging techniques have improved their detection over the years. While asymptomatic UD does not need to be excised, symptomatic UD can prove to be a diagnostic and therapeutic challenge. Careful and thorough evaluation is imperative to allow for consideration of other associated conditions, and meticulous surgical technique can provide excellent results for our patients.

111 Diagnosis and Management of Female Urethral Stricture Disease

Victor W. Nitti and Aqsa Khan

INTRODUCTION

Urethral stricture is a true narrowing or scarring of the urethra that can result in bladder outlet obstruction with subsequent decreased urine flow, elevated postvoid residual (PVR), and a variety of lower urinary tract symptoms (LUTSs). Less common urethral strictures can cause urinary retention, renal failure, hydronephrosis, and pyelonephritis [1,2]. Like any cause of obstruction, patients may present with voiding symptoms and/or storage symptoms (frequency, urgency, urgency incontinence). The incidence of true female urethral stricture is not known, and treatments for it have not been extensively studied. In 2013, Osman et al. performed a systematic review of all surgical techniques for the treatment of female urethral strictures and found only 114 patients reported in the world literature [3]. Despite the relatively sparse data on treatment of female urethral stricture, the diagnosis accounted for 1.2 million office visits in the United States from 1992 through 2000 and had an annual expenditure of $69 million in 2000 [4]. This apparent discrepancy is likely the result on of over diagnosis of women without true stricture disease and underutilization of surgery to treat true urethral strictures. Fortunately, the concept of the “narrow” yet unscarred urethra as a cause of LUTSs and recurrent urinary tract infections is not as popular as it once was, and the practice of urethral dilatation has decreased. In more contemporary series, urethral stricture has been reported to be the cause of urodynamically proven bladder outlet obstruction in 4%–13% of women [5–7].

ANATOMY

Urethral stricture may occur anywhere along the length of the urethra from the bladder neck to the urethral meatus. The female urethra is approximately 3–4 cm in length. It is comprised of an inner mucosal epithelium layer with numerous infoldings, creating an effective seal against the passive loss of urine. Beneath the mucosa lies a rich, vascular network that includes elastic tissue. The proximal 75% of the urethra has two smooth muscle layers, an outer circular and inner longitudinal layer. These layers thin as they traverse distally, and terminate before the urethral meatus. Outside of the smooth muscle layer lays the striated urethral sphincter muscle, which extends the whole length of the urethra and is critical to the continence mechanism. It is horseshoe shaped, more dense dorsally, and is thickest in the middle third of the urethra. Surrounding this is a collagen-rich fibromuscular envelope comprising the periurethral fascia. Other important structures to consider during surgical treatment of urethral structures are the clitoral tissue that surrounds the urethrovaginal complex and supports the urethra along its dorsal aspect, and the neurovascular bundles that traverse along the ischiopubic ramus [8].

There are two primary fascial attachments that provide support to the urethra, the pubourethral ligaments and the periurethral fascia that makes up the suburethral hammock that attaches to the tendinous arch of pelvic fascia on each side. The pubourethral ligaments are a band of fascia that supports the urethra dorsally between the vagina and pubic symphysis. These “ligaments” often serve as a point of anatomic demarcation of the midurethra. The suburethral hammock is comprised of two layers of fascial condensation, the endopelvic fascia and the pubocervical fascia, providing lateral attachment to the tendinous arch. The midurethra is thought to be the center of continence where the striated sphincter complex maintains both active and passive tone.

ETIOLOGY

There are multiple causes of urethral stricture in women. These include infection, inflammation (vulvar dystrophy, lichen sclerosis) radiation, trauma, instrumentation, and prior urethral surgery and aging. However, many times urethral strictures are idiopathic without any obvious cause. Traumatic endoscopic exam or even catheter placement may result in stricture formation. Urethral dilation, one of the treatments of strictures or urethral “narrowing,” may actually cause or worsen strictures. Urethral dilation can result in edema, bleeding, and urinary extravasation that can cause periurethral fibrosis that is often found in pathological specimens of urethral stricture [9]. Rarely strictures may result from estrogen deficiency, usually at the meatus (meatal stenosis). Urethral destruction/ablation may result from urethral trauma, chronic indwelling urethral catheterization (usually in a patient with decreased or absent sensation) or as a complication of urethral surgery.

DIAGNOSIS

The diagnosis of urethral stricture usually requires a high index of suspicion. As with many diagnoses, that suspicion starts with a proper history. The assessment of voiding and storage symptoms (frequency, urgency, incontinence, slow or interrupted stream, hesitancy, incomplete emptying, dysuria), UTI history, and any possible causes of stricture (history of trauma, surgery, catheterization, instrumentation, prior urethral dilation, or urethrotomy) are important. For women with complaints of difficult voiding, slow or hesitant urinary stream, or incomplete bladder emptying, a noninvasive uroflow and PVR can be helpful. Typically, urethral strictures result in a reduced maximum flow rate with a flattened appearance to the flow curve, rather than the typical bell shape. Sometimes, a straining pattern may be noted.

Often, but not always, a significant PVR may accompany the reduced flow. Physical exam may show inflammation or atrophy around the urethral meatus and/or the surrounding vulva. In cases when there is a high suspicion of urethral stricture, one can attempt catheterization (or calibration), and this can be done as part of the physical exam. Some authors have defined failure to admit a 14 French catheter as an inclusion criterion for urethral stricture [10–12]. We usually start with a small 10–12 French catheter. If there is any resistance, the process is stopped, and further, more definitive testings are recommended. In a patient with a true urethral stricture, a 10 French catheter often will not pass [13], but its passage does not rule out a stricture.

Radiographic evaluation of urethral stricture is best accomplished with voiding cystourethrogram; however, in order to perform this test, a catheter must be passed into the bladder. For this, a small 6–8 French catheter can be used if a larger catheter will not pass. In special circumstances, the bladder can be filled via a suprapubic catheter. Sometimes, radiographic evaluation is done as part of a videourodynamics (VUDS) test, where the diagnosis of urodynamic obstruction and localization of the stricture can be made. Typically, one will see distal urethral narrowing with proximal urethral ballooning [1]. Also, for more proximal strictures, VUDS or cystogram allows one to determine the level or point of continence. For example, if the bladder neck is closed with Valsalva, that is usually the level of continence. However, if with straining the bladder neck opens and the level of continence is at or near the stricture, there may be concern for posturethroplasty incontinence.

When malignancy, periurethral or extraurethral pathology is suspected (e.g., palpable mass, prior or current history of genitourinary malignancy), further evaluation of the urethra and surrounding structures may be warranted. In such cases, we prefer MRI as the radiographic test of choice, though CT scan may also be considered.

Finally, endoscopic evaluation can be helpful to evaluate the extent of the stricture. It is often necessary to use a pediatric cystoscope or ureteroscope. If not possible, endoscopy can be deferred until repair. Gentle dilatation of the stricture can be performed to facilitate endoscopy, especially if a biopsy is desired. It is often done with the patient under anesthesia.

TREATMENT OF URETHRAL STRICTURE

The treatment algorithm for female urethral stricture is not as well defined as in the male. Perhaps, this discrepancy is attributable to the relative rarity of stricture disease in women, combined with the more varied causes of strictures in women. In men, urethral strictures are commonly caused by blunt trauma; however, due to the female urethra’s short length, its anatomic position behind the pubic arch, and its relative mobility, the incidence of stricture following trauma in females is low (range of 0%–6%). More commonly, stricture disease in women is seen following endoscopic or open urethral surgery, urethral dilatation, and pelvic radiation therapy for gynecological malignancies.

Treatment of urethral strictures can be divided into four categories:

1. Conservative management—urethral dilatation and/or self-catheterization
2. Endoscopic
3. Urethroplasty
4. Salvage procedures (bladder neck closure and/or urinary diversion)

The driving factors for treatment of female urethral stricture will often be based on the patient's degree of obstruction, bothersome symptoms, and emptying patterns. In cases in which a patient is adequately emptying and not encumbered with bothersome symptoms, they may be offered the option to be conservatively monitored with routine follow-up. In cases in which treatment is warranted, the course of treatment should be based on the degree of urethral stenosis and/or retention, the functionality of the bladder, and the risk for any upper tract dysfunction. Additionally, if the underlying mechanism of stricture formation can be ascertained, such as radiation, this should be kept in consideration. Ultimately, if there is suspicion for urethral stricture in a woman, it is imperative to fully assess them in order to make an accurate diagnosis for which a proper treatment course may be offered. For example, in cases of pelvic floor dysfunction or dysfunctional voiding, it may present and appear as a urethral stricture, but the treatments are profoundly different. Counseling the patient is very important throughout the process, as symptoms of frequency and urgency may persist even after treatment of a stricture [13].

CONSERVATIVE MANAGEMENT

Conservative options for management of female urethral strictures include self-catheterization or urethral dilation. Selfcatheterization involves teaching the patient how to perform intermittent catheterization at various intervals based on the degree and timing of scarring. If a stricture is diagnosed early, self-catheterization can likely be initiated without requiring urethral dilations or surgical therapies. The patient should be followed at regular intervals to ensure no problems with or worsening symptoms between catheterizations. If a patient fails intermittent self-catheterizations or elects to have more definitive therapy, a discussion regarding other conservative and surgical options should be initiated with the patient.

Urethral dilation gained rapid popularity in the 1960s when it was proposed to dilate a "contraction ring" noted in the urethras of young girls up to 32–45 French [14]. This notion as a treatment for "urethral syndrome" in those with recurrent urinary tract infections and chronic urethritis subsequently expanded. Since then, studies have demonstrated that in the absence of a true stricture, urethral dilation does little in the way of helping with urinary symptoms of frequency and urgency [15,16]. In general, emerging literature advocates against the use of urethral dilation in the absence of a true urethral stricture. This change in management trends is reflected in surveys given to practicing urologists, with those trained within the 10 years prior to 1999 considering dilation to be as largely unsuccessful, contrasted by 21% of those trained more than 10 years before 1999 considering it to be very successful [17].

Despite changes in perception, however, it is still a common practice. Osman et al. recently performed a systematic review of the literature on female urethral stricture and found that 107 of the 221 women studied underwent urethral dilation, making it the most commonly performed procedure for urethral strictures [3]. Of these, one-third had already failed a prior dilation. Another recent British survey found that 69% of urologists still regularly perform urethral dilation despite data to suggest its lack of efficacy [18]. It is unclear why this practice continues, and it has been suggested that generous reimbursements by Medicare may play a role. Analysis of public datasets estimate an annual cost of $61 million for treatment of stricture disease in women, of which the majority (67%) were for ambulatory surgery visits [19]. Diagnosis of urethral stricture in a woman averages a cost of $8444 in health-care costs compared to $4658 in those with similar complaints without that diagnosis.

Long-term data on outcomes of dilation are scarce, and many studies are performed in the absence of the diagnosis of a true urethral stricture. Three recent case–control studies provide some input. Smith et al. evaluated seven patients with stricture less than 14 French diagnosed from findings on cystoscopy and/or VUDS [20]. They were dilated to 30 French, left with a catheter for 1 week, and then asked to intermittent catheterized once a day for 6 months. At a mean follow-up of 21 months, there was an improvement in AUA symptom score by 10.7 points, but three of seven required repeated dilations. Takao et al. [20] evaluated 17 women diagnosed with true urethral stricture that underwent serial dilation over 6 months to 30 French and studied with uroflow 1 week after their last dilation. They found that the urethral calibration increased to a mean of 23.5 French from 18.1 French and the mean uroflow increased to 11.2 mL/s from 9.4 mL/s. Blaivas et al. [21] retrospectively evaluated data for 17 women over a period of 12 years diagnosed with urethral stricture by cystoscopy, urethral obstruction per the Blaivas–Groutz nomogram on urodynamics, and urethral circumference less than 17 French. All women had at least one prior dilation prior to presentation, and of those that underwent another dilation, nearly all had a recurrence (16 of 17 patients) subsequently requiring another dilation or urethroplasty. Success rate at a mean follow-up of 2 years was a meager 6%, thereby prompting the authors to conclude that urethral dilation is very rarely effective. The review by Osman et al. found a mean failure time of 12 months, of which redilations were performed in 56% [3]. At a mean follow-up of 43 months, the urethral dilation success rate was 47% with higher rates of success in those that had not had a prior dilation (58%) than if they had a prior dilation (27%). The authors concluded that in cases of repeat dilation, it often serves primarily a palliative purpose rather than as a cure likely due to extension of the scarring.

Imaging has been used as an aid to dilation. The use of fluoroscopy or transvaginal ultrasound (US) may be required to ensure proper placement and dilation. A case report of the use of transvaginal US during dilation described urethral strictures as having a hypoechoic center that represents the mucosa and a surrounding hyperechoic region that correlates to the nondistensible spongiofibrosis of the periurethral tissue [22]. In this report, 1 month after dilation, a follow-up US showed a normal urethra. In addition to aiding in dilation and other treatments, US may serve as a tool in the future to evaluate for early recurrence or degree of fibrosis and scarring.

A recent study was conducted by Heifari et al. to compare outcomes between intermittent scheduled dilations and on-demand dilations [23]. Women with primary urethral stricture diagnosed by uroflow, elevated PVR (>60 mL), and US were randomized to either undergoing intermittent dilation every 2 months for a total of three dilations or on-demand dilation in case of recurrence. At 6 months, the on-demand group demonstrated no recurrences requiring repeat dilation, and there were similar improvements in PVRs and uroflow between both groups. The group concluded that on-demand dilations are superior because they provide similar outcomes with less urethral manipulation.

Finally, adjunctive therapy with vaginal estrogen in order to improve atrophy and improve tissue either pre- or posttreatment can be considered [13,24]. Atrophic vaginitis and other postmenopausal changes that often cause LUTSs or meatal stenosis are also often helped with topical vaginal therapy and may also be an option to consider [25].

ENDOSCOPIC MANAGEMENT

In the cases in which dilation fails or the patient elects to undergo other therapies, some have considered endoscopic management with either direct visual internal urethrotomy (DVIU) or laser treatment of the scar. Very scant literature exists on endoscopic management of urethral strictures in women. Massey and Abrams in 1988 reported 80% success in women that underwent dilation or DVIU [26]. Alternatively, a laser could be used to endoscopically incise a stricture (CO_2, argon, KTP, Nd:YAG, holmium:YAG, excimer lasers) with the goal being to vaporize tissue without causing significant harm to surrounding tissue. Most of the existing literature for lasers is for the treatment of male urethral strictures and as with literature in female strictures is sparse [27,28].

URETHROPLASTY

There are a number of procedures that can be performed to reconstruct the strictured urethra. These range from meatoplasty to vaginal inlay flaps for distal strictures, more extensive vaginal flap urethroplasty for midurethral strictures, and onlay grafts for mid and proximal urethral strictures. We will describe examples of each of these techniques based on the anatomic location of the stricture. Successful urethral reconstruction, no matter where the location of the stricture, is based on several principles including identification of the entire stricture, tension-free reconstruction, and adequate drainage/stenting when necessary.

Meatal stenosis and stricture of the distal urethra are two of the most common indications for urethral reconstruction. The distal urethra is particularly susceptible for stricture from instrumentation, trauma, radiation, and aging. The two most common types of urethral reconstruction that we utilize for distal urethral stricture are (1) distal urethrectomy with advancement meatoplasty for very distal strictures (usually involving the distal 1 cm of the urethra) and meatal stenosis and (2) a proximally based distal vaginal flap urethroplasty (Blandy urethroplasty) for lesions 1–2 cm proximal to the urethral meatus. Stricture and other lesions of the midurethra often result from iatrogenic injury associated with urethral diverticulectomy, incontinence surgery or urethral instrumentation, and endoscopic trauma. They can be associated with urethrovaginal fistulae or loss of the mid to distal urethra that can occur as a result of long-term indwelling catheters. For midurethral lesions, beyond the limits of a Blandy urethroplasty, we will typically employ a vaginal flap urethroplasty or, in cases when suitable vaginal tissue cannot be found or is not appropriate, a free graft using buccal mucosa. For proximal strictures and strictures involving the entire urethra, the buccal mucosal graft is our procedure of choice.

Distal Urethrectomy with Advancement Meatoplasty

Meatotomy can be performed to treat distal stenosis by simple ventral incision of the meatus and suturing the cut end of the meatus to the vaginal wall. However, in our experience, circumferential, distal urethrectomy and advancement meatoplasty work best for distal strictures and urethral prolapse. It can be applied to meatal stenosis and strictures within approximately 1 cm from the meatus, but works best for true meatal stenosis [29].

To start, the extent of the stricture is identified to make certain that distal urethrectomy is appropriate. If desired, interrupted absorbable sutures can be placed in the more proximal, healthy urethral mucosa (at least 2 mm proximal to the strictured segment), at the 6 and 12 o’clock position, so that the mucosa does not retract inward. Identification of healthy mucosa can be aided with a nasal speculum. Sometimes, a small ventral urethrotomy is necessary to determine the proximal extent of the stricture. The procedure is described in Figure 111.1. Depending on the degree of reconstruction, a urethral catheter may be left in place for 1–3 days postoperatively. This is particularly useful as postoperative swelling can cause urinary retention.

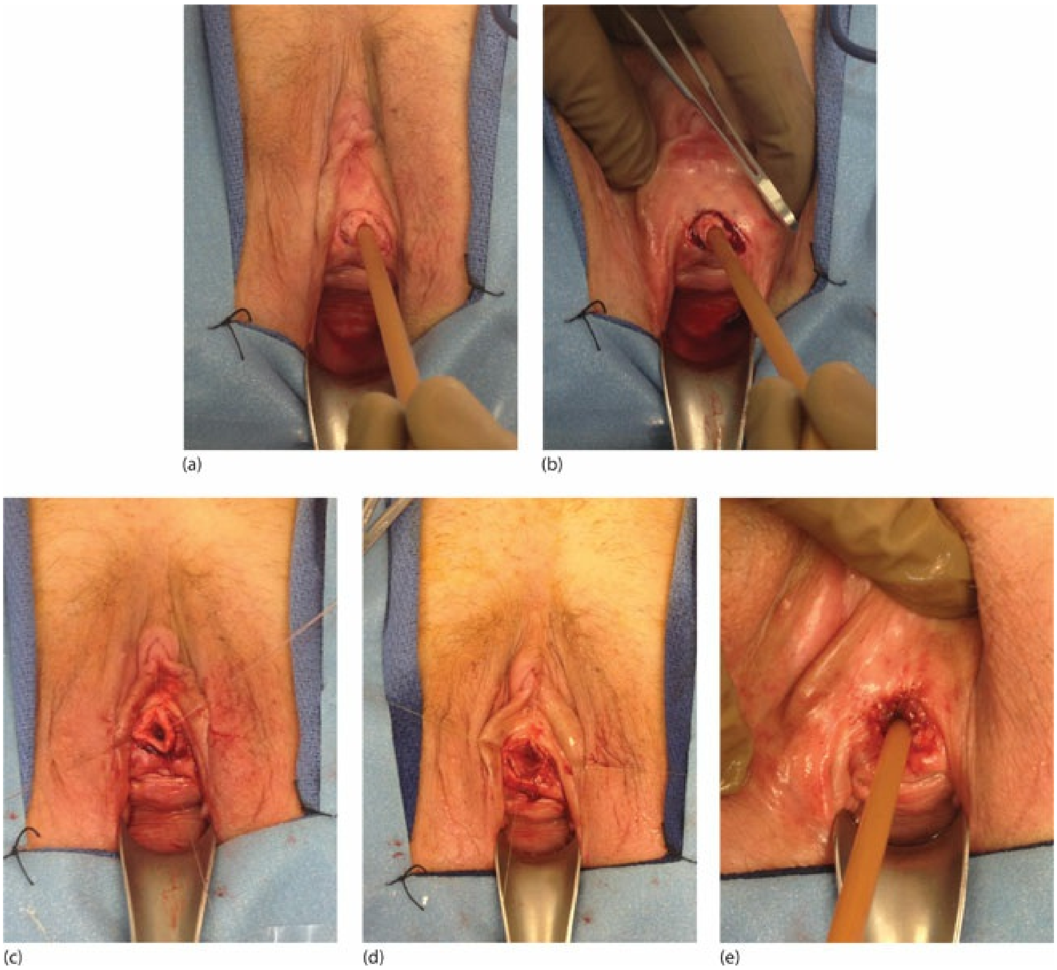

Figure 111.1 Distal urethrectomy with advancement meatoplasty. (a) A circumferential incision is made around the urethra at the mucosal/epithelial junction. (b) The urethra is dissected off of the periurethral fascia for the extent of the stricture. (c) Stay sutures of 4-0 delayed absorbable suture (polyglycolic acid or Monocryl) can be placed proximal to the portion of the urethra to be excised. (d) The distal urethra is excised and the stay sutures are brought through the vaginal epithelium. (e) Circumferential suturing of the urethral mucosa to the vaginal epithelium completes the meatoplasty.

Distal Urethroplasty with Vaginal and Vestibular Inlay Flaps

For distal strictures that have a proximal limit of up to 2 cm from the urethral meatus, a Blandy urethroplasty or proximally based vaginal pedicle inlay flap can be done. The procedure was originally described but never reported by Blandy, but was subsequently reported on by Schwender et al. [30]. This procedure recreates the ventral portion of the urethral meatus and replaces the distal ventral urethra with a flap of vaginal wall. The procedure is described in Figure 111.2 [29]. As with any stricture, the first step is identifying the proximal extent of the stricture. After completion on the urethroplasty, a 14–16 French Foley catheter is left indwelling for several days. Montorsi et al. [32] described a similar procedure where the distal urethra is incised dorsally and a vestibular pedicle is sutured to the dorsal distal urethra. Here, the blood supply of the flap is distally based.

Outcomes for Distal Urethral Reconstruction

Early postoperative complications of distal urethral reconstruction are generally self-limiting and include bleeding, transient urinary retention secondary to swelling, and urinary tract infection. There is little in the literature regarding the outcomes for distal urethral reconstruction. Schwender et al. [30] reported an 89% success rate (no further treatment necessary) for eight women undergoing distal ventral vaginal flap inlay urethroplasty. Onol et al. [31] reported 100% objective success in 10 patients. Using a similar vestibular flap inlay pedicle, Montorsi et al. reported that 88% of 17 women had relief of obstruction [32]. Regarding distal urethrectomy and advancement meatoplasty, we would expect similar success rates. When this procedure occasionally fails, it is usually due to the reformation of scar tissue caused by inadequate resection at the initial procedure.

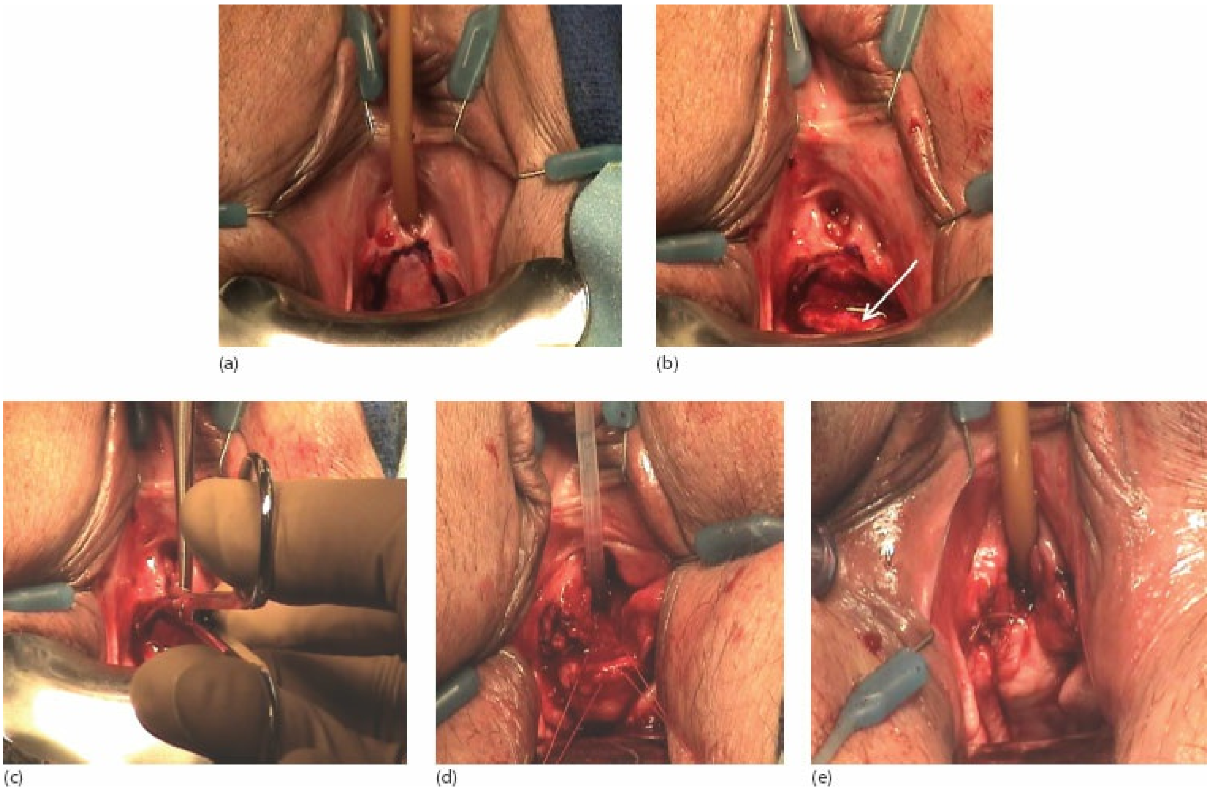

Figure 111.2 Distal urethroplasty with vaginal inlay flap (Blandy urethroplasty). (a) The vaginal inlay flap is

outlined with a marker. (b) An inverted-U incision is made in the anterior vaginal wall with the apex of the U at the urethral meatus, and using sharp dissection, a proximally based vaginal flap is raised that is slightly longer than the length of the stricture, usually 2–3 cm. (c) The ventral urethra is incised ventrally at the 6 o'clock position, from the meatus through the stricture into normal urethral mucosa. (Cystoscopy can also be used to aid in the identification of the limit of the stricture.) (d) The apex of the vaginal flap is advanced to the apex of the incised ventral urethra and is secured with 4-0 polyglycolic acid or Monocryl sutures. (e) The edges of the vaginal flap are approximated to the urethral mucosal edges using an interrupted, 4-0 polyglycolic acid or Monocryl sutures completing the urethroplasty. (From Nitti VW and Rosenblum N, Female urethral reconstruction, in: Nitti WW, Rosenblum R, and Brucker BM, eds., Vaginal Surgery for the Urologist, Elsevier Saunders, Philadelphia, PA, 2012, pp. 137–154. With permission.)

Vaginal Flap Urethroplasty

The mid or proximal segment of the female urethra, between the true bladder neck and pubourethral ligaments, contains the striated sphincter complex and levator ani insertion. The most critical components of both active and passive continence are located in this important segment of urethra. The Blandy proximally based vaginal flap urethroplasty (described earlier) can be used to treat some midurethral strictures, particularly those that are at the more distal portion of the midurethra. In cases of strictures that are isolated to the midurethra and do not include the distal urethra, one may also consider a free graft, such as buccal mucosa (see section "Onlay Urethroplasty Using a Free Graft" and Figure 111.5).

Vaginal flap urethroplasty, popularized by Blaivas [33], can be utilized to recreate a functional urethra by way of local, healthy tissues. It can be used for strictures as well as ablation/erosion of the mid to distal urethra. This technique can also be applied in cases of a shortened urethra associated with vaginal voiding in order to improve urethral length. In cases of urethral stricture, a longitudinal incision is made in the anterior vaginal wall directly beneath the urethra. The urethra is exposed and a longitudinal incision is made in the ventral urethra exposing the entire segment of strictured or diseased urethra, until more proximal, viable tissue is identified. This will become the dorsal plate of the urethra. In cases of urethral ablation, the vaginal wall distal to the urethra meatus becomes the ventral plate of the urethra.

There are two variations of the vaginal flap urethroplasty that we commonly employ. In the first, a flap of full thickness vaginal wall, including the epithelium, in a U configuration can be employed as a patch or ventral plate of neourethra (Figure 111.3). The second, for cases of urethral ablation, where there is compromised anterior vaginal wall tissue proximal to the urethra, medially based flaps can be created from the vaginal wall distal to urethra. In both cases, an autologous rectal fascia pubovaginal sling can be done simultaneously if there is coexisting stress urinary incontinence (Figure 111.4). In both cases, a Foley catheter is left indwelling for 10–14 days after the surgery.

Outcomes for Vaginal Flap Urethroplasty

Success rates for vaginal flap urethroplasty are quite good. In the largest series in the literature, Flisser and Blaivas reported successful anatomic repair in 93% of 72 women [33]. Sixty-two of the patients were incontinent and underwent simultaneous pubovaginal sling with a success rate of 87%. Incontinence occurred postoperative in 25% of women who were continent preoperatively. Potential complications of vaginal flap urethral reconstruction include recurrent urethral stricture/meatal stenosis, vaginal flap necrosis, de novo stress or urgency incontinence, vaginal shortening, and dyspareunia. Simonato and colleagues used a distal C-shaped flap for midurethral strictures [11]. The procedure is similar to that described in Figure 111.4. The distal to midurethral is incised from the meatus through the stricture, and the vaginal wall is mobilized from one side on a laterally based pedicle to create a new ventral mid to distal urethra. They reported "normal voiding" at a mean follow-up of 70.8 months in all six patients who had the procedure, but one needed to do intermittent self-catheterization. Overall, the success rate was 83%.

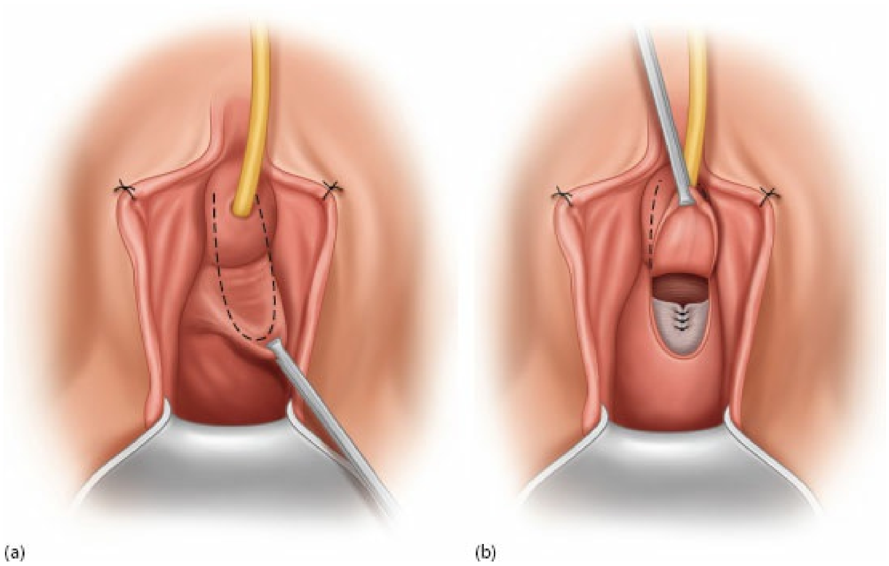

Figure 111.3 Proximally based vaginal flap urethroplasty. (a) U-shaped incision is made in the anterior vaginal wall. The dimensions of the U are approximately 1–1.5 cm wide and 2–3 cm long. In cases of stricture, where the opened urethra will be used as the dorsal plate of the neourethra, the top of the U is at the level of the proximal part of the opened urethra. In cases of urethral ablation (shown here), the top of the U extends to where the neomeatus will be. (b) The flap is then flipped up and sutured to the edges of the open distal urethra (stricture) or proximal vaginal wall (ablation) using a running 4-0 PDA suture on each side. Lateral vaginal wall flaps are made so that the anterior vaginal wall can be closed primarily, creating a second layer of tissue beneath the newly created urethra. If desired, an autologous fascia or biological pubovaginal sling can be placed at the bladder neck. (Adapted from Nitti VW and Rosenblum N, Female urethral reconstruction, in: Nitti WW, Rosenblum R, and Brucker BM, eds., *Vaginal Surgery for the Urologist*, Elsevier Saunders, Philadelphia, PA, 2012, pp. 137–154. U-flap closed to lateral incisions creating additional layer

Figure 111.4 Distally based vaginal flap urethroplasty. (a) A rectangular or square island of vaginal wall is created by making lateral, vertical, proximal, and distal lateral incisions around the urethral meatus. In addition, an inverted-U incision is made with the apex of the U at the level of the lower border of the rectangle flap. (b) The flap is then dissected medially on both sides so that the vaginal wall can be tubularized over a catheter, creating a neourethra using 4-0 polyglycolic sutures. This is usually done over a 14 French Foley catheter. (c) The proximal inverted-U flap is then advanced over the neourethra and closed to the lateral incisions where the rectangular flap was taken, as an additional layer of tissue. If desired, a pubovaginal sling can be placed prior to advancement of the inverted-U flap. (Adapted from Nitti VW and Rosenblum N, Female urethral reconstruction, in: Nitti WW, Rosenblum R, and Brucker BM, eds., *Vaginal Surgery for the Urologist*, Elsevier Saunders, Philadelphia, PA, 2012, pp. 137–154. Onlay Urethroplasty Using a Free Graft

When suitable vaginal tissue is not available or practical for urethral reconstruction, we prefer using a free graft to patch the urethra. It is our procedure of choice for proximal and panurethral strictures. Buccal mucosa, which has been used extensively in male urethral reconstruction, is currently the most widely used free graft in female urethral reconstruction as well. Some authors have used lingual mucosa harvested from the ventral–lateral aspect of the tongue claiming that it has many of the same properties as buccal mucosa, and avoid potential injury to the parotid duct and mental nerve. Free grafts can be placed dorsally or ventrally. We prefer dorsal placement primarily because graft is well supported mechanically and rests on a well-vascularized bed. Also, sacculation and the risk of urethrovaginal fistula can be minimized.

A stepwise description of the procedure is as follows:

1. The urethra is cannulated with a small catheter (5–6 French).
2. A suprameatal inverted-U incision is made to expose the dorsal urethra. Traction sutures may be placed in the urethral mucosal at the meatus at the 3 and 9 o’clock positions.
3. The urethra is sharply dissected from the vulvar epithelium, and a plane is developed between the urethra and clitoral cavernosal tissue with care so as not to damage the bulb, clitoral body crura, or the anterior portion of the striated sphincter that should be reflected upward.
4. The urethra is incised dorsally at the 12 o’clock position from the urethral meatus through the stricture, to normal unscarred urethral mucosa (Figure 111.5a). A stay suture of 4-0 or 5-0 polyglycolic acid or Monocryl can be placed at this point.
5. The stricture is measured so that an appropriately sized length of buccal (or lingual) mucosa approximately 1.5–2 cm wide can be harvested.
6. The graft is fixed to the apex of the stricture with the previously placed stay suture.
7. The sides of the graft are sutured to the urethra with 4-0 or 5-0 polyglycolic acid or Monocryl sutures over a 14–18 French Foley catheter (Figure 111.5b).
8. The graft is fixed dorsally with one suture, and the augmented dorsal urethra is quilted to the clitoral body to cover the new urethral roof.
9. The vulvar epithelium is closed.

Outcomes for Free Graft Onlay Urethroplasty

Outcomes for buccal and lingual musical onlay grafts come from relatively small series (1–15 patients) but are quite good in the short term with a mean follow-up 6–27 months [31,34–38]. Success rates for dorsal onlay are 93%–100% in 28 patients from combined studies [31,34–37], compared to 50%–100% for 4 patients with ventral onlay [31,38].

SALVAGE PROCEDURES

In cases of complete urethra destruction or refractory stricture, one may consider bladder neck closure or total urinary diversion. The bladder neck can be closed via a vaginal or abdominal approach. We prefer the transvaginal approach. It must be combined with either a suprapubic tube or a continent (e.g., catheterizable stoma such as a Mitrofanoff procedure) or incontinent (e.g., ileal chimney) urinary diversion. Although there are not a large number of reports on bladder neck closure in the literature, success rates are high. Zimmern et al. [39] reported 100% success in six women. One potential consequence of this procedure is bleeding from retropubic vessels, which can be difficult to control. When this happens, the case should be completed expeditiously. Other complications include ureteral injury (which can be minimized by giving intravenous dye that is excreted by the kidney or by urethral stenting) and vesicovaginal fistula formation. Alternatively, the surgeon and the patient may opt for a complete urinary diversion (with or without cystectomy) if there is a concern that the bladder neck closure will not heal, e.g., in cases of severe radiation damage.

Ureteral and Bladder Reconstruction

Nadir I. Osman, Altaf Mangera, and Christopher R. Chapple

INTRODUCTION

Complex reconstructive surgery aims to restore function to the lower urinary tract (LUT) in patients with congenital or acquired disorders. The success of this type of surgery is dependent upon a sound and comprehensive preoperative evaluation of LUT function based upon urodynamic investigation, endoscopy, and radiological techniques. In addition, it is imperative that the operator is familiar with pelvic anatomy and the abnormalities associated with pathological or iatrogenic insult that are encountered. The application of the surgical tenants applicable to any form of reconstructive surgery is essential, including the excision of ischemic tissue, obliteration of dead space, interposition of vascularized tissue, avoidance of infection and hematoma, and tension-free anastomosis.

Although in contemporary practice complex reconstructive surgery is often restricted to the tertiary specialist setting, the basic underlying principles are fundamental to the practice of all surgery. In addition, it is essential that the surgeon is knowledgeable of and is able to apply the full gamut of available reconstructive techniques that may be appropriate for the given situation.

This chapter presents a brief exposition of complex reconstructive surgery in urogynecological practice including the reconstruction of ureteric, bladder, and urethral injuries in addition to the surgical management of severe detrusor overactivity (DO) refractory to conventional treatment.

URETERIC INJURY

The ureter is rarely injured as result of external trauma due to its elasticity and well-protected passage in the retroperitoneum. Most injuries are iatrogenic sustained during abdominal or pelvic surgery. The potentially lethal sequelae of sepsis and renal failure demands that any ureteric injury undergoes careful appraisal and timely intervention.

Iatrogenic Ureteric Injury

The overall incidence during abdominal surgery was found to be 0.4% in a series that included 4665 operations [1]. However, the actual incidence of ureteric injury is likely much higher due to the occurrence of occult injuries.

A systematic review of benign gynecological surgery estimated that ureteral injury ranged from 0.2 to 7.3 per 1000 surgeries [2]. In gynecologic oncologic surgeries, the incidence is much higher at 30%–35% [3–7].

Traditionally, gynecological surgery accounted for approximately two-thirds of iatrogenic injuries to the ureter. The vast majority sustained during hysterectomy, surgery for ovarian tumors, or incontinence surgery. Injuries are also sustained during colorectal surgery (15%), endoscopic ureteric procedures (2%–17%), vascular surgery (6%), laminectomy/spinal fusion (1%), bladder neck suspension procedures (3%), appendicectomy (1%), and cesarean section (1%) [8].

With the rise of laparoscopic approaches in contemporary gynecological surgery, laparoscopic injuries are becoming more common accounting for as many as 25% of all gynecological injuries to the ureter [9]. A similar rise can be seen in urological practice with the advent of more sophisticated endoscopes that allow better manipulation in the ureter for the treatment of urolithiasis. In a recent review of 165 ureteric injuries, urological surgery accounted for 42% compared to 34% and 24% for gynecological and general surgery, respectively. Most urological injuries were attributable to endoscopic procedures (79%) [10].

Risk Factors for Iatrogenic Injuries

Several factors are thought to increase the risk of iatrogenic injury to the ureter. These include congenital abnormalities such as ureteric duplication and ectopic ureter. Inflammatory or fibrotic conditions include the following: endometriosis, retroperitoneal fibrosis and pelvic infections, prior pelvic surgery or irradiation, and resection or large bulky tumors [11,12].

Types of Iatrogenic Injury

The pelvic ureter is involved in 80% of iatrogenic ureteral injuries, making it by far the most commonly involved segment [13]. The mechanisms of injury include the following:

1. *Avulsion*: Avulsion occurs when the ureter is forcefully retracted particularly if the tissues are weakened by infection or necrosis.
2. *Transection*: This occurs due to sharp injury by scissors or a scalpel, especially when the ureters are enveloped within tumor or fibrous tissue. Common sites of such injuries during gynecologic surgery include the following:
   a. The pelvic brim, where the vascular pedicle to the ovary is in close proximity to the ureter
   b. The broad ligament, where the ureter is crossed by the uterine artery
   c. The ureteric canal in the cardinal ligament, 1 cm lateral to the supravaginal cervix and 1 cm above the lateral vaginal fornix
3. *Ligation*: This occurs when the ureters are mistaken for bleeding vessels. It can also occur during vaginal hysterectomy when the uterine arteries are being ligated and in procidentia when the ureters prolapse with the uterus.
4. *Crushing*: This may occur when clamps are used blindly to control hemorrhage and is seen at the sites similar to transection injury, especially during radical hysterectomy for cancer. Necrosis and ultimately stricture or fistula formation can result.
5. *Devascularization*: This occurs when extensive or overenthusiastic dissection of the ureter is performed. The ureter is supplied in 80% of individuals by a single artery along its entire length with anastomotic feeding vessels at each end and in the middle. Devascularization results in ischemic necrosis, which ultimately leads to fistula or stricture.
6. *Perforation*: This is commonly caused by ureteroscopy and associated endoscopic manipulation for ureteric stones. The edematous tissue surrounding the stone and the tissue traumatized by lithotripsy are predisposing factors. Needle injury during open surgery may result in perforation but is rarely a cause of problems in healthy tissues.
7. *Fulguration*: This can occur during transurethral resection of the bladder cancers resected close to the ureteric orifices and then extensively diathermied. Laparoscopic diathermy and laser treatment of endometriotic lesions are an increasingly important cause of thermal injury to the urinary tract that has seen an increase in parallel with the rise of laparoscopic surgery in gynecology.
8. *Fistula formation*: This can follow transection, ischemic necrosis, or perforation if the distal end of the ureter is not in continuity or is obstructed. The urine will then discharge from the vagina, operative wound, or drain site or into the peritoneal cavity or retroperitoneal space.
9. *Stricture formation*: This can follow any of the aforementioned injuries and ultimately lead to obstruction of the ureters, hydronephrosis, and renal damage.
10. *Kinking*: This can occur when the tension is placed on ureteral wall or periureteric tissue. This is commonly seen in certain apical prolapse repairs.

Noniatrogenic Ureteric Injury

Ureteric injuries, not due to iatrogenic injury, are rare but potentially lethal injuries due to the potential for sepsis and high incidence of concomitant injuries (>90%) including the colon (51%), small intestine (49%), and large blood vessels (38%) [14,15]. A recent retrospective analysis of the 22,706 genitourinary injuries found ureteral trauma responsible for 2.5% [15].

A recent review of the data from the U.S. National Trauma Data Bank found that 62% of ureteric injuries are penetrating in nature, while 38% are blunt [15]. This is interesting as traditionally it was thought that blunt injuries are relatively much rarer. Penetrating injuries typically occur due to gunshot or stab wounds, whereas blunt injuries are typically sustained during motor vehicle accidents or falls. A 25-year review from San Francisco General Hospital showed that ureteral injuries in 70% cases involved the upper ureter [16].

Radiation injury to the ureters is rare and can occur in radiotherapy for cervical, bladder, rectal, and other pelvic tumors. Most postirradiation ureteral strictures, however, are due to recurrent tumor. Presentation may be from 3 months up to 10 years, usually with a long threadlike stenotic lesion or a localized constriction about 4–6 cm from the bladder. These are thought to be due to endarteritis obliterans resulting from radiotherapy. Subsequent surgery on such poor-quality tissues also predisposes to a higher complication rate involving the ureters [17].

Presentation

Ideally, any iatrogenic ureteral injury should be identified and dealt with intraoperatively; however, 50%–70% are diagnosed postoperatively [18,19]. Diagnostic delays can vary from 2 days to 12 years [20,21]. Early signs of ureteral injuries are subtle and usually missed, the injury being discovered several days or weeks later when a complication occurs. In urological surgery, however, where injury is most commonly associated with ureteroscopic procedures for stone disease, 77% are diagnosed intraoperatively. Of these ureteric injuries, 91% occur in the lower third, 7% in the middle third, and 2% in the upper third.

Diagnosis

Injuries recognized and repaired intraoperatively carry a better prognosis of cure than those that become manifest postoperatively as a result of complications [10,20,22,23]. In a review of 165 ureteral injuries by Selzman and Spirnak, the number of procedures required to repair urological injuries was 1.2 for those diagnosed intraoperatively compared to 1.6 for those diagnosed postoperatively [10]. Compared to 16% in gynecological surgery and 56% in general surgery, 77% of injuries were diagnosed intraoperatively. This difference is mainly due to the different procedures that cause such injuries in these specialties in presumably the greater familiarity with ureteric anatomy among urologists.

Features of postoperative presentation can be nonspecific and therefore a ureteral injury must first be suspected to be detected. The symptoms and signs include persistent fever, flank pain, ileus, abdominal mass, and excessive drain output or wound or vaginal leakage. Flank pain occurs in 36%–90% of cases of hydronephrosis [21,22,24]. Fistulae of the vagina and skin tend to be present 7–10 days after surgery with urinary leakage [18,20–22,24]. Excessive wound drainage or leakage per vagina may be collected and analyzed for urea and electrolyte levels to determine if it is urine.

In contemporary practice, a CT intravenous urogram (CT-IVU) is mandatory whenever ureteric injury is suspected postoperatively. This will usually demonstrate the site of injury as well as associated pathology such as hydronephrosis and ureteric fistulation and urinomas in addition to allowing the assessment of other associated abdominal and pelvic injuries. Should the CT-IVU be inconclusive, cystoscopy and retrograde pyelogram or antegrade nephrostogram is often useful; higher concentrations of contrast in these studies allow demonstration of leakage and will establish the diagnosis in most cases.

Prevention

Iatrogenic injuries are best managed by preventive rather than corrective measures. Avoidance of ureteric injury is invariably the principle of all good surgical practice and begins with a thorough knowledge of the course of the ureters, the nature, and the site of potential ureteric injuries and an adequate preoperative evaluation. This may include a CT-IVU or IVU to define anatomy if major pelvic or retroperitoneal surgery is planned. A preoperative IVU allows for comparative studies should a postoperative IVU become necessary. However, preoperative IVUs have not been shown to be of value prior to routine hysterectomy and cannot substitute for good surgical technique and identification of anatomic landmarks [18,25].

Congenital anomalies, ectopic ureters, and ureteric duplications should be recognized in advance and may be defined on preoperative imaging. Where radical surgery is being carried out and the ureters are involved or displaced by the pathology, their course should be mapped and the necessary precautions taken. Identification of the length of ureter within the operative field should significantly reduce the risk of damage. The ureters are recognized by the glistening appearance of their sheaths, peristalsis on stimulation, and characteristic feel on palpation. Dissection of the ureters may be necessary, especially when in close proximity to resection margins. Sharp dissection along the line of the ureter, incorporating a generous cuff of periureteric adventitia, should reduce the risk of ischemic injury.

The close anatomical relationship of the uterine artery and the last 3 cm of the ureter make it vulnerable to injury when mass ligature and blind clamping of an injured artery occur. Proper identification and isolation of the uterine artery before ligation and digital compression of the internal iliac artery to control hemorrhage can avoid the need for blind clamping. Most unexpected hemorrhage can be controlled by suitable compression of the bleeding point until the ureter is identified.

If ureteric injury is suspected during open surgery, indigo carmine dye may be useful in identifying the presence and site of the lesion. Contrast solution with intraoperative imaging is more useful during ureteroscopic procedures.

Preoperative ureteral stenting has long been advocated as a method of making intraoperative identification of the ureters easier in order to avoid ureteral injury. However, a recent randomized trial that compared preoperative ureteral stenting *versus* no stenting for major gynecologic surgery, a rate of injury of less than 1% occurred in each group with no statistical difference between the groups [26]. Illuminated or lighted stents have been advocated in laparoscopic practice given the lack of tactile feedback. In recent series of 145 complex laparoscopic surgeries in which theses stents were used, no ureteral injuries occurred [27]. If the efficacy of lighted stents in preventing injury is established, this would need to be balanced against the risks of ureteral stenting (e.g., hematuria and postoperative renal impairment due to ureteric edema) and the additional costs incurred.

Management of Ureteric Injury

The management of a ureteral injury depends on its extent and location, its etiology, associated injuries, and the time of its recognition.

Timing of Surgery

Ureteral injuries discovered intraoperatively and repaired immediately have excellent results, probably due to the absence of sequelae following urine leak and complications such as infection [10,28]. If the injury is incurred during a ureteroscopic procedure, an internal stent placed retrograde across the defect may be all that is required. Small perforations usually heal within 1–2 weeks, whereas larger defects and thermal injuries require up to 6 weeks of internal stenting. If immediate stenting is impossible, initial percutaneous nephrostomy and subsequent antegrade placement of the ureteral stent is indicated [9].

Injuries diagnosed postoperatively may initially be managed conservatively using nephrostomy drainage and/or subsequent ureteric stenting if the ureteric defect is short (<2.5 cm) and a stent can be passed across the defect, either retrograde or antegrade. About half of all ureteric injuries can be treated by such endoscopic stenting, whereas the remainder will require an open procedure for definitive repair. In a series of 165 iatrogenic ureteric injuries, 49% were treated with 6 weeks of internal stenting, 89% showing no evidence of obstruction on follow-up lasting 1–20 years (mean of 8.5 years) [10]. A further series of 50 ureteric injuries reported that endoscopic treatment performed for defects of <2 cm required less operating time, had fewer complications, and shorter hospital stays compared with those undergoing open surgery [29]. No recurrences were noted over a 2-year follow-up period. However, 14 of the 30 patients selected for endoscopic treatment failed ureteric stenting and subsequently required open repair (all were ureteric injuries diagnosed 3 weeks or more after injury). The authors concluded that endoscopic management of ureteral injuries should be carried out only in those with defects < 2 cm in length diagnosed within 3 weeks of injury.

In a further series of 27 patients, it was reported that percutaneous nephrostomy alone or in conjunction with ureteral stenting was successful in treating 11 (65%) of the 17 ureteral injuries considered suitable for endoscopic stenting [18]. As reported by Cormio et al. [29], only 1 of 20 attempted retrograde ureteral stenting was successful in those with delayed diagnoses. All ureteric fistulae required ureteric stenting for healing, and percutaneous nephrostomy was successful only in those with demonstrable ureteric obstruction. These cases presumably represent ligation or crush injuries requiring time for dissolution of sutures and tissue healing. Ureteric obstruction persisting after 8 weeks of percutaneous drainage will require open exploration and repair [18]. In a series of 20 patients with ureteric injuries who had percutaneous nephrostomy with or without a stent as a primary procedure, 80% had spontaneous recovery of the injured ureter without further intervention. Morbidity and reoperation rates were reduced compared with 24 ureteric injuries treated by immediate open ureteric repair [30].

For those that require open surgical correction, immediate repair has increasingly been shown to have similar if not better results compared with the traditional approach of waiting for 6 weeks to 3 months before definitive repair. A number of series support early surgical intervention within 3 weeks [20,22,23,31–34]. Selzman and Spirnak also found that complications were five times higher in the group treated by delayed compared with immediate repair for urologically injured ureters [10].

Open Surgical Management

Ureteral transection is best repaired by immediate spatulated ureteroureterostomy. This should be carried out with a tension-free anastomosis using interrupted absorbable sutures. Sutures should not be too close together in an attempt to achieve a watertight anastomosis, as ischemia and subsequent stricture formation may result. A ureteral stent is often used as a splint and removed between 2 and 6 weeks. Ligation injuries are simply deligated, but crush injuries may be of greater extent due to ischemia and must be handled carefully [24]. If doubt exists as to the viability of the ureter, partial excision and spatulated reanastomosis may be required (Figure 112.1).

For injuries at or below the pelvic brim, an antireflux ureteroneocystostomy is the treatment of choice, for which various methods have been described. In the event of a gap between the end of the ureter and bladder, extra length can be obtained with a psoas hitch [35]. Alternatively, a Boari flap may be employed to achieve a tension-free anastomosis [36,37] (Figure 112.2). A graft length to width ratio of 3:2 is necessary, using a vascular pedicle based on the superior vesical artery. As the tubularized flap has no functional activity, the tube should be openmouthed for adequate drainage [38]. The theoretical advantage of the psoas hitch is the better preservation of the blood supply that may be more precarious in the Boari flap. Other practical advantages include the relative ease of closure of the incision in thick-walled bladders. The incision is relatively smaller to produce an equivalent length of tube, thereby facilitating a nonrefluxing reimplantation, and the subsequent ureteric positioning facilitates ureteroscopy.

For ureteric defects above the pelvic brim, additional length of the ureter of a few centimeters can be obtained by mobilization of the kidney, allowing spatulated ureteroureterostomy. Other options to foreshorten the ureteric course include calicoureterostomy, transureterostomy, and autotransplantation [39–41]. If all else fails, nephrectomy is a final resort.

A number of nonbiological ureteral substitutes have been investigated with limited and generally short-lived success. The ileal ureter has proved the most reliable ureteric replacement to date [42,43]. The main drawbacks to the use of the bowel, as in other bowel replacement surgery, relates to the production of mucus (which can cause obstruction), inadequate peristalsis, anastomotic stricture, and reabsorption of excretory waste products. Consequently, contraindications to ileoureteric substitution include uncorrected bladder outlet obstruction and impaired renal function. Recurrent urinary tract infection and subsequent renal impairment are potential complications [38]. The appendix is an alternative biologic substitute but is of limited length [44]. The fallopian tube has been employed but is limited by its relatively small caliber.

Postoperative Care and Follow-Up

Postoperative care following surgery for ureteric injuries requires close monitoring of renal function with appropriate fluid and electrolyte replacement, especially in the presence of postobstruction diuresis. Adequate antibiotic cover, wound care, and prophylaxis against deep vein thrombosis follow standard surgical practice. Meticulous care of catheters and drains is critical, given the dependence of renal function and uneventful postoperative recovery on these devices.

Common complications include urinary leakage, infection, and hematoma and complications related to drains and catheters. Percutaneous nephrostomy tubes may kink or become displaced due to their awkward locations in the flank. Proper anchoring techniques and aftercare are therefore essential. Chronic and recurrent infections can also result from the use of long-term nephrostomy drainage. Alternatively, the use of internal stents may avoid such complications but often causes storage LUT symptoms and, in the long term, may become encrusted if not changed every 4–6 months. Vesicoureteric reflux may occur following reimplantation and may present with loin pain, recurrent infection, and dilation of the pelvicalyceal system.

Monitoring of wound drainage and contrast radiography immediately after placement of stents or drains is essential. Tube nephrostograms are useful for diagnostic purposes. A repeat imaging study by an appropriate modality such as an IVU or CT urogram following stent removal and long-term follow-up (including IVU at 6 weeks and possibly longer) are recommended.

Conclusions

It is evident that it is important to diagnose ureteral injury as soon as possible and, if identified at the time of surgery, to carry out ureteral stenting (if possible) during endoscopic surgery or direct repair during open surgery. Failing this, a number of open surgical options to foreshorten the course of the ureter are available. If this is not possible, either ureteral substitution or autotransplantation should be considered.

Definitive management of ureteric injury diagnosed postoperatively depends on the level and the extent of ureteric loss, its etiology, associated injuries or complications, and time to discovery. The functional status of the kidneys and the age, condition, and prognosis of the patient are similarly important. Most injuries below the pelvic brim can be treated with a neoureterocystostomy employing a bladder elongation procedure. Mid and upper ureteric injuries above the pelvic brim, however, are more challenging. Small defects above the pelvic brim can be repaired with a spatulated ureteroureterostomy. In cases of extensive ureteral loss, measures such as mobilizing the kidney, transureteroureterostomy, renal autotransplantation, and ureteral substitution using small bowel may be required.

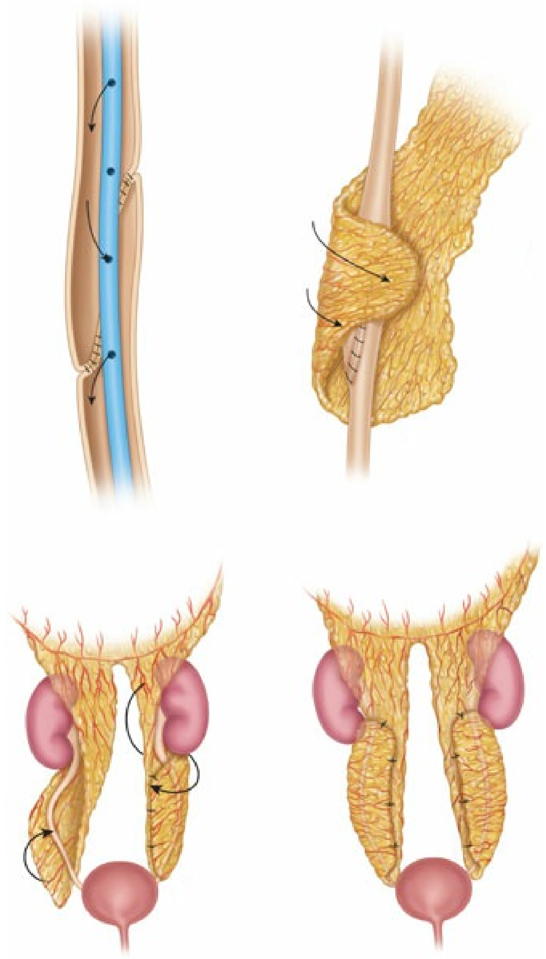

Figure 112.1 The principle of end-to-end spatulated anastomosis of the ureter with omental wrap around to provide support to the repair.

Although reconstruction should be attempted whenever possible, in rare situations, based on the general condition of the patient, the function of both kidneys, and the degree of damage to the ureter, nephrectomy may represent the most appropriate management.

BLADDER RECONSTRUCTIVE SURGERY

Bladder reconstruction and urinary diversion may be preformed for refractory cases of defunctionalized bladder (e.g., from radiation [45]), nonreconstructable fistulae [46], destroyed bladder outlet and refractory bladder overactivity, and impaired compliance.

Overactive bladder (OAB) syndrome and neurogenic bladder can lead to considerable morbidity in patients. Idiopathic DO (IDO) is a urodynamic finding that is demonstrated in approximately 69% of men and 44% of women with OAB-dry and 90% of men and 58% of women with OAB-wet symptoms [47]. Neurogenic DO (NDO) may also lead to renal impairment that may result from voiding dysfunction and back pressure on the upper tracts in association with high-pressure phasic detrusor contractions and detrusor sphincter dyssynergia. In both conditions, first-line pharmacotherapy is still anticholinergic agents, often combined with bladder retraining. More recently, B3 agonists have been shown to be beneficial in patients with OAB [48] with or without IDO. However, their role in NDO still requires further exploration. In the context of neurogenic bladder dysfunction, the clinical picture is complicated by an admixture of other functional problems associated with uncoordinated detrusor contractions, poor bladder compliance, and varying degrees of sphincteric obstruction.

It is secured to the psoas muscle. (h) Postoperative cystogram.

In the past decade, the treatment of pharmacologic refractory OAB and NDO has changed. In previous years, the mainstay of therapy for bladder overactivity was augmentation cystoplasty, mostly using the *clam* technique [49]. Four further options have also been explored: bladder autoaugmentation [50], sacral neuromodulation [51], posterior tibial nerve stimulation [52], and intravesical botulinum neurotoxin injection therapy [53]. In cases of OAB, both neuromodulation and intradetrusor botulinum injections (discussed elsewhere in the book) are used prior to major reconstructive surgery. In addition, botulinum toxin has been found to be effective for NDO. The efficacy of these two treatments for decreased bladder compliance is not well documented. Bladder reconstruction and urinary diversion is often reserved for patients that have failed or are not candidates for neuromodulation and botulinum toxin. These will be discussed here; while a number of surgical techniques for the treatment of DO have been described, it is now widely accepted that procedures such as detrusor transection and transtrigonal phenol injection produce unpredictable and temporary improvement with potentially serious side effects. Their routine use can therefore no longer be supported. We will focus our discussion on surgical procedures that preserve the bladder and increase its functional capacity and reduce storage pressures and those that create a new storage reservoir.

Augmentation Cystoplasty

The principle underlying augmentation cystoplasty is that by bivalving a functionally OAB or high-pressure bladder in neurogenic patients and introducing a segment of detubularized intestine, a low-pressure bladder with an increased functional capacity will result.

The two commonly used intestinal segments are ileum and sigmoid colon. The sigmoid is usually used in patients where a short small bowel mesentery renders the use of ileum difficult. Ileum is preferred as it produces lower reservoir pressures and better compliance. The original technique described for clam cystoplasty is still widely used, but modifications to this include opening the bladder in the sagittal plane that appears to be equally effective or opening the bladder as a *star* [54]. This specific modification can be particularly useful in patients with NDO where the bladder is small and thick walled. An alternative surgical technique popularized by McGuire is his modification of the hemi-Koch procedure. This utilizes a transverse *smile* incision (looking posteriorly), which is fashioned 3 cm above the ureteral orifices, creating an anteriorly based detrusor flap [55]. Most surgeons find coronal or sagittal bivalving of the bladder to be effective and acceptable, provided that adequate opening of the bladder is performed right down to the ureteral orifices, both to adequately open the bladder and to prevent *diverticulation* of the cystoplasty segment. The ileal segment should also be detubularized as this will greatly increase bladder capacity (law of Laplace) and reduce the effect of peristaltic activity [56]. In addition, it is advisable that bladder capacity is increased to in excess of 500 mL especially in the neuropathic population.

Although the majority of bladder augmentation procedures are performed via an open technique, laparoscopic and robot-assisted techniques have been described [57,58]. The aim of minimally invasive surgery is to minimize the trauma of surgery, allow earlier recovery, and return to activities without compromising the surgical outcomes. Whether this is achieved with current laparoscopic or robotic procedures is still debatable.

A number of studies attest to the efficacy of augmentation cystoplasty in children, adolescents, and adults with DO and NDO [59–62]. Mundy and Stephenson reported a series of 40 cases in whom 90% were cured at a mean follow-up of 1 year [54]. Mean functional bladder capacity was increased from 280 to 440 mL, reduced compliance was improved in 70% of patients, and DO abolished in 50%, the remainder having low-pressure DO. In a series of 26 adolescents undergoing enterocystoplasty, 19 of whom had a *clam* cystoplasty, the results were satisfactory in all 3 males but poor in 5 out of the 16 females. In three patients, difficulty was experienced with clean intermittent self catheterization (CISC) [60].

- In a series of 39 children with spina bifida, bladder capacity at safe storage pressures of <29 cm of saline was achieved in all patients with a reduction in upper tract dilatation in 91.7% of the kidneys [61]. A satisfactory result was achieved in all but one patient.
- Singh and Thomas [63] reviewed 67 patients who underwent augmentation cystoplasty. Of these, 47 had an ileal segment and 20 had a sigmoid segment. These data are presented in combination with a further 11 patients who had an ileocecal cystoplasty. Fifty-two patients had an artificial sphincter, nine had a colposuspension, and one had both. Acceptable continence was achieved in 93.6% of patients.
- Hasan et al. [62] reported on 48 patients who underwent augmentation cystoplasty for IDO (n = 35) or NDO (n = 13). Mean follow-up was 38 months, with 83% achieving a good outcome, 15% a moderate outcome, and 2% an unsatisfactory result.
- Flood et al. [64] reported on 122 augmentation cystoplasties. It must, however, be borne in mind that the “McGuire” technique used was different from the standard clam procedure reported for all the other series described earlier, and this was a very mixed group of patients: 67% had an ileal augmentation, 30% a detubularized cecocystoplasty, and 3% sigmoid. In 19 patients, this procedure was related to undiversion and 17% had IC, 7% radiation cystitis, 13% miscellaneous conditions, and the remainder was either NDO or DO. Mean follow-up was 37 months. Bladder capacity was increased from a preoperative mean of 108–438 mL, and, of 106 successful patients, 75% had an excellent result, 20% were improved, and 5% had major, persistent problems.

The earlier literature supports augmentation cystoplasty as being an effective therapy with a low operative morbidity and satisfactory long-term results, although most of the reported series have a follow-up of less than 5 years. It must be remembered that this is major surgery, and despite adequate preoperative counseling, many patients take some months to adapt to their new bladder and to learn to void effectively by abdominal straining. It is important to monitor postoperative residual urine volumes. CISC is necessary for a number of these patients, particularly those with NDO. Interestingly, the reported incidence of CISC varies from 15% up to 85% of cases [58]. It is evident that a number of factors contribute to the need for CISC. These include the level of residual deemed acceptable by the supervising urologist and the concomitant use of procedures directed at the bladder outflow either urethral dilation (rebalancing) or treatments for stress incontinence. A particular debate centers on the treatment of coexisting stress incontinence at the time of clam cystoplasty; contemporary opinion remains divided on this matter since measures designed to treat stress incontinence will generally increase the need for CISC.

Other problems encountered with augmentation cystoplasty include persistent mucus production, recurrent or persistent urinary tract infections, and metabolic disorders, which are usually mild and subclinical. The metabolic picture is usually of a hyperchloremic metabolic acidosis. This should be managed with 2–6 g sodium bicarbonate therapy. Provided that patients are counseled preoperatively, this is rarely a problem. Persistent urinary infection can be troublesome, particularly in female patients, and has been reported in up to 30% of cases, often requiring long-term antibiotic therapy. Long-term bowel dysfunction occurs in up to a third of patients and is thought to be related to the interruption of the normal enterohepatic circulation [65]. Bladder perforations have been reported in up to 10% of patients [61]. At present, a lifelong follow-up of these patients is recommended, not only because of the aforementioned complications but also in view of the suggestion that augmentation cystoplasty predisposes to the subsequent development of malignancy. However, there remains no convincing evidence to support an association with tumor in the absence of other predisposing factors such as previous tuberculosis or chronic urinary stasis such as that associated with paraplegia [66].

Augmentation cystoplasty is an effective management option in contemporary practice in patients with intractable DO or NDO resistant to conventional therapy. In addition, cystoplasty can be used as part of an undiversion procedure. Although a proportion of patients are not significantly improved by this procedure, one series found a *good to moderate* outcome in only 58% of patients with DO [62]. It must be borne in mind that up to 30% of patients experience increased frequency and looseness of bowel motions and a tendency to incontinent episodes, with a significant number of patients requiring long-term CISC.

Bladder Autoaugmentation/Detrusor Myectomy

In 1989, Snow and Cartwright initially reported a technique that they named bladder autoaugmentation [68]. This procedure involves the excision of the detrusor muscle over the entire dome of the bladder, leaving the underlying bladder urothelium intact. A large epithelial *bulge* is created, which functions by augmenting the storage capacity of the bladder, and this is referred to as autoaugmentation.

Following initial studies in six dogs, this technique was extended to seven patients aged 4–17 years, all of whom had poorly compliant bladders documented on pressure flow urodynamics. Following excision of the dome detrusor muscle, the lateral margins of the detrusor were fixed bilaterally to the psoas muscles. Patient follow-up was short. A subsequent report by these workers after studying a total of 19 patients concluded that, with a follow-up of between 3 months and 4 years, 80% of patients were continent and another 10% were significantly improved. A significant increase in bladder capacity of >50 cc occurred in only 40% of patients, with minimal change in 35%; 25% actually had a decrease in capacity. The procedure was, however, accompanied by improved continence and reduced rates of hydronephrosis [68].

In 12 pediatric patients with low-capacity bladders and demonstrable DO (aged 4–14 years, 10 with NDO), 6 months following autoaugmentation, the mean increase in bladder capacity was 40% with a 33% decrease in mean leak-point pressure [68]. Postoperative complications were minor. A modification of the previous technique was used whereby a vesicomyotomy was performed rather than vesicomyectomy with no fixation of the bladder laterally to the psoas muscles. A subsequent preliminary report in five adult patients, with the follow-up ranging from 12 to 82 weeks, reported an increase in bladder capacity, which varied from 40% up to 310%; this was measured at an intravesical pressure of 40 cm H_2O.

Stohrer et al. reported a series of 29 patients aged 14–64 years with an average age of 35 years. Of these patients, 24 were felt likely to have NDO. All patients underwent preoperative urodynamic evaluation. The technique reported by these authors is based on the original one described by Snow and Cartwright with an extraperitoneal approach filling the bladder to 200–250 mL [67]. A 7–8 cm diameter section of the detrusor around the urachus is dissected completely and removed leaving the mucosa intact. The detrusor is not fixed to the psoas muscle and all bands of detrusor overlying the urothelium are removed. The authors now have follow-up to 7 years and while they find that 50% of patients can void without significant residuals, up to half require ISC. They found an improved compliance and increasing capacity of 130–600 mL [69].

An alternative surgical approach that has been explored in case reports is laparoscopic-assisted autoaugmentation, but comment on this cannot be made in the absence of adequate numbers of patients and no significant follow-up [70]. It is recognized that spontaneous perforation of an augmentation cystoplasty bladder is a potential risk, occurring in up to 10% of cases. This may be due to high intravesical pressure [71] and can usually be managed successfully by conservative measures [72]. Patients may be at even greater risk of perforation following autoaugmentation because of the thinness of the mucosa in the bulging *diverticulum* produced by the operation. Evidence in support of this is provided by animal studies where autoaugmentation resulted in higher risk of perforation at lower pressures than augmentation cystoplasty [73]. To date, this complication has yet to be reported in clinical series, possibly because of ingrowth of fibrous tissue around the mucosal diverticulum with time, which may also account for the limited increase in capacity seen following the procedure. This phenomenon, if progressive, may limit the durability of this operation.

At present, while autoaugmentation has a number of attractive features, it is clear that the resultant increase in bladder capacity and reduction in DO are far less pronounced than following augmentation cystoplasty. The number of cases reported in the literature is small with relatively short follow-up. However, Abrams has reported good results with reference to symptoms and urodynamic parameters in an IDO population. In 24 cases followed up for a minimum of 2 years and median (range) follow-up of 79 (28–142) months, autoaugmentation was successful in 80% of patients with IDO but only in 2/6 with NDO [74]. The positive results reported by this group have not been reproduced elsewhere. It is questionable whether the associated benefits adequately compensate for the limited long-term efficacy of the procedure, and this procedure has been largely abandoned. The search for less invasive techniques therefore continues.

Urinary Diversion

Urinary diversion may be either temporary or permanent. All surface diversions are simple surgical endeavors to correct the urinary waste disposal problems of patients who are unfortunate enough to have either lost or never actually achieved normal bladder function.

While clearly *diversion is diversion* and *cystoplasty is cystoplasty*, the development of the so-called continent diversion has confused this distinction. The surgical principles and the procedures that are used to create the urinary reservoir of this diversion are identical to those for a total cystoplasty. Because the only difference between these is the mechanism of their emptying, we would suggest a more rational terminological distinction, that is, *stoma-cystoplasty* and *sphincter-cystoplasty*.

The two key components of the creation, or re-creation, of a naturally functioning bladder are bladder-base sensation and a sufficiency of functional sphincter muscle. These are irreplaceable, but, all too often, one or both are sacrificed at the time of a urinary diversion.

Even a small area of urothelium that has normal sensation can make all the difference when it is available for inclusion in a functional reconstruction because the sensation of bladder fullness avoids the need to time its emptying. Similarly, the remnants of an incompetent sphincter mechanism can sometimes be made to function satisfactorily. Thus, it is important to preserve every bit of the functional tissue that might be important to a future reconstruction even if one cannot envisage either the possibility of an undiversion or that it could subserve a useful purpose. The opportunity of restoration of sphincteric function *today* has often been denied by the excisions of *yesterday*.

Similar considerations apply to the rectal sensation and the sphincteric control of defecation. An anal mechanism, or even its apparently useless remnants, should never be excised needlessly as many patients have lost their chance of anorectal continence as a result of an unnecessarily extensive routine abdominoperineal resection.

Options for Urinary Tract Diversion and Reconstruction

A consideration of the range of procedure options available for urinary diversion, some of which are no longer advocated, summarizes the practical experience upon which the evolution of current preferences are based. These options can be conveniently considered in four distinct categories:

1. *Free-draining surface diversion of the upper urinary tract*: This naturally requires the collection of continuously draining urine. The need for this may be temporary; however, it may be permanent if the surgical retrieval of the reservoir function of the LUT is not possible.
2. *Incontinence surface diversion of the lower tract*: This is often required for the management of voiding difficulties; when these are irremediable, this may be a long-term arrangement. An indwelling urethral catheter may be either drained continuously into a bag or intermittently released. Intermittent emptying of the natural bladder reservoir can also be achieved by intermittent catheterization of the urethra or a leak-proof suprapubic conduit (Figure 112.3).
3. *Cystoplastic reconstruction of a urinary reservoir that is emptied either by sphincter control or by stomal catheterization*: A total substitution cystoplasty may be appropriate when the whole bladder has to be removed; however, many bladder abnormalities require only a readjustment or a partial cystoplastic substitution. A reconstructed cystoplastic reservoir, partial or total, may be controlled by the sphincter mechanism *sphincter-cystoplasty* or it may be emptied by intermittent catheterization of a leak-proof conduit *stoma-cystoplasty* (Figure 112.4).
4. *Internal urinary diversion controlled by the anal sphincter—ureterosigmoidostomy*: For some patients, a rectosigmoid urinary diversion is a preferable alternative to surface diversion when the circumstances are appropriate. For nephrological and carcinogenic reasons, this procedure fell into disrepute for a number of years but procedural developments have addressed some of the potential problems: these include the limitation of renal damage and the early detection of malignant change [75] (Figure 112.5).

When satisfactory sphincteric control of a cystoplasty is irretrievable, many alternative procedures such as catheterizable stoma-cystoplasty reservoirs enable patients to achieve a reasonably acceptable quality of life.

The surgical procedures of *cystoplasty* and of *continent diversion* have evolved as a result of the great endeavors and contributions of numerous colleagues over the years—whole textbooks have been written about them. However, the value of the terminological distinction between *cystoplasty* and *continent diversion* is questionable because the functional requirements and the surgical principles of creating their reservoirs are essentially similar.

Cystoplasty is a generic term for a reconstructive procedure (plasty) to recreate the functional capacity of a bladder reservoir (cysto). Like the term *urodynamics*, *cystoplasty* is commonly used, understood, and misunderstood to mean different things. This adds additional confusion to the already complex field of the retrieval and the construction of functional urinary reservoirs.

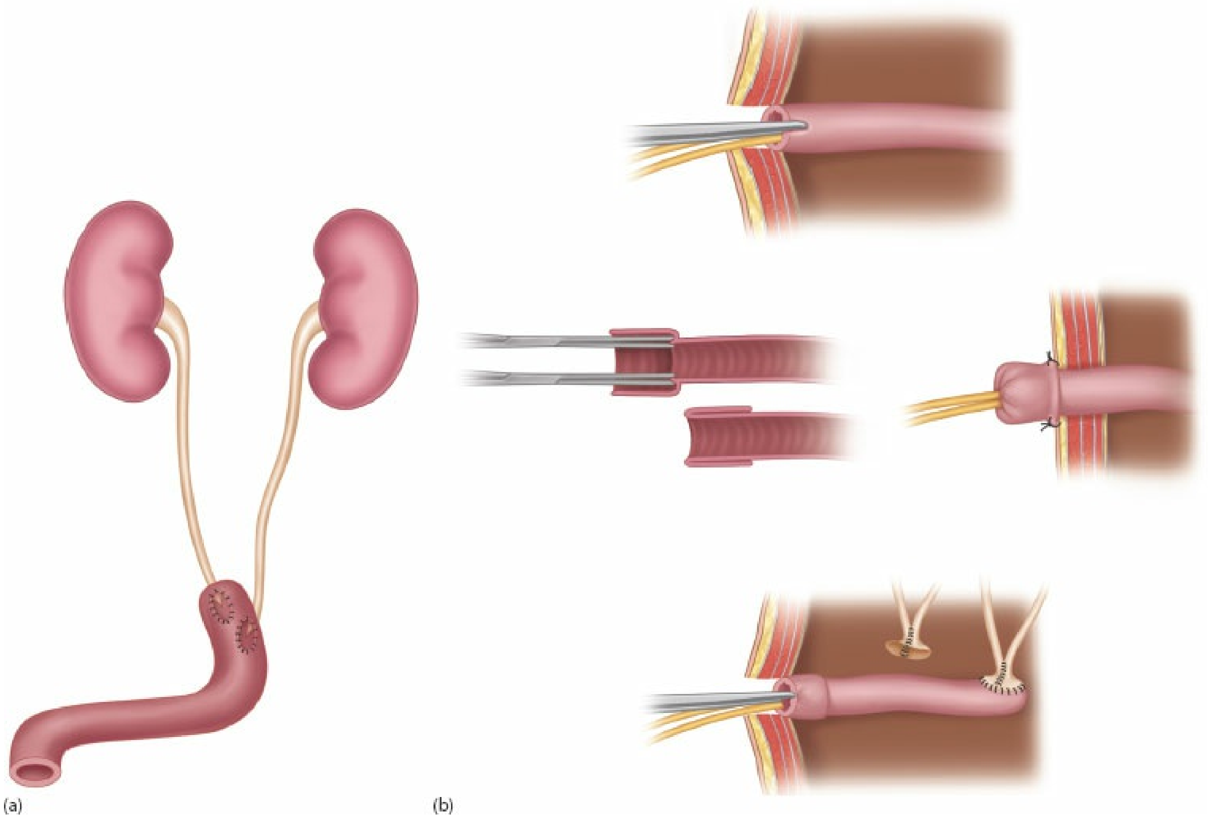

Figure 112.3 (a) An ileal conduit. (b) Formation of the ileal conduit.

Some *simple* cystoplasty operations restore the natural functional reservoir capacity of the bladder without involving any substitution procedure and not all substitution procedures involve the use of bowel. Other tissues used in substitution include the stomach [76] and dilated ureter [77]. Attempts at using tissue-engineered substitutes are still at early stages and require considerable development [78,79]. However, the term *cystoplasty* is commonly used somewhat loosely, as a *semispecific shorthand* to denote the substitution of the bladder reservoir, partial or total, generally with the tacit assumption that bowel is used for the substitution and also that the functional control of the outlet is the natural urethral sphincter mechanism.

Developments in the surgical retrieval of the natural bodily function of *intermittent urinary waste disposal* often involve the creation of catheterizable leak-proof abdominal stoma conduits that are used for the intermittent emptying, either of normal bladders when the urethra is irremediably dysfunctional or of substitution urinary reservoirs that are either partially or totally reconstructed. Thus, an integrated reconsideration of the practical principles of cystoplasty and diversion seems appropriate, together with an integrated reconsideration of terminology. In this section, we use simple descriptive terminological exactitudes.

A *urethra-cystoplasty* is a reconstructed urinary reservoir, the outlet of which is the urethra. When this is controlled by the sphincter, it is a *sphincter-cystoplasty;* if it is emptied by self-catheterization, it is a simple *urethra-cystoplasty*. The reservoir of a sphincter-cystoplasty may be either a partial or a total substitution of the bladder. If bowel is used for the substitution, it can be optionally identified as an *ileal sphincter-cystoplasty* or a *colonic sphincter-cystoplasty*—as opposed to an *omental urethra-cystoplasty*.

A urethro-cystoplasty is a different entity because it denotes reconstruction of both the bladder and the urethra.

A *stoma-cystoplasty* is a urinary reservoir with an abdominal stoma-conduit outlet. Its *continence* is usually maintained by a valved leak-proof conduit that can be catheterized intermittently. The reservoir may be the native bladder—a partial substitution in situ or a total substitution that is either in situ or ex situ. Alternatively, a stoma-cystoplasty can be less precisely described as a *continent diversion*.

The functional characteristics and the principles involved in the construction of the bowel substitution urinary reservoirs of both a stoma-cystoplasty and a sphincter-cystoplasty are essentially similar; the difference is simply the mechanism of their evacuation.

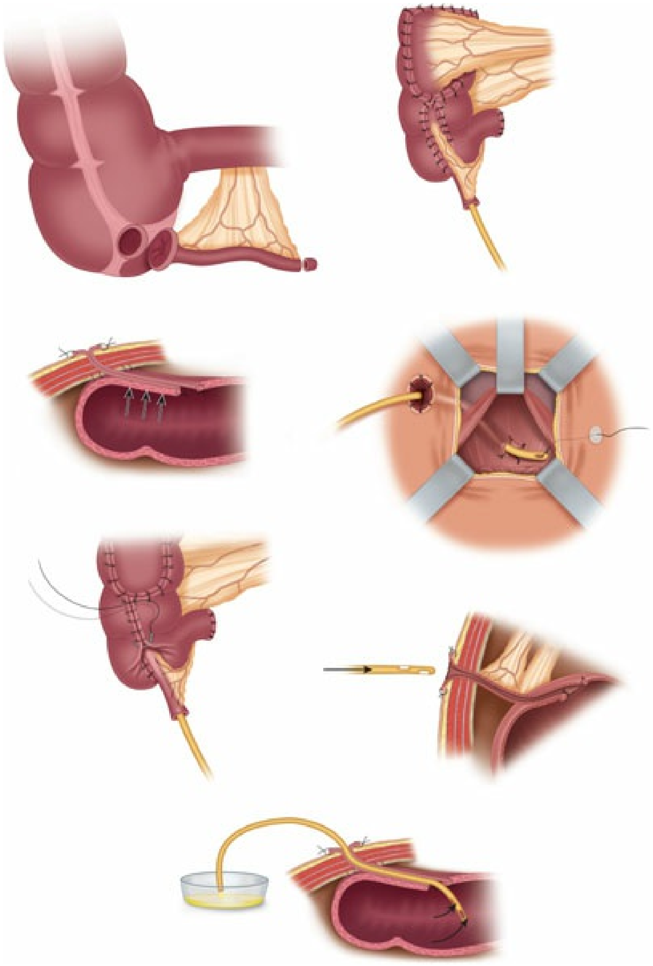

Figure 112.4 Formation of a pouch with a catheterizable stoma.

A leak-proof stoma conduit is a mechanistic construction specifically designed for emptying the reservoir by catheterization. The reliable sphincteric control of a sphincter-cystoplasty is often dependent upon a careful urodynamic assessment and appropriate surgical adjustment and management: this requires quite separate consideration.

Whether or not this terminology will be generally adopted, time will tell; it seems preferable to the ill-defined *continent diversion*. A particular advantage is that it facilitates an independent analytical consideration of the three separate component procedure principles of cystoplastic reconstruction:

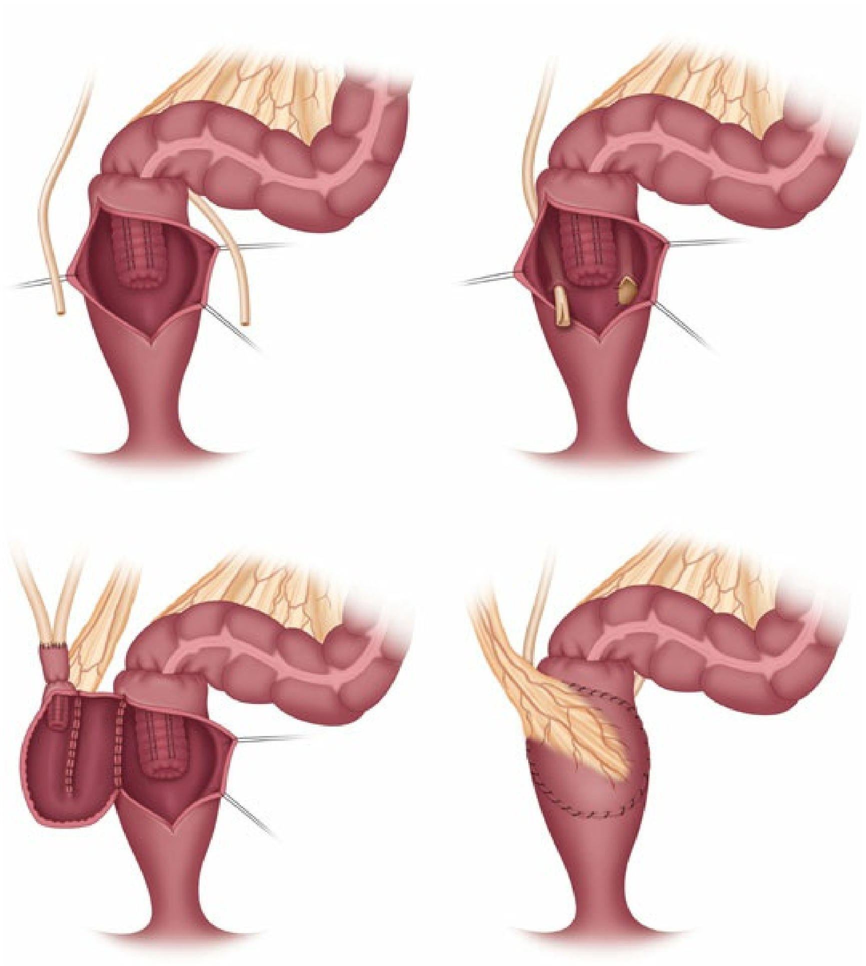

Figure 112.5 Formation of a ureterosigmoid pouch of the Mainz II type. Cystoplasty, stoma-cystoplasty, and sphincter-cystoplasty—a perspective of urinary reservoirs that are emptied intermittently.

1. The creation of a urinary reservoir that has low-pressure and reflux-proof ureteric implantations (these requirements are common to the reservoirs of both a sphincter-cystoplasty and a stoma-cystoplasty).
2. The intricate mechanistic construction of a valved leak-proof stoma conduit that is required for the evacuation of the reservoir of a stoma-cystoplasty by self-catheterization.
3. A functionally orientated urodynamically controlled adjustment is often required to ensure the voiding efficiency and sphincteric control of a sphincter-cystoplasty.

113 Gynecological Developmental Abnormalities

Melissa C. Davies and Sarah M. Creighton

The Müllerian system develops from the sixth week of life and it is estimated that the prevalence of congenital abnormalities is approximately 5% [1–3]. These anomalies may be major or minor and may occur in isolation or in conjunction with other congenital malformations or as part of a syndrome. Many patients with simple anomalies will remain asymptomatic and may be diagnosed incidentally while being investigated for other problems or undergoing routine gynecological/obstetric procedures. The others present in a variety of ways depending upon the abnormality present. The commonest means of presentation are primary amenorrhea, obstructed uterus or vagina, dyspareunia, and on investigation for infertility or recurrent miscarriage. Those diagnosed, such as neonates, will usually be patients in whom there are associated major anomalies of the genitourinary and alimentary tracts such as persistent cloacal anomalies and anorectal malformations.

DEVELOPMENT OF THE MÜLLERIAN TRACT

An understanding of the embryological development of the urogenital system is essential to the diagnosis and management of developmental abnormalities. This subject is covered in more detail in Chapter 22.

Primordial gonads (genital ridges) appear during the sixth week of embryogenesis. The associated Müllerian and Wolffian ducts also develop. The fate of these undifferentiated ducts depends upon the genetic sex of the embryo. In XY embryos, the SRY gene (sex-determining region of the Y chromosome) stimulates testicular differentiation. The developing testes produce androgens and anti-Müllerian hormone (AMH), which cause virilization and regression of Müllerian structures. In XX individuals, absence of the SRY gene allows the gonads to develop into ovaries, and the subsequent lack of AMH allows the Müllerian ducts to develop into a uterus, fallopian tubes, and vagina.

The Müllerian ducts grow in a caudal and medial direction and fuse in the midline to form the primitive uterus. These ducts form the right and left fallopian tubes and midline fusion of these structures produces the uterus, cervix, and proximal two-thirds of the vagina. This rudimentary vagina fuses with the posterior urethra at week 7 to form the urogenital sinus. Fusion of the Müllerian ducts also brings together the lateral peritoneal folds that form the broad ligaments. The vagina develops from a combination of the Müllerian tubercles and the urogenital sinus. Cells proliferate from the upper portion of the urogenital sinus to form structures called the sinovaginal bulbs. These fuse to form the vaginal plate that extends from the Müllerian ducts to the urogenital sinus. This plate begins to canalize, starting at the hymen and proceeds upward to the cervix (see Figure 113.1). This process is not complete until 21 weeks of gestation [4].

The external genitalia in females consist of the genital tubercle, the urogenital sinus, and the urethral and labioscrotal folds [5]. The genital tubercle becomes the clitoris and the urethral folds develop into the labia minora, and the labioscrotal folds become the labia majora. By week 12 of development, these structures are recognizably female. These structures are sensitive to androgens and form the penis and scrotum in normal male development.

IMAGING

Accurate imaging is pivotal to the diagnosis of many of the conditions described later. Ultrasound is routinely used as the primary mode of investigation. Recent developments in this field have allowed better assessment of uterine anomalies, particularly with the introduction of high-resolution transvaginal ultrasound probes. This may not be appropriate in children or young teenagers or in those whose primary diagnosis is vaginal absence. In addition, ultrasound is more technically difficult to perform in those people who have had multiple surgical procedures and extensive abdominal scarring. More recently, 3D ultrasound has been employed in the diagnosis of uterine anomalies; its benefits include the fact that it is noninvasive and allows for more accurate diagnosis compared with conventional ultrasound [6]. Recent advances in 3D ultrasound technology have improved the sensitivity and specificity of this imaging modality [7], and in experienced hands, it is reported to be more sensitive than other imaging modalities. Ultrasound has the benefit of being safe in pregnancy, which is useful given the subjects are nearly all young fertile women; it also allows concomitant assessment of neighboring structures such as the urinary tract. Renal dysplasia and renal agenesis are associated with Müllerian anomalies and must not be overlooked [8].

Magnetic resonance imaging (MRI) is still considered the gold standard of imaging in this patient group [9]. It is an extremely useful tool in assessing these complex malformations [10,11], particularly where there is no vaginal cavity in which to put an ultrasound probe, or in children or adolescents who have not engaged in sexual activity (see Figure 113.2). There are limited data comparing the accuracy of MRI with 3D ultrasound; however, it appears that the two imaging modalities are comparable in terms of sensitivity and specificity [12].

Other imaging modalities may give useful information. Hysterosalpingography (HSG) gives information about the internal contour of the uterus and allows an assessment of the size and extent of uterine septa. However, it does not provide enough information to allow one to discern between a septate uterus and bicornuate uterus. It has two main drawbacks: first, many patients consider it to be an uncomfortable procedure, and it may be complicated by pelvic inflammatory disease. Also, it is not appropriate for the investigation of the adolescent patient and its main use is in the evaluation of subfertility.

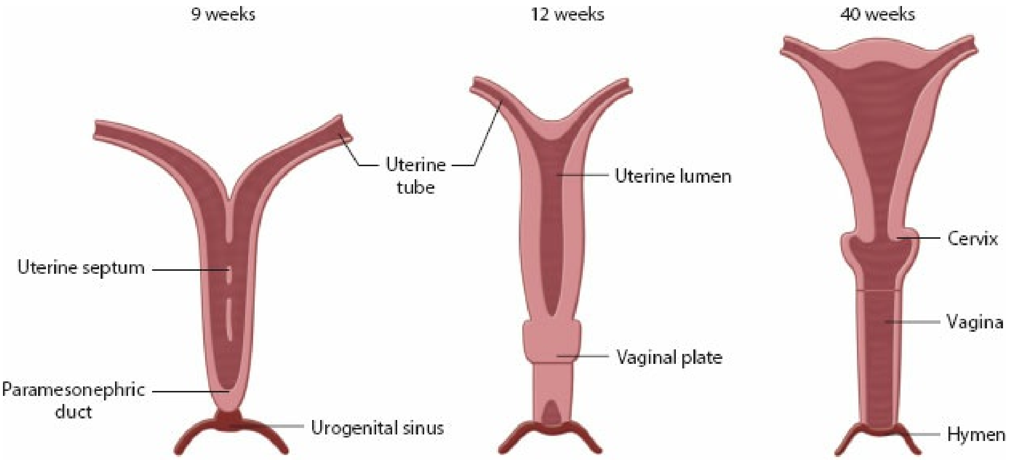

Figure 113.1 Embryological development of the Müllerian system.

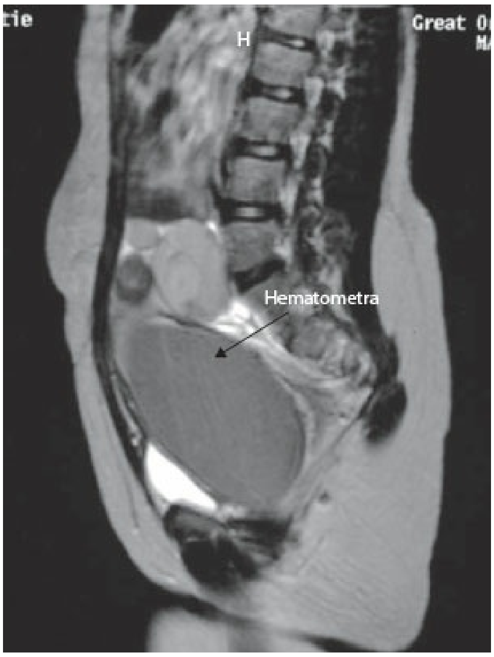

Figure 113.2 Magnetic resonance imaging of an obstructed uterus in a young girl with cloaca.

Hysteroscopy can be useful in the diagnosis of uterine anomalies and has the benefit of allowing treatment in some cases, particularly in septa and arcuate uterus [13]. As hysteroscopy does not provide any information on the outer surface of the uterus, it may be difficult to distinguish between a septate and bicornuate uterus.

Diagnostic laparoscopy should be undertaken only in cases where all other imagining modalities have failed, and the potential for combining this with laparoscopic treatment should also be considered [14].

SIMPLE/ISOLATED ANOMALIES

Imperforate Hymen

The hymen is the embryological septum between the sinovaginal bulbs above and the urogenital sinuses below. The incidence of imperforate hymen is estimated to be 1 in 1000 live female births [14]. Hymen malformations are not usually associated with other Müllerian or uterine anomalies. Failure of this septum to perforate in embryo or early childhood may present at adolescence with obstructed menstrual flow. The diagnosis may be made prenatally [15] or rarely in the neonatal period with obstruction of the urinary tract [16]. However, the history is usually of several months of cyclical abdominal pain in an adolescent without menstruation. A pelvic mass may be palpated or found on ultrasound scan. On inspection of the vulva, it is usually possible to see a bulging vaginal membrane. The treatment for these patients is a simple incision with excision of a quadrate of hymenal tissue to allow drainage of the vagina and uterus. Wide excision of the hymen too close to the vaginal epithelium may result in stenosis at the introitus [17].

There have been case reports of familial cases of imperforate hymen usually between siblings, suggesting a recessive mode of inheritance [18]. There has also been a report of imperforate hymen in two generations of the same family [19], which suggests a possible dominant mode of transmission.

Transverse Vaginal Septa

This uncommon condition occurs in approximately 1 in 70,000 females [20]. It occurs due to a failure of the Müllerian ducts and urogenital sinus to canalize. These septa are most commonly found at the junction of the middle to upper two-thirds of the vagina. In cases of a complete transverse septum, associated uterine anomalies are common; one series reports the rate to be as high as 95% [21]. Most presentations of this condition are in young girls after the menarche with cyclical pelvic pain as a result of hematocolpos, which may be complicated by hematometra, bilateral hematosalpinges, and possibly endometriosis. It can usually be easily distinguished clinically from an imperforate hymen as there is no bulging membrane seen at the introitus. It can rarely occur before puberty when the presentation is with pelvic pain; the obstruction in this case is thought to be due to a buildup of mucous secretions from the cervical glands.

In one interesting case, expectant management was employed, where the thickness of the septum and volume of the dilated vagina were monitored regularly using ultrasonography. The thickness of the vaginal septum decreased from 26 to 8 mm over a period of 5 years, thus allowing a less complicated surgical procedure in a more mature patient [22]. The thinning of the septum was felt to be due to a pressure effect of the hematocolpos. The use of vaginal dilators (see Figure 113.5) to achieve a similar thinning effect has also been described in a single case report [23].

However, in the majority of cases, the treatment is surgical excision without delay. Accurate imaging usually with MRI is essential to determine the operative approach. Menstruation can be suppressed with luteinizing hormone releasing hormone (LHRH) analogues while planning surgery. If the septa are thin and low, it may be possible to remove using a vaginal approach [24]. Care must be taken to ensure the septum is entirely removed as vaginal stenosis may result if the procedure is incomplete. Thick transverse septa or those located higher up in the vagina will require an abdominoperineal approach, which may be open or laparoscopic [25]. In those cases where the distance between the margins is too great, then some form of graft, either with skin or intestine, will be required.

Longitudinal Vaginal Septa

Longitudinal septa are often asymptomatic and may not present until the patient is sexually active with dyspareunia, or in some cases during labor where there may be a delay in the second stage [26]. They result as a failure of reabsorption of the vaginal septum during embryogenesis. It may be complete, and extend from the cervix to the introitus, or partial, which may be of any length along the course of the vagina. The management for the majority of these is usually surgical resection if symptomatic. Care must be taken to resect the septum right up to the cervix or dyspareunia will continue.

Rarely, one hemivagina is obstructed, with the other functioning normally. This may cause an unusual clinical picture of apparently normal menstruation, from the unaffected side associated with pelvic pain. Vaginal examination may reveal a unilateral swelling due to hematocolpos. As menstruation appears initially normal, this results in delayed diagnosis of obstruction that would normally be made much quicker in the absence of any menstrual flow. Also, as this is an uncommon condition presenting in young females, the patient may present to a pediatrician rather than a gynecologist, especially as the patients are having what appears to be normal periods. Further investigation of these patients may demonstrate uterine anomalies. The imaging modality of choice in these cases would normally be MRI [11]. Over 80% are thought to have an associated uterine malformation, the commonest of which is a complete uterine septum [21].

Surgical treatment of simple vaginal longitudinal septa is generally uncomplicated and is approached vaginally. As the vagina is a vascular structure, care should be taken with hemostasis. As with transverse septa and imperforate hymen, postoperative vaginal stenosis should be looked for and treated if necessary.

Uterine Anomalies

Traditionally, it has been reported that uterine anomalies are present in 0.5%–2.0% of women [27,28]. However, a recent cross-sectional study undertaken in Denmark has demonstrated an anomaly rate of 9.8% [29]. Anomalies were associated with oligomenorrhea and being nulliparous. However, there was no association with miscarriage and Müllerian anomalies reported, which is contrary to previous reports in the literature [27]. Attempts have been made to classify uterine anomalies. The most widely accepted classification system for uterine anomalies is from the American Society for Reproductive Medicine [30]. This classification organizes the anomalies into six major uterine anatomic types (see Figure 113.3).

The resulting anomalies can be considered to be due to one of four events [31]:

1. Failure of one or more of the Müllerian ducts to develop: *Agenesis, unicornuate uterus without rudimentary horn*
2. Failure of the ducts to canalize: *Unicornuate uterus with rudimentary horn*

3. Failure of or abnormal fusion of the ducts: *Uterus didelphys, bicornuate uterus*
4. Failure of the reabsorption of the midline uterine septum: *Septate uterus, arcuate uterus*

The most common of these appears to be septate uterus, which accounts for approximately 35% of all uterine anomalies [31]. The extent of the septum varies and may be partial or complete. It is known to result in early pregnancy loss and infertility, and this is how the majority of these patients present. However, septa can also be found by chance in women with an uncomplicated obstetric history and so the decision on treatment can be complex. If treatment is recommended, then the most appropriate treatment for septate and arcuate uterus is resection of the septum, which can be achieved via hysteroscopic metroplasty, thus avoiding the need for a laparotomy and an incision in the uterus. There is some evidence that metroplasty may improve reproductive outcomes in these women [32].

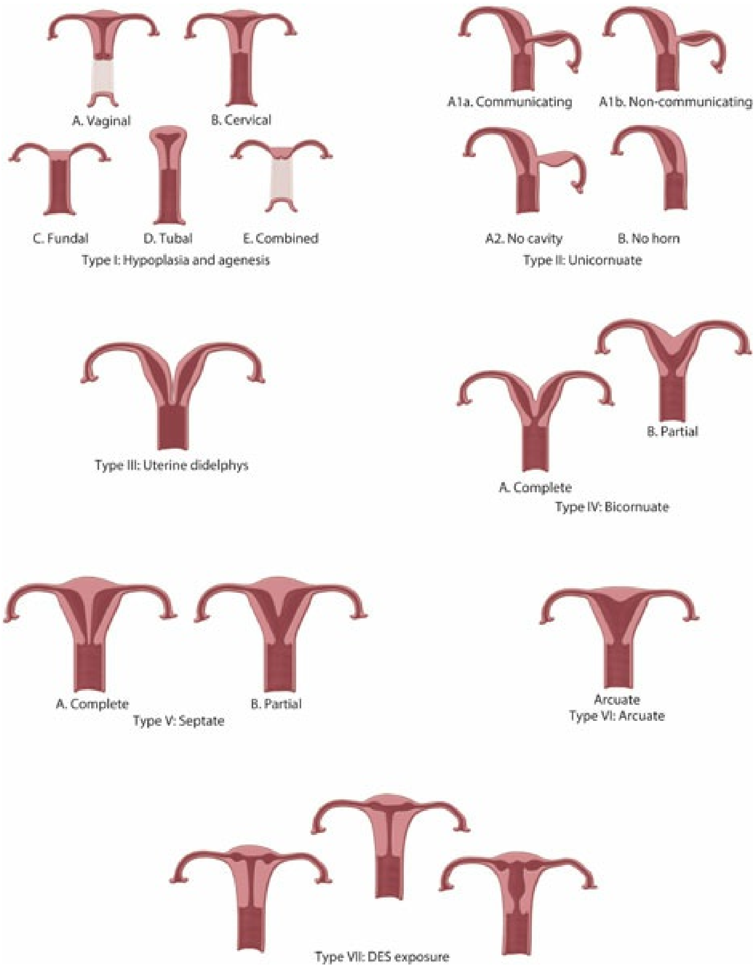

Figure 113.3 The American Fertility Society Classification of Müllerian Anomalies.

Bicornuate uterus accounts for 25% of uterine anomalies [31]. These patients also have recurrent miscarriage, premature delivery, and infertility. There have also been reported neonatal risks, and these include low Apgar scores and small-for-date infants. Surgical options for these patients are limited. Pregnancies do occur in these women and they should be carefully monitored throughout. This is complicated further if there are multiple pregnancies, and twin pregnancies in bicornuate uterus have been reported [33,34].

Unicornuate uterus results from the normal differentiation of only one Müllerian duct. This may present with miscarriage or preterm delivery. One study demonstrated a preterm delivery rate of 25% and early miscarriage rate of 37.5% [35]. Noncommunicating rudimentary horns with functional endometrium usually present with pain; this necessitates the removal of the horn, which may be carried out laparoscopically (see Figure 113.4) [36]. Presentation as an adolescent can be delayed as the presence of normal menstruation from the unobstructed side leads to a low index of suspicion. Removal of the horn is essential to treat pain but also as pregnancy may occur within the horn [37]. There have been reports of removal of pregnant uterine horns, and in this situation the risks are greater as the pregnant uterus is a more vascular structure. It is essential to obtain renal imaging such as preoperative intravenous pyelogram (IVP) as up to 30% will have associated renal tract anomalies [38]. Furthermore, it is suggested that the standard treatment of cases such as these should include fetocide and methotrexate; this in addition to gonadotropin-releasing hormone would allow a safer approach to the laparoscopic removal of the uterine horn. The obstetric outcomes in subsequent pregnancies of this group of patients are better than expected. In a large cohort of 120 consecutive females with a diagnosis of unicornuate uterus having a total of 341 pregnancies, the live birth rate was reported as 72.1% (227/315), with a preterm birth rate of 18.5% [39].

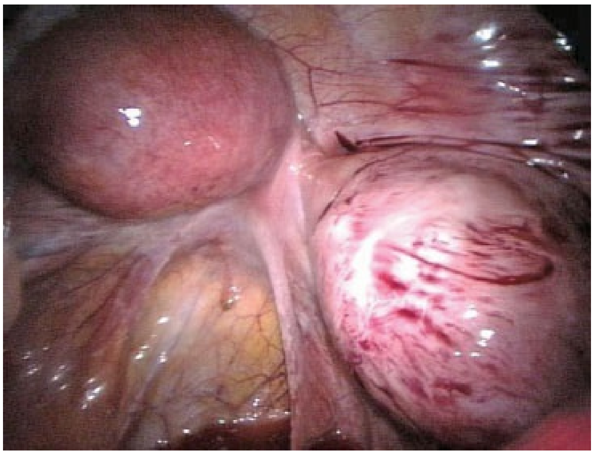

Figure 113.4 Laparoscopic view of an obstructed uterine horn.

Didelphic uterus is often associated with a hemivagina, or a vaginal septum of varying degree, and possible duplicated kidneys or renal agenesis. It is thought to account for 10% of all uterine anomalies.

Absent Cervix

Congenital absence of the cervix is a rare condition and occurs in 1 in 80,000–100,000 births [40]. It is known to be associated with vaginal aplasia, both partial and complete, and renal anomalies. In a recent retrospective review of 18 patients, 39% had associated vaginal aplasia. [41]. Presentation is usually with primary amenorrhea and cyclical lower abdominal pain. Endometriosis or pelvic infection may result from the chronic hematometra. The differential diagnosis includes high transverse vaginal septum, and in some cases, the actual diagnosis may not be clear until surgery.

The management of this condition has changed in recent years with the advances of reproductive technology. Previously, patients with cervical atresia were offered a total hysterectomy as complications of recanalizing the cervix were common and a viable pregnancy was unlikely [26,42]. Now the recommended treatment options consist of either suppression of menses with preservation of the uterus for pregnancy with reproductive assistance or uterovaginal anastomosis, which can now be performed laparoscopically [40]. There are very little data on fertility outcomes following uterovaginal anastomosis; the largest study published stated that the postoperative complication rate was low with only 22% requiring further surgery. Furthermore, they report six spontaneous pregnancies in four of their patients [41]. Despite these encouraging results, it is important to realize that the possibility of serious complications exists and postoperative sepsis after uterovaginal anastomosis has resulted in septic shock and death [43].

Reproductive technology has advanced to allow these patients an opportunity to become pregnant and in vitro fertilization techniques have assisted these patients to become pregnant. There have been case reports of implanting embryos transmyometrially, which have resulted in a viable pregnancy [44,45]. In the latter case report, the patient underwent uterovaginal canalization using amniotic membrane at the time of cesarean section [45]. One of the difficulties of these techniques is the management of miscarriage should it occur. Cervical dilation and curettage is often not an option as there may be no obvious cervix, or a small scarred stenosis. Therefore, most cases would require a laparoscopic or open removal of the remnants of pregnancy. One case report has used a conservative approach of observation where the patient's B-hCG level was monitored with ultrasound examination of the uterus [40].

COMPLEX ANOMALIES

Complex anomalies can be considered in two groups: anatomical or endocrine. This allows us to distinguish between them based upon the underlying cause rather than the system affected. Complex anatomical anomalies include the Mayer–Rokitansky–Kuster–Hauser (MRKH) syndrome.

Congenital Absence of the Vagina

Agenesis of the vagina occurs in approximately 1 in 5,000–30,000 live female births [46,47]. It is commonly referred to as MRKH syndrome. In the majority of suffers, there is no discernable vagina present, while approximately 25% will have a short blind-ending pouch. This is almost always associated with an absent or rudimentary uterus. The karyotype is XX and the ovaries are normal. Anomalies of the urinary tract are present in an estimated 34% of patients, and spinal anomalies are found in 12% [48]. Although the etiology of this condition is unknown, there has been speculation as to a genetic cause and currently possible implicated genes include HNF1b and members of the Wnt gene family [49–51].

Treatment usually involves formation of a vagina. The preferred method for this is nonsurgical with the use of pressure dilation therapy [52]. This involves the use of graded dilators applied to the perineum at the point where the vagina would normally be sited (see Figure 113.5). In most patients while there is no vagina, there is often a vaginal dimple that acts as a guide for patients to apply pressure on the site. Success of this treatment is high [49] but is limited to motivated patients, and it is recommended that they are seen regularly during this treatment and offered psychological support to improve outcomes.

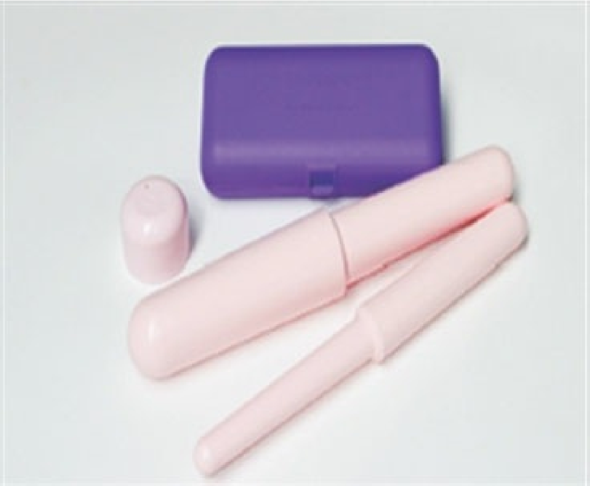

Figure 113.5 Femmax dilators.

For those in whom dilation has not worked or is not possible, then surgical construction is necessary. The timing of this procedure should be carefully considered, as many of those who have surgery will need to use some form of pressure dilation subsequently to maintain the vagina. Numerous forms of vaginoplasty have been employed in the treatment of these patients. They range from simple skin grafting to more complex intestinal vaginoplasties. The use of bowel segments for vaginoplasty has been reported in the literature as early as 1907 [53]; segments of the rectum, ileum, and sigmoid colon may be employed. Stenosis (apart from at the introitus) is rare and the vagina remains moist and of appropriate caliber. However, a vagina constructed from the intestine will be relatively insensitive and may have excess mucus production requiring the patient to wear pads permanently. There have been reports of diversion colitis with colovaginoplasty and this can be difficult to treat [54]. This seems to be less common with ileal vaginoplasty. Vaginal malignancy has also been reported following both intestinal and skin graft vaginoplasty [55] with a mean length of time to diagnosis of carcinoma of approximately 17 years [56]. More recent reports of laparoscopic techniques that have become available have been presented, including laparoscopic Davidov, Vecchietti, and balloon vaginoplasty procedures [57–59]. Of these, the laparoscopic Vecchietti procedure is the most widely performed (Figure 113.6). An olive-sized Perspex bead is inserted into the vaginal dimple. Nylon threads are passed through a small hole in the olive and passed up through the vaginal vault under laparoscopic vision. The threads are brought out onto the abdominal wall and attached to a traction device. Traction is applied to the device daily to stretch the vagina. The procedure is painful requiring hospital admission but a vagina suitable for intercourse can be created in a few days [57].

Tissue engineering technological advances have allowed the formation of autologous vaginal tissue in the research setting. Raya-Rivera et al. [60] have presented their findings from four patients who underwent vaginal reconstruction using tissue-engineered graft from cells obtained following a vulvar biopsy. A follow-up of these patients at 81 months demonstrated a viable vagina; furthermore, Female Sexual Function Index scores were reported to be in the normal range.

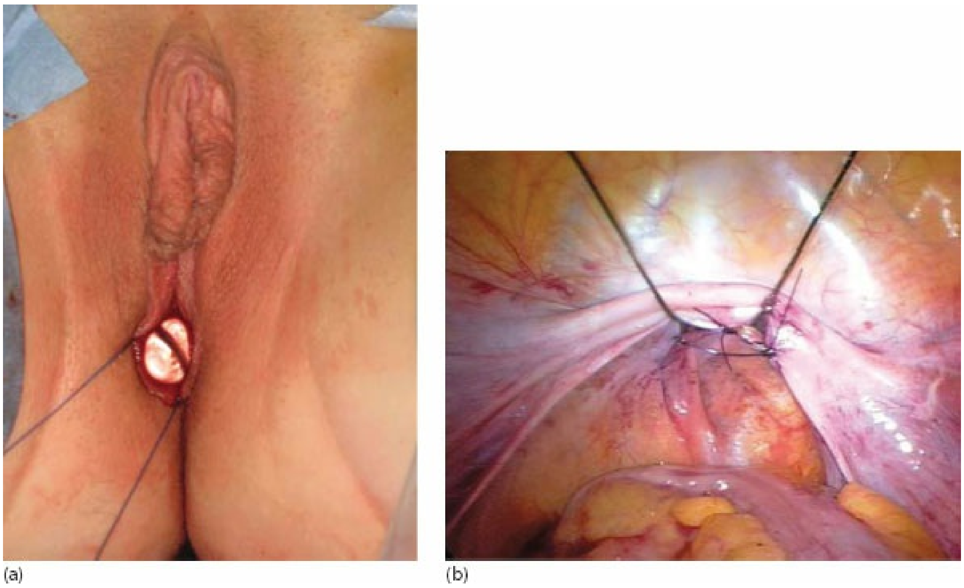

Figure 113.6 Laparoscopic Vecchietti. (a) The Vecchietti “olive” positioned at the vaginal introitus, (b) laparoscopic view after introduction of threads from vaginal dimple through peritoneal cavity.

Psychological preparation is essential both before and after any surgery. The maintenance of the neovagina postoperatively often requires regular dilatation until regular sexual intercourse occurs. This is of particular importance in skin graft vaginas. The patient should be emotionally well adjusted and mature [61].

Fertility options for these patients are limited, but as they have normal functioning ovaries, then surrogacy is an option. There have been reports of successful surrogacy treatment in patients with Rokitansky syndrome [62–64].

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) is the most common cause of ambiguous genitalia and occurs in approximately 1 in 14,000 births in the United Kingdom. The pathogenesis in the majority of cases is 21-hydroxylase deficiency. The lack of this enzyme leads to a decrease in the level of cortisol, which in turn causes an increase in adrenocorticotrophic hormone (ACTH) secretion. This causes an increase in the levels of cortisol precursors that are forced along the androgen pathway. In its most severe form, aldosterone levels will also be low, which may lead to salt wasting, volume depletion, hypotension, reduced renal blood flow, and raised renin activity. The aim of treatment in these patients is to replace the aldosterone with fludrocortisone and replace glucocorticoid to suppress the ACTH overactivity.

The presentation differs depending upon the form of disease and ranges from neonatal salt wasting crisis and ambiguous genitalia to precocious puberty or virilization at puberty. The majority of cases however are diagnosed in neonates who are noted to have ambiguous or masculinized genitalia at birth. Virilization of the female genitalia occurs to a varying degree, causing labial fusion, clitoromegaly, and a confluence of the vagina and distal urethra (see Figure 113.7) [65]. While fertility rates are lower than normal in these females, pregnancy rates appear unchanged [66].

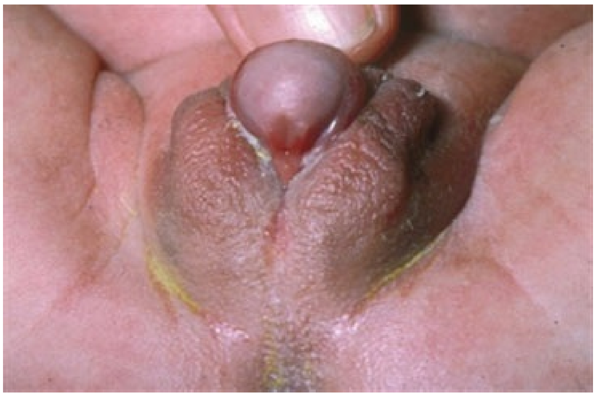

Figure 113.7 Newborn with congenital adrenal hyperplasia.

Current standard practice includes corrective genital surgery to separate the labia, reduce the size of the clitoris, and separate the vagina and urethra [67]. The aims of this are to create a feminine appearance, allow passage of menses, preserve sexual function, and prevent subsequent urinary tract complications [68]. This is usually performed as a *one-stage* procedure in infancy, although many patients require further surgery in adolescence to facilitate menstrual flow and allow penetrative sexual intercourse. There has been increasing recent controversy among clinicians and patient peer support groups as to the need for and timing of feminizing genital surgery. Genital surgery is associated with damage to the sensory innervation of the clitoris and is associated with loss of sexual sensation and an increased risk of sexual dysfunction [69]. Long-term data are however scanty and at present no consensus has been reached.

Androgen Insensitivity: Complete and Partial

Androgen insensitivity syndrome has an incidence thought to be somewhere in the region of 1 in 13,000–40,000 live births [47,70]. The condition is known to be due to a defect in the androgen receptor (AR) gene. It is an X-linked recessive disorder where affected individuals have an XY karyotype with a spectrum of clinical manifestations and is generally subdivided into complete and partial. All patients have testes and normal testosterone production and metabolism with either a female or ambiguous phenotype. There are usually no Müllerian structures present.

Patients with partial androgen insensitivity are diagnosed at birth, as there is ambiguity of the genitalia, and a decision regarding the sex of rearing needs to be made. This is a difficult and sensitive issue and should be handled in a specialist center with a full multidisciplinary team of experts available, including psychologist, pediatric urologists, and endocrinologist. Those with complete androgen insensitivity may present later in life with primary amenorrhea or in some cases with inguinal hernia containing testes. Of those girls diagnosed in childhood with Androgen Insensitivity Syndrome (AIS), over half presented with inguinal hernia and Complete Androgen Insensitivity Syndrome (CAIS) should be considered in all girls presenting with inguinal hernia [71].

Recommended treatment for these patients includes removal of gonads as there is a potential for malignant change and lengthening of the vagina if necessary. Gonadectomy may be delayed until after puberty, which allows the young woman to undergo puberty spontaneously and minimizes disruption to schooling for hospital appointments and surgery. The gonadectomy should ideally be carried out laparoscopically, and preoperative imaging is required to accurately locate the gonads. After removal of the gonads, patients will require hormone replacement, typically until 50 years of age, when most women would experience a natural decline in hormone levels. Patients should also undergo regular monitoring of bone mineral density. Vaginal lengthening may be undertaken at any time, and the patient should be counseled appropriately before. The treatment options for vaginal lengthening are as for MRKH with dilation therapy as the first-line choice of treatment.

ASSOCIATED WITH OTHER ANOMALIES OR AS PART OF A SYNDROME

Anorectal Malformation and Cloaca

Many patients with gynecological developmental abnormalities may have other anomalies and the converse is also true. Females born with a persistent common cloaca channel will not only require reconstruction to separate the common cavity into three distinct structures—vagina, urethra, and rectum—but there are also a significant percentage of these patients with associated gynecological anomalies. The commonest of these is a duplicate vagina [72]. In patients with a persistent cloaca, the rate is quoted as being as high as 50% [73]. Yet many of these patients are not routinely investigated for gynecological developmental anomalies. In one recent study, 36% of female patients born with a cloacal anomaly presented with an obstructed uterus in puberty; all of whom required surgery [74]. Any surgery required is more difficult in these patients as they have often undergone multiple surgical procedures as young children. Furthermore, fertility issues are also complicated by the fact that these women once pregnant will need to deliver via cesarean section with an experienced surgeon present.

Traditionally, patients have undergone vaginal substitution with usually some form of bowel graft. More recently, there have been attempts to reconstruct the vagina using native vaginal tissue in those individuals with duplicate vagina [75].

Turner Syndrome

Turner syndrome (TS) is the most common sex chromosome disorder in females and occurs in 1 in 2000 live female births [76]. It is the result of a complete or partial X chromosome monosomy. The syndrome is phenotypically characterized by short stature, webbed neck, wide carrying angle, and low posterior hairline.

Ovarian dysgenesis is documented as occurring in 95% of TS sufferers [77]. Ovarian failure occurs in the first few months or years of life. Therefore, these patients are not able to undergo a spontaneous puberty, and amenorrhea and minimal breast development are the norm, though not inevitable. One study has shown that 16% of its Turner's population have undergone spontaneous puberty [78]. However, few patients with TS are fertile and spontaneous pregnancy occurs in approximately 5% [78], usually in patients who have mosaicism [79]. Furthermore, those who mange to become pregnant have documented poor outcomes, with a 29% miscarriage rate, 7% perinatal death rate, and a 20% chance of having offspring with a chromosomal abnormality, e.g., Down syndrome and TS [80].

Initial management of these patients includes an echocardiogram and renal tract ultrasound as there are a significant percentage of associated cardiac and renal anomalies. Growth hormone therapy should be considered in childhood to try and increase final height. Estrogen replacement is also necessary to induce a normal puberty. After puberty, nearly all TS patients will require long-term hormone replacement to prevent the onset of osteoporosis and atherosclerosis [81]. Due to the complex nature of this disease, it is best managed by a multidisciplinary team where appropriate advice and counseling can be given.

CONCLUSION

As these conditions are rare, the diagnosis is often missed or delayed causing much anxiety for both the patients and her family. The key to managing these patients is thoroughness and attention to detail and it is imperative to provide as accurate a diagnosis as possible.

Many of these conditions have adverse implications for fertility or sexual function. Psychological input is crucial and should be offered to the family as a whole. Support will need to be ongoing, in many cases through childhood and adolescence. Full information about the diagnosis and its implications must be made available to the family and should be explained clearly so that the patients and their parents can fully appreciate what the problem is and what future holds for them. Other helpful resources that are available to these patients include patient support groups and written literature. Such complex and rare conditions need the input of a multidisciplinary team comprising at the very least a psychological, surgical, and endocrinological component. Specialized backup services such as imaging, biochemistry, and genetics are also essential. Patients with complex developmental anomalies should be referred to specialized clinics that can provide the services required and optimize future sexual and reproductive potential.

Currently, the main areas of research in the field of Müllerian anomalies are related to improved diagnosis through imaging and genetic studies and improved surgical outcomes with the utilization of tissue-engineered graft materials. It is likely that reliance upon MRI will decrease with the advance of 3D ultrasound improving the possibility of accurate office assessment and diagnosis. Tissue engineering has the ability to change the surgical landscape of vaginal reconstruction, and it is likely that as technology improves, the concept of growing replacement body parts will become feasible and preferable to the use of intestine or cutaneous flaps in the reconstruction of the genital tract.

114 Pediatric Urogynecology

Angela M. Arlen, Howard M. Snyder, and Andrew J. Kirsch

INTRODUCTION

Anomalies of female embryogenesis may result in a wide spectrum of problems related to the development of the urinary and genital tracts. Many of the clinical abnormalities seen in girls and young women that appear to involve the genitalia alone may be the harbinger of related urinary tract disorders. Abnormalities presenting in infancy may be easy to recognize secondary to abnormal antenatal ultrasonographic or physical examination in the newborn period. Many urogenital malformations, however, are elusive and may become evident only after a clinical problem arises.

The most common urogynecological disorders prompting childhood evaluation focus on problems of urinary continence and introital abnormalities. Interlabial masses, often included in the differential diagnosis of urinary incontinence, as well as difficulties with appropriate gender identification in genetic and phenotypic females, are discussed in this chapter. As congenital abnormalities result from abnormal embryogenesis, it is appropriate to begin with a brief overview of normal female embryology.

FEMALE EMBRYOLOGY

Congenital abnormalities commonly involve both the urinary and genital tracts. An understanding of normal embryogenesis is imperative for understanding congenital abnormalities. A detailed discussion of the embryology of the lower urinary tract is provided by Marshall [1] and Stephens et al. [2].

The divergence of normal sexual differential into male and female phenotypes begins in week 9 of gestation. If no Y chromosome is present, the ovaries develop, whereas the testes and Sertoli cells do not. As a result, the Wolffian system regresses (absence of androgen production) and the Müllerian ducts form the fallopian tubes, uterus, and proximal part of the vagina (absence of Müllerian inhibiting factor). The embryologic origins and adult counterparts of the female genital tract are shown in Figure 114.1 and described in Table 114.1.

URINARY INCONTINENCE IN GIRLS

Etiology

Female urinary incontinence may have a functional or neurogenic etiology or may be secondary to congenital abnormalities of the lower urinary tract. The most common cause of severe urinary incontinence in children is related to a neurologic deficit. The leading causes of neurogenic incontinence include myelomeningocele (spina bifida), sacral agenesis, and vertebral or spinal cord lesions. In these conditions, changes within the spinal cord may occur over time, making careful evaluation and close follow-up essential.

In all children presenting with urinary incontinence, urinalysis should be performed to assess the presence of infection, hematuria, proteinuria, glucosuria, or renal concentrating defect (early morning specific gravity < 1.008). Chronic nighttime wetting, polyuria, or nocturia may indicate renal failure or diabetes and requires thorough medical evaluation.

Incontinence can be broadly divided between that requiring surgical intervention and that requiring medical or behavioral therapies. In general, incontinence related to primary nocturnal enuresis or infrequent voiding tends to resolve with time and does not require surgery. The following sections address the clinical presentation, evaluation, and treatment of lower urinary tract abnormalities associated with urinary incontinence in girls.

FUNCTIONAL CAUSES OF URINARY INCONTINENCE

Functional causes of urinary incontinence include primary nocturnal enuresis, dysfunctional voiding, and pseudoincontinence (i.e., vaginal voiding).

Nocturnal Enuresis

Primary nocturnal enuresis is defined as persistent nighttime wetting past the age of 5 years. Nocturnal enuresis occurs in approximately 20% of 5-year-old children and is more common in boys than girls [3]. Daytime wetting, urinary urgency, and frequency are more common in girls. Diagnosis and treatment of nocturnal enuresis is multifactorial, relying on both the pathophysiology and psychological analysis of the child. Simple behavioral strategies to help children gain control include star charts and other reward systems, fluid restriction, bladder training (including retention control training), and wakening. These are often used as a first attempt to control bedwetting and can be undertaken by families with less professional involvement [4]. Treatment using desmopressin, bedwetting alarm, or combination therapy is often successful in children that do not respond to behavioral modification alone [5–7]. Daytime and nighttime symptoms such as wetting, urgency, and frequency may be treated with anticholinergic medications as well as biofeedback [8,9].

Dysfunctional Voiding and Voiding Dysfunction

Although the terms “dysfunctional voiding” and “voiding dysfunction” are often used interchangeably, such usage is incorrect. According to the Standardization Committee of the International Children’s Continence Society, children with dysfunctional voiding void against a tightened or contracted external urethral sphincter [10]. The term describes malfunction during the voiding phase only. These children have difficulty relaxing their pelvic floor musculature and habitually contract the urethral sphincter during voiding. The rectum and urethra both traverse the pelvic floor. As a result, day- and nighttime wetting, urinary frequency, urgency, hesitancy, urinary tract infections, constipation, and/or encopresis is common. These children respond well to biofeedback [8]. Botulinum toxin A (Botox®) can be injected into the external sphincter in severe cases that are refractory to more conservative management options [11].

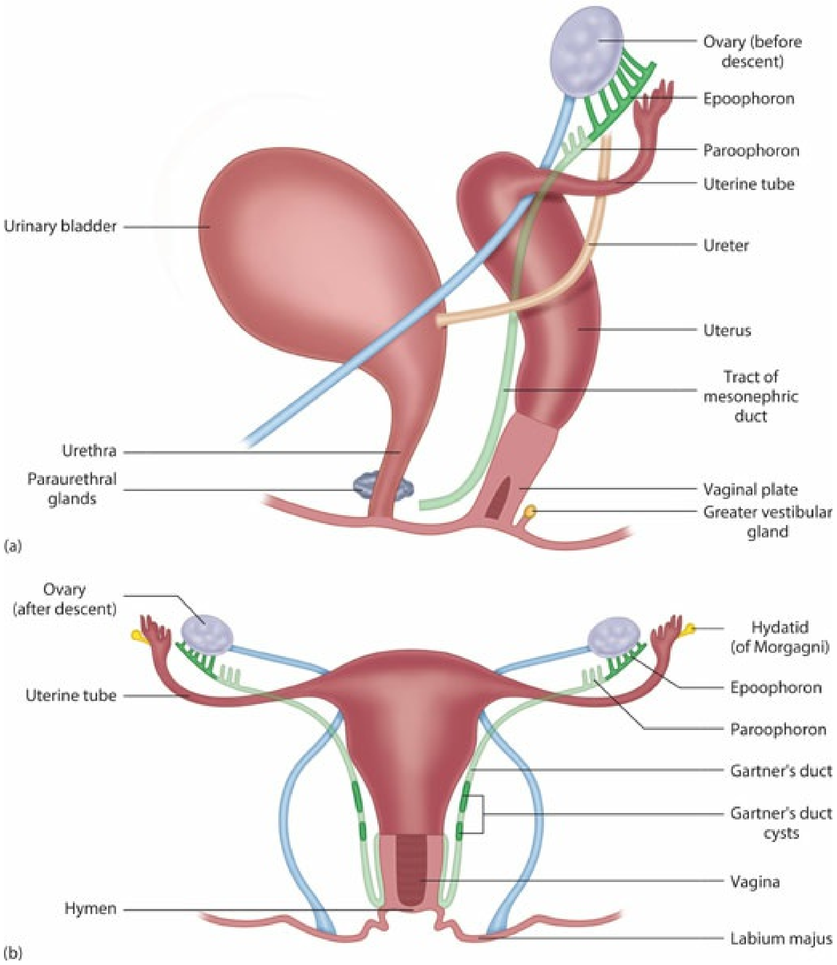

Figure 114.1 Embryology and development of the female genital tracts: (a) a 12-week fetus and (b) a newborn female (urogenital sinus, mesonephric duct, paramesonephric duct).

Table 114.1 Female Embryology

Weeks of gestation	**Embryonic structure/event**	**Adult counterpart**
7–8	Genital ridge transformed	Ovary
9–10	Müllerian ducts fuse distally	Fallopian tubes, uterus, cervix, proximal vagina
12–20	Sinovaginal bulbs elongate and form vaginal plate; canalization of plate at urogenital sinus	Distal vagina
	Genital tubercle elongates	Clitoris, hymen
	Urethral folds do not fuse	Labia minora
	Labial swellings enlarge	Labia majora
	Urogenital groove remains	Introitus
	Mesonephric ducts	Ureters
	Vestigial structures: Mesonephric duct	
	Proximal end	Appendix vesiculosa, paroöphoron, and epoöphoron
	Distal end	Gartner's duct/cysts

Voiding dysfunction, on the other hand, is a much broader term that encompasses all disorders of urinary elimination and storage. These problems can significantly affect a child's quality of life. A thorough history, physical exam, and noninvasive evaluation are essential to ruling out organic causes and to establish an etiology [12]. It is helpful for patients and their families to keep an elimination diary to ascertain the child's specific toileting habits. For example, many parents are not aware that their child has constipation unless specifically queried as to the frequency and caliber of the stool. Simple treatment of constipation with stool softeners (i.e., mineral oil, Kondremul) or laxatives (i.e., milk of magnesia, Dulcolax, or polyethylene glycol 3350) permit better overall toileting behavior. Voiding dysfunction may be treated by behavior modification or pharmacological agents and rarely requires surgical intervention. A rare consequence of dysfunctional elimination is *phantom* urinary incontinence—an entity whereby children sense wetness when they are, in fact, dry. This phenomenon is strongly associated with obsessive compulsive disorder and responds completely to effective treatment of constipation [13]. A list of common pharmacotherapeutic agents for bladder dysfunction is provided in Table 114.2.

Vaginal Voiding

Vaginal voiding is often confused with true urinary incontinence. Micturition into the vagina results in leakage when the child stands upright, allowing efflux of urine from the vaginal vault. Clinical findings consistent with vaginal voiding include postvoid dribbling, labial fusion, and leaning forward at an extreme angle during micturition [14]. Simple maneuvers to direct the urinary stream more accurately by separating the legs further during voiding, and waiting a few minutes after micturition to allow efflux into the toilet, usually solve the problem (Figure 114.2).

Table 114.2 Pharmacotherapy for Neurovesical Dysfunction

Drug	Action	Dose/frequency
Bethanechol	Cholinergic	0.6 mg/kg/day 3–4 times daily
Dicyclomine	Anticholinergic	5–10 mg 3–4 times daily
Oxybutynin	Anticholinergic	0.2 mg/kg 2–4 times daily
Propantheline	Anticholinergic	1.5 mg/kg/day 3–4 times daily

CONGENITAL ABNORMALITIES CAUSING INCONTINENCE

Congenital anomalies may cause incontinence by interfering with the function of the sphincter mechanisms or the storage capacity of the bladder, or by anatomically bypassing normal sphincter mechanisms (Table 114.3).

Imaging studies are essential to define the anatomic abnormalities causing the incontinence. The first studies obtained are usually renal and bladder ultrasonography and voiding cystourethrogram (VCUG). The plain abdominal scout film of the VCUG assesses bony abnormalities and the presence or absence of fecal impaction. Magnetic resonance urography and intravenous pyelogram are useful to identify ectopic ureters, duplication anomalies, and ureteroceles, as well as providing useful information regarding renal function. Urodynamic studies are often useful in detecting sphincteric, storage, and urinary flow abnormalities and are essential in all patients with neurogenic incontinence. The goals of treatment for congenital abnormalities of the female urogenital tract are restoration of physical appearance and function, preservation of renal function, and achievement of manageable urine storage and continence.

Abnormal Storage

Bladder Exstrophy

Bladder exstrophy (Figure 114.3) is a rare congenital malformation, resulting in a lower abdominal wall defect exposing an open bladder and urethra, a wide diastasis of the pubic symphysis, and an epispadic urethral opening. It has an incidence between 1 in 10,000 and 50,000 live births and is less common in females than in males [15,16]. Debate continues about the development of the bladder wall and matrix proteins. Why some children develop normal bladder capacities while others go on to develop small and poorly compliant bladders is incompletely understood.

A range of surgical techniques (complete versus staged repairs) have been employed to achieve successful primary bladder closure with or without pelvic osteotomies. Early bladder closure within 72 hours was advocated in the past; more recently, delayed primary closure has demonstrated comparable outcomes [17,18]. Bladder augmentation or diversion are surgical options later in life, although some patients require no such intervention [19]. Bladder neck reconstruction may be performed at the time of bladder closure or afterward. Continence rates vary greatly depending upon the strictness of definition as well as length of follow-up. Stress incontinence has been managed successfully with injections of dextranomer/hyaluronic acid (Deflux®) into the bladder neck [20,21]. In a survey of women who underwent closure of bladder exstrophy as infants, most experienced normal menses, the majority were sexually active and satisfied with their social lives, and some had borne children (all via cesarean section). Unfortunately, almost half reported some degree of psychological distress resulting from their malformation [22].

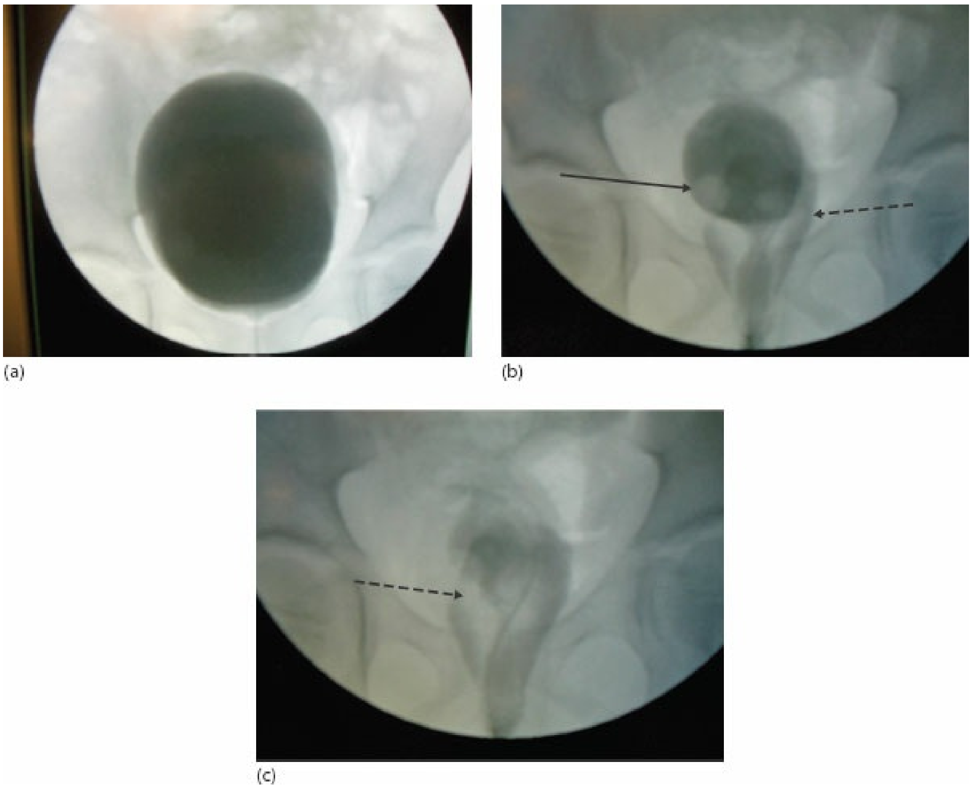

Figure 114.2 A 4-year-old girl with bilateral vesicoureteral reflux and daytime dampness was treated with endoscopic implantation of Deflux. A voiding cystourethrogram 3 months later shows cure of reflux, but the presence of vaginal voiding. (a) Bladder filling; (b) voiding phase showing absence of reflux, the presence of filling defects in bladder base (Deflux implants, solid arrow), and beginning of vaginally voided contrast (dashed arrow); (c) postmicturition film showing the presence of dense contrast within the vagina (dashed arrow) and nearly empty bladder.

Table 114.3 Mechanisms of Incontinence in Congenital Genitourinary Anomaliesa[a]

Abnormal storage	Abnormal sphincter	Bypass sphincter
Bladder exstrophy	Epispadias	Ectopic ureters
Cloacal exstrophy	Urogenital sinus	Vesicovaginal fistulae
Bladder agenesis	Ectopic ureteroceles	
Bladder duplication	Neurogenic[b]	
Neurogenic[b]		

[a] Multiple mechanisms for incontinence often coexist in a given patient.

[b] Abnormalities of storage or sphincteric function may be seen with neurogenic bladders (e.g., spina bifida) and may be related to detrusor hypo- or hyperactivity, or from secondary changes within the detrusor muscle, resulting in stiff (noncompliant) or floppy (very compliant) bladders.

Cloacal Exstrophy

Cloacal exstrophy (Figure 114.4) has an incidence of 1 in 200,000–400,000 and is much less common in females. Cloacal exstrophy is much more complex than bladder exstrophy and is commonly referred to as the omphalocele, exstrophy of the bladder, imperforate anus, and spinal abnormalities (OEIS) complex [15].

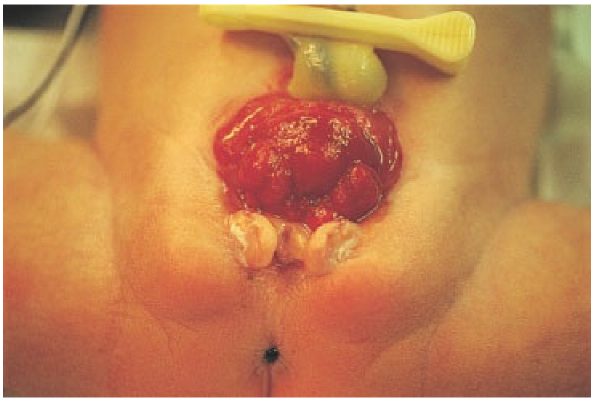

Figure 114.3 A newborn girl with bladder exstrophy. Note separation of the labia and clitoris, and the normal vagina.

Management of cloacal exstrophy requires a multidisciplinary team–based approach, with the principal goals of treatment focusing on patient function, psychosocial development, and overall quality of life. The treatment of storage abnormalities of the bladder resulting from this anomaly usually involves bladder augmentation with intestinal segments. Clean intermittent catheterization (CIC) may also be required to maintain urinary continence.

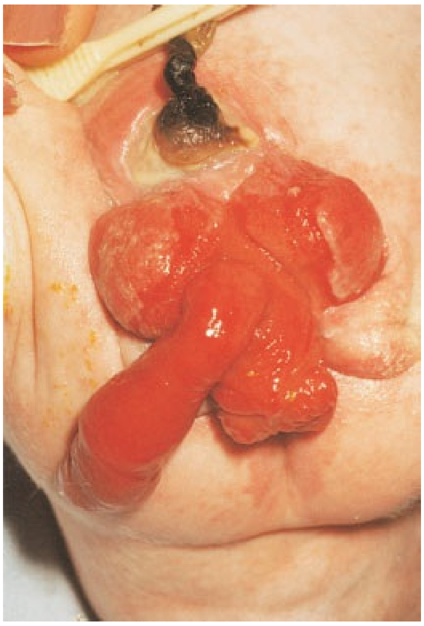

Figure 114.4 Newborn with cloacal exstrophy illustrating separation of bladder halves, herniation of the hindgut, and prolapse of the ileocecal segment.

Myelomeningocele

In the pediatric population, myelomeningocele (Figure 114.5) is the most common cause of neurogenic bladder leading to problems with urinary storage, sphincteric function, and elimination. In the United States, the prevalence is approximately 1 in 1000 live births. The goals of management of pediatric neurogenic bladder include achieving low-pressure urinary storage and providing urinary continence while preserving upper tract function. CIC in conjunction with anticholinergic medication has brought about a dramatic improvement in the management of patients with myelomeningocele. The use of CIC has been shown to promote continence, preserve renal function, and decrease the incidence of symptomatic pyelonephritis [23]. McGuire et al. [24] determined that leak-point pressure > 40 cm H_2O was predictive of renal deterioration over time. CIC serves to keep bladder pressure low, thereby decreasing significantly the risk of upper tract deterioration. Bladder augmentation, with creation of a cutaneous continent catheterizable channel and/or bladder neck procedures, is a frequent component in attaining management goals in a substantial number of children who fail medical management.

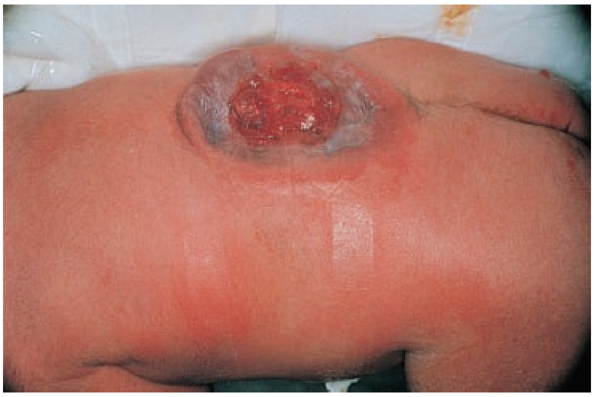

Figure 114.5 A newborn with characteristic appearance of myelomeningocele protruding from the lower back.

Abnormal Sphincter

Anatomic abnormalities may impede normal development of the bladder neck. Incompetence of the bladder neck may result in primary urinary incontinence and is seen in conditions such as female epispadias, urogenital sinus, bilateral ureteral ectopia, and ectopic ureteroceles. Conservative measures to improve sphincteric function are limited and surgical intervention is warranted. Surgical options focus on the creation of an increase in bladder outlet resistance or a new sphincter mechanism.

Female Epispadias

Female epispadias (Figure 114.6) occurs in 1:480,000 female births [25] and may result in variable presentations, depending on the severity of the urethral defect. In mild cases, the diagnosis may not be apparent until the child remains wet into childhood. In complete epispadias, incontinence results secondary to (1) a foreshortened and widened urethra, (2) a partially absent external urethral sphincter, and (3) a poorly developed bladder neck. Treatment is directed at the reconstruction of these deficient structures and ureteral reimplantation proximal to the reconstructed bladder neck [26,27]. Persistent incontinence may be treated with urethral bulking agent injection at the bladder neck.

Urogenital Sinus Anomalies

Persistence of a urogenital sinus may result in the urethra emptying into the vaginal vault. This may not be readily apparent unless the urethra is not visualized during attempt at catheterization. Infants may present with a dilated vagina, possibly resulting in an abdominal mass, if the posterior lip of the hymen causes partial obstruction at the orifice of the urogenital sinus (Figure 114.7). Retained urine in the vagina (urocolpos) and uterine canal may increase to enormous volumes. Drainage of urine with vaginal catheterization followed by a vaginogram showing contrast within the cervical canal and uterus, and possibly into the peritoneal cavity, is diagnostic. Treatment involves endoscopic division of the posterior hymenal lip. Further reconstructive surgery is often required (see discussion of congenital adrenal hyperplasia in the “Disorders of Sexual Differentiation” section).

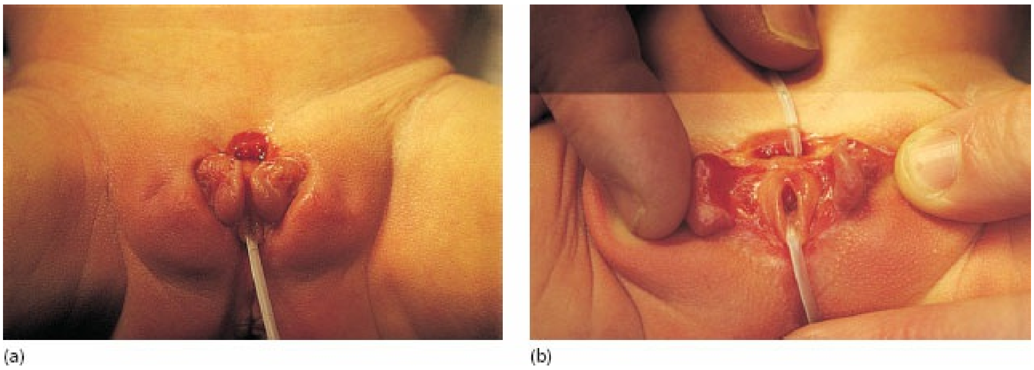

Figure 114.6 (a) Appearance of a newborn girl with epispadias and (b) note the open bladder neck with a catheter introduced superior to a normal catheterized vagina and separation of the labia and clitoris.

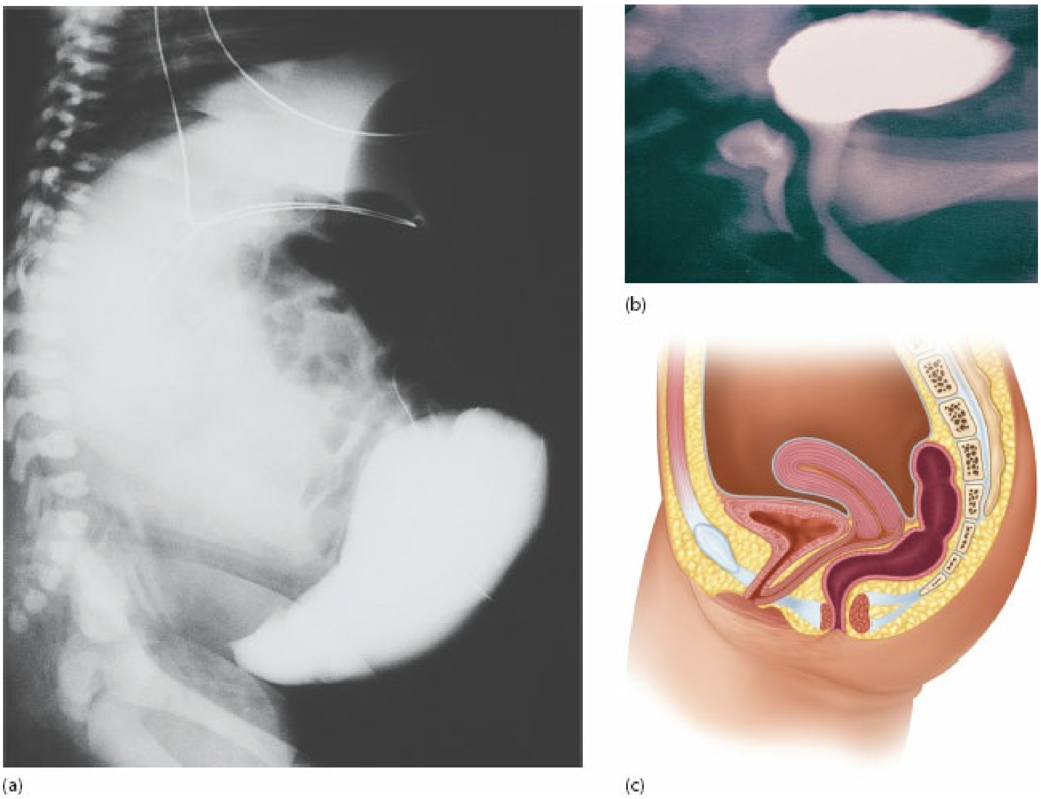

Figure 114.7 (a) This contrast vaginogram in a newborn girl with an abdominal mass shows retained fluid and an obstructed vagina (urocolpos) secondary to a urogenital sinus abnormality. (b) A flush genitogram in another patient reveals a urogenital sinus with contrast seen within the bladder and vagina. (c) Line drawing showing the relationship between the urethra, narrow distal vagina, and urogenital sinus.

Duplicated Ectopic Ureters

An ectopic upper pole ureter may join the lower end of the remnant mesonephric duct system comprising Gartner's ducts. These ureters are associated with nonfunction of the associated renal moiety and may result in cystic dilation of Gartner's duct with eventual rupture of the cyst and drainage into the vaginal opening. Drainage of fluid or pus into the vagina prompts further investigation. Renal and pelvic ultrasound may demonstrate a dilated or abnormal upper pole renal moiety, and a cystic structure may be seen in the pelvis or vaginal area. Computerized tomography scanning or magnetic resonance imaging are helpful in further delineating the anatomy, while retrograde fluoroscopic studies are diagnostic if the often-elusive ectopic orifice can be identified (Figure 114.8).

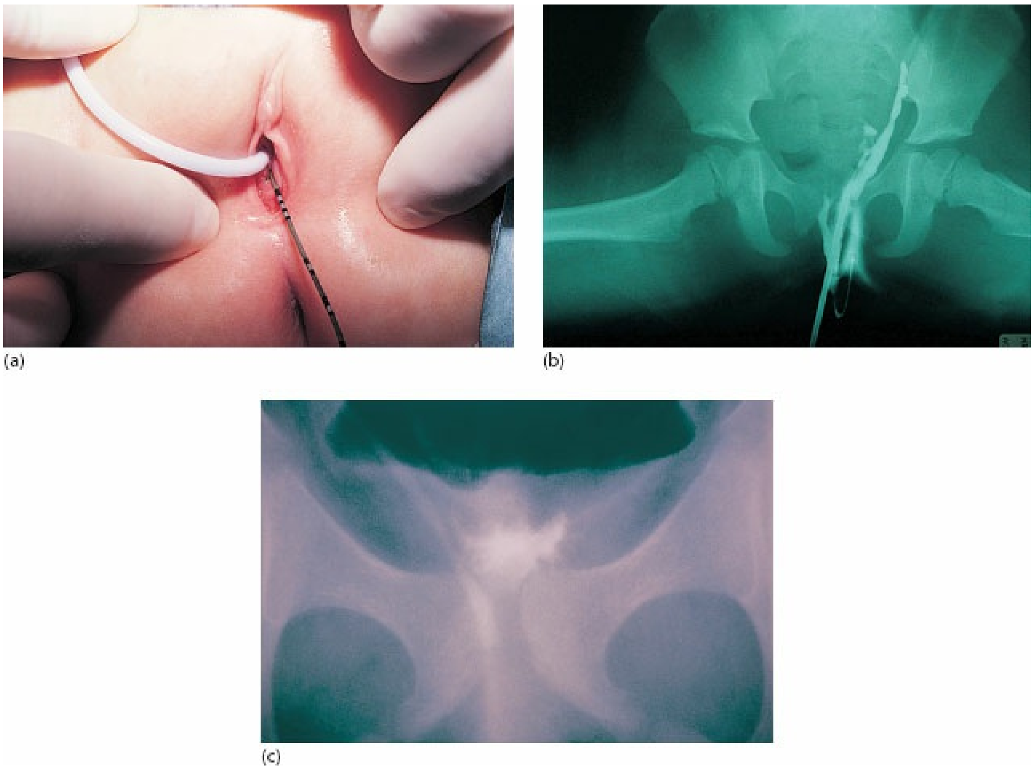

Figure 114.8 A young girl with continuously damp underpants was found to have ureteral ectopia to her vagina: (a) the vagina showing a ureteral stent placed within the ectopic ureter and a Foley catheter within the urethra; (b) retrograde pyelogram showing contrast within the ectopic ureter; and (c) an intravenous urogram in another patient revealing an ectopic ureter of an upper pole moiety terminating beyond the bladder neck and into the vaginal introitus.

Appropriate treatment of ureteral ectopia is dependent upon whether or not there is ureteral duplication and whether the ectopic ureter drains into the genital or urinary tract. Ectopic ureters to the genital tracts may be treated by simple upper pole nephrectomy; ectopia to the urinary tract usually involves ureterectomy in addition to heminephrectomy in order to prevent postoperative urinary reflux and infection (Figure 114.9).

Bypass of Sphincter Mechanism

In instances where the bladder neck and sphincter mechanism have developed normally, urinary incontinence may develop as a result of ureteral ectopia distal to the continence mechanism. The most common cause of this abnormality is ectopic ureters. Incontinence may not be purely secondary to a bypass mechanism, as abnormal urethral development may also contribute to poor urinary control.

Bilateral Single Ectopic Ureters

Ectopic ureters result when a ureteric bud develops more cranially than usual from the mesonephric duct. In females, ectopic ureters usually open into the urethra, vestibule, or vagina. Incontinence is a common complaint in girls with ectopic ureter(s). Bilateral ectopic ureters may enter the urethra just distal to the bladder neck. Because of inadequacy of urethral length associated with this condition, incontinence may result. In single ectopic ureters, a cyclic VCUG may demonstrate vesicoureteral reflux when the bladder neck relaxes upon micturition; reflux is often not demonstrated during bladder filling when the bladder neck is in a contracted state. Treatment involves ureteral reimplantation and bladder neck reconstruction for bilateral single ectopic ureters and upper pole partial nephrectomy and lower pole reimplantation for duplicated ectopic ureters. In unsuccessful cases, a continent catheterizable channel (i.e., appendicovesicostomy) or continent urinary diversion may be considered [28].

INTERLABIAL MASSES

Vaginal masses in infants and young girls are generally referred to as interlabial masses. Although many of these lesions arise within the introitus, those arising in the urethra or bladder must be recognized to afford proper management. Many patients with masses within the vaginal area complain of leakage of fluid (i.e., urine, pus, transudate). Thorough physical examination of the introitus is mandatory in the complete evaluation of urinary incontinence.

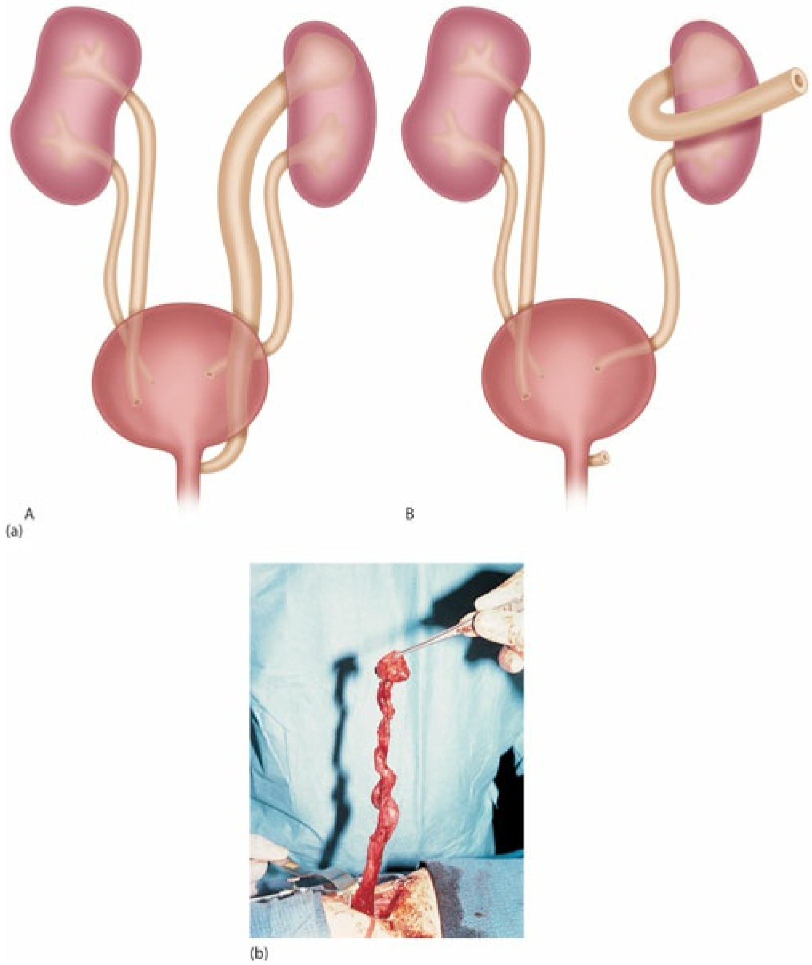

Figure 114.9 (a) Illustration of nephroureterectomy: (A) preoperatively and (B) postoperatively. (b) Nephroureterectomy specimen from the patient in Figure 114.7.

Skene’s Glands (Paraurethral Glands)

The tubular Skene’s glands (Figure 114.10) arise from the urethral epithelium and are the counterparts to the male prostate gland. In females, these glands may be present at the urethral meatus and hymen. Cysts (tense, yellow, thin-walled) partially arising within the urethral meatus but mostly external to it may resemble a bulging hymen associated with hydrometrocolpos, or a prolapsing ureterocele (fleshy, compressible, protruding through the urethra).

Bartholin’s Glands

The major vestibular glands of Bartholin arise from the urogenital sinus and open into the vestibule on either side of the hymen. The main glands lie against the ischiopubic ramus deep to the bulbospongiosus muscle and cavernous tissue. Blockage of the main ducts of Bartholin’s glands may lead to cystic dilation at any age but rarely become infected prior to puberty.

Prolapsed Ureterocele

Ureterocele is a dilated distal ureter within the detrusor muscle that may extend beyond the bladder neck (cecoureterocele). Ureteroceles are often associated with an upper pole renal moiety of a duplicated collecting system [29]. They may be ectopic or orthotopic. An interlabial or vulvar mass may be identified if the ectopic ureterocele extends through the urethral meatus (Figure 114.11). Treatment is directed at ureterocele excision, bladder neck reconstruction, and ureteral reimplantation [30].

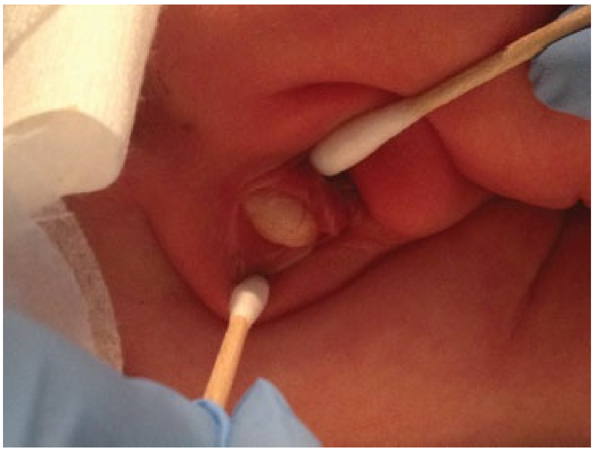

Figure 114.10 Skene's glands in a newborn girl.

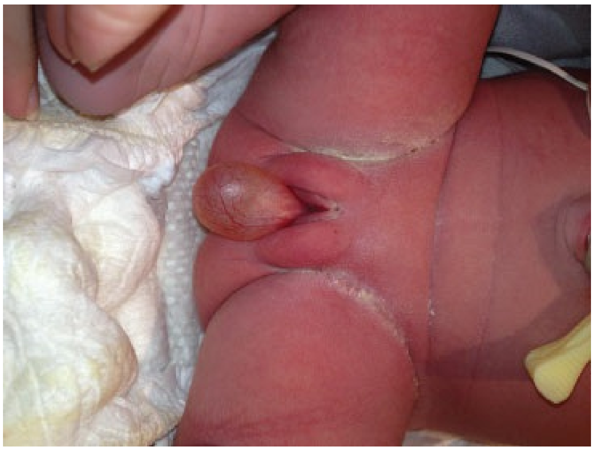

Figure 114.11 A newborn girl with urinary obstruction: external appearance of a prolapsing ectopic ureterocele.

Hydro(metro)colpos

Circulating maternal estrogen in the female neonate may result in an increased production of cervical mucus. Hydrocolpos and hydrometrocolpos result when mucus collects in the vaginal vault and uterus, respectively. The vaginal orifice may be blocked secondary to imperforate hymen, urogenital sinus, anatretic rectocloacal canal, or vaginal/uterine atresia. Hydrometrocolpos, by virtue of its abdominal extension, may compress the urethra, rectum, and ureters.

Treatment of hydro(metro)colpos secondary to a normally located imperforate hymen may involve simple perforation of the hymen when the infant is in the newborn nursery. If the hymen appears thickened, incision under general anesthesia may be required. Higher obstruction involves a more formal approach to treat the associated urogenital abnormalities (i.e., urogenital sinus, atresia, rectocloacal canal).

Urethral Prolapse

Eversion of the distal urethral mucosa through the meatus results in a circumferential interlabial lesion (Figure 114.12). Urethral prolapse may be painful or may bleed or weep serosanguinous fluid, prompting medical attention; however, such lesions do not lead to urinary incontinence. On examination, urethral prolapse appears edematous or necrotic, with the urethral meatus seen within its center. This lesion should be distinguished from neoplasms of the vagina or bladder (see Figure 114.14). A prolapsed urethra associated with mild edema without necrosis or significant pain may reasonably be treated conservatively with sitz baths and estrogen cream over a 2 to 3-week period. More significant lesions should be excised [31].

Rhabdomyosarcoma

Rhabdomyosarcoma of the vagina and bladder (Figure 114.13) most commonly presents with vaginal bleeding and a palpable cervical or vaginal mass [32]. Classically, a cluster-of-grape-like lesion is visualized as an interlabial mass [33]. Because of the propensity of these lesions to spread, a complete endoscopic and radiographic evaluation is indicated to confirm the diagnosis and rule out local extension and metastatic disease. Primary chemotherapy has resulted in improved bladder salvage and is often curative in the setting of metastatic disease. Surgical excision, with or without radiation therapy, is reserved for postchemotherapy biopsy-proven residual masses [34]. In recent years, a multimodal approach to genitourinary rhabdomyosarcoma has led to increased survival as well as pelvic organ preservation [35].

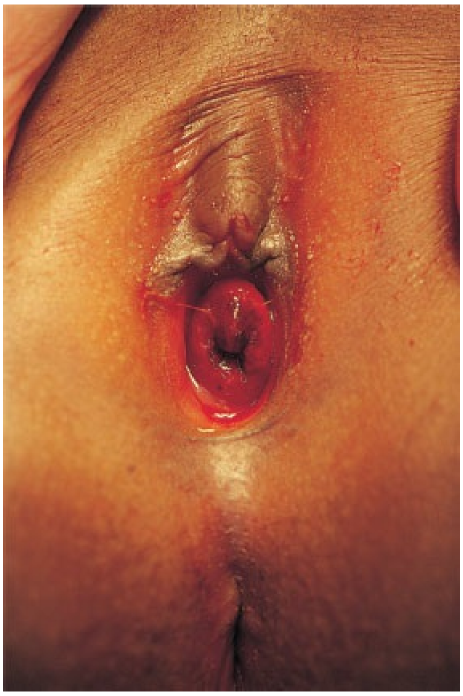

Figure 114.12 An 8-year-old African-American girl with urethral prolapse presented with *vaginal* pain and blood spotting.

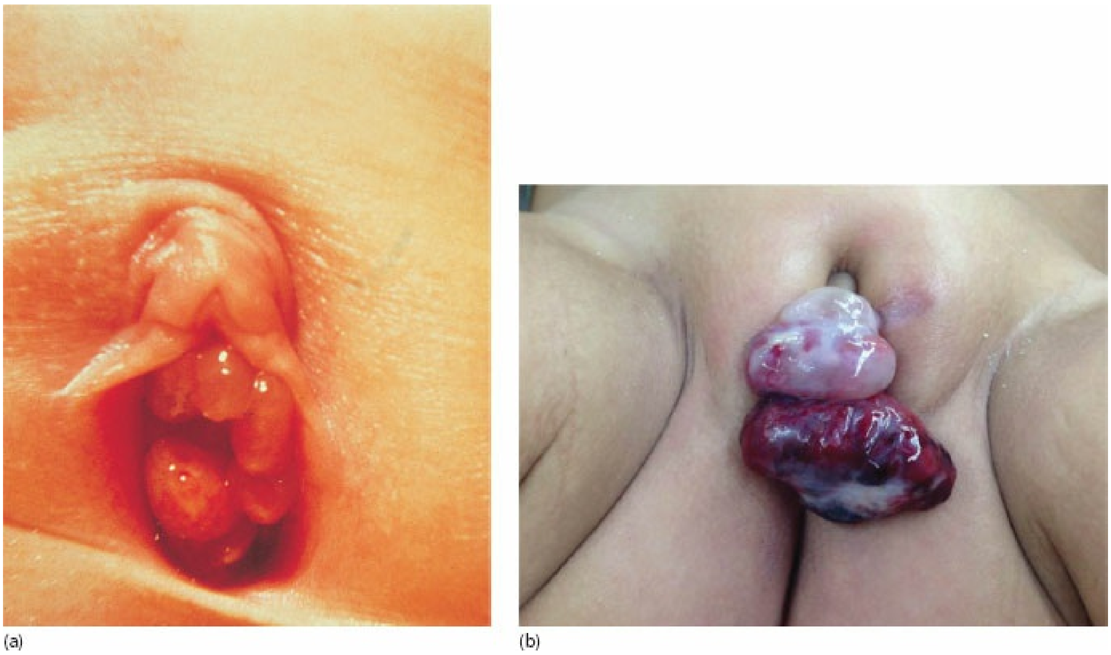

Figure 114.13 (a) A 5-year-old girl with rhabdomyosarcoma of the vagina (sarcoma botryoides) presented with blood spotting and dysuria. (b) An 18-month-old little girl with embryonal rhabdomyosarcoma who initially presented with urinary retention and prolapsed bladder tumor.

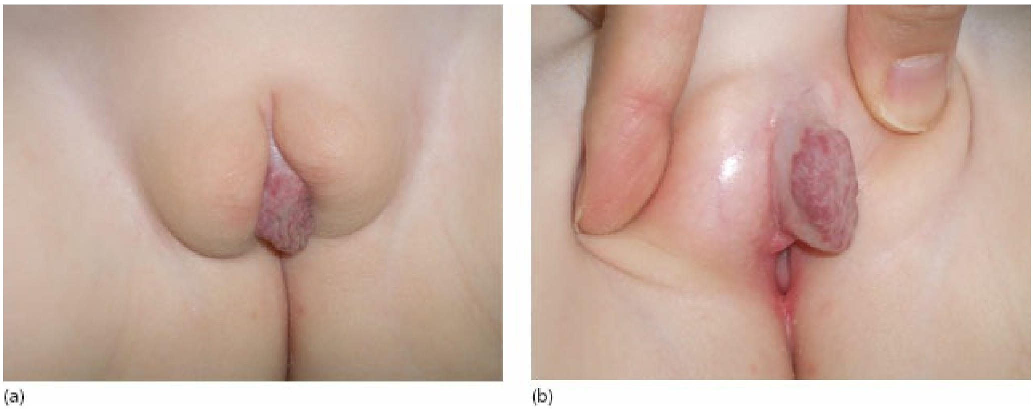

Figure 114.14 (a, b) A 1-year-old girl presenting with an enlarging introital mass revealing a large cavernous hemangioma of the clitoris.

Introital Hemangiomas

Hemangiomas of the female genitalia are rare. In most cases, hemangiomas are congenital and can involve any part of the genitalia. Cavernous hemangiomas (angioma cavernosum, cavernoma) are similar to strawberry hemangiomas but are more deeply situated. They may appear as a red-blue spongy mass of tissue filled with blood. Some of these lesions spontaneously involute, usually as a child approaches school age. Hemangiomas can be quite large and may be confused with tumors, or—if involving the clitoris—may appear as clitoromegaly similar to that seen in cases of congenital adrenal hyperplasia (Figure 114.14). Treatment options include steroid injection, potassium-titanyl-phosphate laser ablation and/or excision, depending on the size and location.

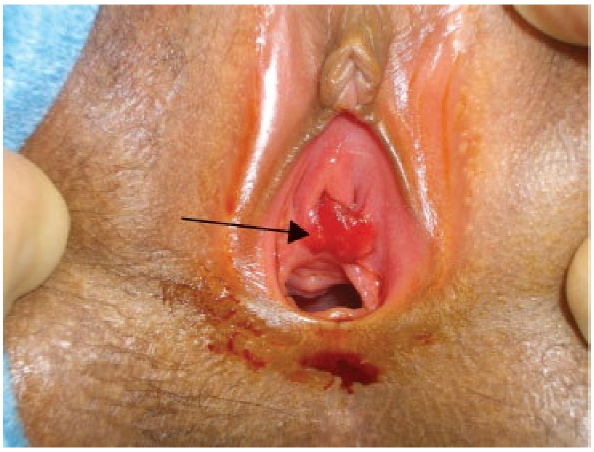

Figure 114.15 A 6-year-old girl presenting with blood spotting in underwear and dysuria. Arrow shows urethral polyp.

Urethral Polyps

Urethral polyps are rare anomalies, characterized as benign urothelial-lined masses attached to a fibrovascular stalk, and may lead to symptoms by obstructing the ureter or bladder neck by a ball–valve mechanism. Some of these polyps, diagnosed later in life, may represent acquired lesions. Polyps may occur anywhere along the urinary tract. Primarily they are composed of connective tissue covered by epithelium. Additionally, smooth muscles and islands of glandular cells and even nerve tissue have been found. Treatment is by endoscopic ablation or excision, depending on origin. Fibroepithelial polyps may present as interlabial masses and may lead to bleeding or dysuria when located in the urethral meatus (Figure 114.15).

DISORDERS OF THE FEMALE GENITALIA

Disorders of Sexual Differentiation

A complete description of the array of intersex disorders is beyond the scope of this chapter. However, urologists and gynecologists must be familiar with the more common disorders of sexual differentiation whereby gender assignment and rearing is along female lines. These conditions include girls of normal appearance who are genetically male (46,XY DSD; previously referred to as male pseudohermaphrodite) and genetic females appearing as males (46,XX DSD; previously female pseudohermaphrodite) [36].

46,XX DSD (Female Pseudohermaphroditism)

Females with 46,XX DSD may appear as males with nonpalpable testes (Figure 114.16). The most common etiology is congenital adrenal hyperplasia (21-hydroxylase deficiency in >90%). This autosomal-recessive disorder is among the most common heritable metabolic disorders [37]. The absence of 21-hydroxylase leads to the overproduction of androgens and results in a wide spectrum of genital abnormalities, ranging from mild masculinization of the clitoris (clitoromegaly) to complete masculinization. The labioscrotal folds are often rugated and hyperpigmented, giving the physical appearance of severe hypospadias with cryptorchidism. In virtually all cases, however, the internal female anatomy is normal. After the diagnosis is established, surgical treatment is individually tailored; feminizing genitoplasty entails reduction clitoroplasty, vaginoplasty, and urogenital mobilization [38,39]. These patients generally require lifelong glucocorticoid (hydrocortisone) and mineralocorticoid (9-alpha-fludrocortisone) supplementation [40].

46,XY DSD (Male Pseudohermaphroditism)

46,XY DSD patients are genetic males but may appear as phenotypic females. Testicular feminization is the most common cause of 46,XY and results from the lack of androgen receptors at the cell surface of all tissues. This diagnosis should be suspected in all girls with inguinal hernias; the hernia sacs may contain testes. The diagnosis should also be considered in adolescent girls with normal development and primary amenorrhea [36]. Development and sexual identity is female. Treatment involves bilateral orchiectomy. The availability of estrogen-replacement therapy allows for the option of early gonad removal at the time of diagnosis that also takes care of the associated hernia, psychological problems with the presence of testes, and the malignancy risk. Estrogen must be replaced at puberty in girls who have undergone prepubertal orchiectomy, which is the standard of care due to risk of malignancy.

Vaginal Agenesis and the Mayer–Rokitansky Syndrome

Agenesis of the vagina in genetic females (Figure 114.17a) may be associated with various other defects of the genitourinary tract. Most patients present in adolescence with amenorrhea or pain, but this condition may also present in young girls with urinary tract infection or hydrocolpos. Genital defects range from vaginal agenesis alone to agenesis of the uterus and fallopian tubes. These genital anomalies are associated with (ipsilateral) renal agenesis [41]. In some patients, stress urinary incontinence may result after having urethral intercourse.

Treatment of the Mayer–Rokitansky syndrome (vaginal agenesis and solitary kidney) may include progressive vaginal dilation, vaginoplasty, or neovaginal reconstruction with bowel. Many iterations and modifications of vaginal dilation exist. Most simply, the patient can self-dilate with progressively larger vaginal dilators. Alternatively, an olive-shaped dilator or balloon can be (laparoscopically) placed into the vaginal dimple through the retropubic space. Upward traction is progressively applied via a pulley mechanism attached to the abdominal wall [42,43]. Alternatively, skin can be grafted into the vaginal space [44], or sigmoid colon can be used in vaginal replacement [45] (Figure 114.17b). Longterm outcomes of patients undergoing creation of bowel neovagina indicate it is a durable and functionally desirable reconstructive option [46].

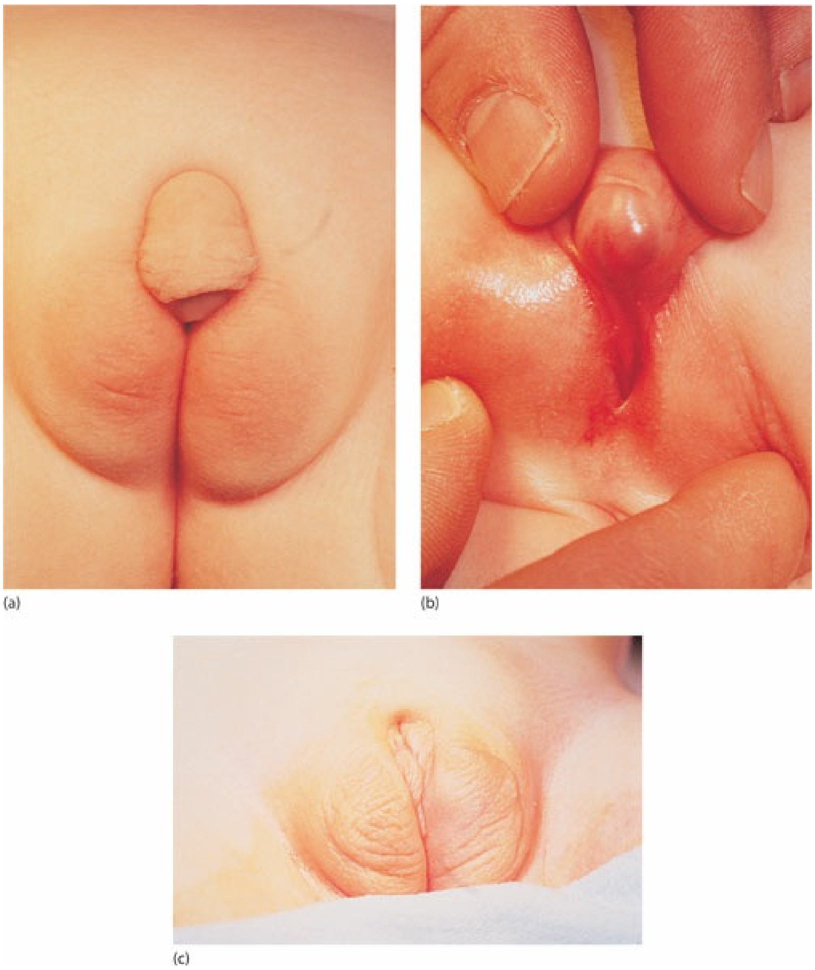

Figure 114.16 This newborn with ambiguous genitalia, elevated 17-hydro-oxyprogesterone and XX chromosomes was diagnosed with congenital adrenal hyperplasia (21-hydroxylase deficiency): (a)

preoperative appearance showing phallic structure and nonpalpable gonads; (b) prominent scrotal folds and clitoromegaly; and (c) appearance 6 months after reduction clitoroplasty and scrotoplasty.

URINARY TRACT RECONSTRUCTION

Lower Urinary Tract Reconstruction

Since 1950, bowel segments have been used to replace a diseased or severely dysfunctional bladder. The current success in reconstruction of the lower urinary tract reflects improved understanding of the physiological principles involved in bladder and urethral function [47–52]. Spontaneous voiding can occasionally be achieved with an abnormal lower urinary tract, provided that the pressure gradient between the bladder and distal urethra is low. It follows, then, that even in cases where the bladder is replaced in part (intestinal cystoplasty) or entirely (neobladder), patients may still be able to empty their bladders satisfactorily. Many patients require bladder neck reconstruction [53] or a sling procedure to achieve continence and most will require CIC [54]. Since the advent of injectable urethral bulking agents, many patients with sphincteric incontinence owing to various causes have benefitted from antegrade and retrograde bladder neck bulking [55].

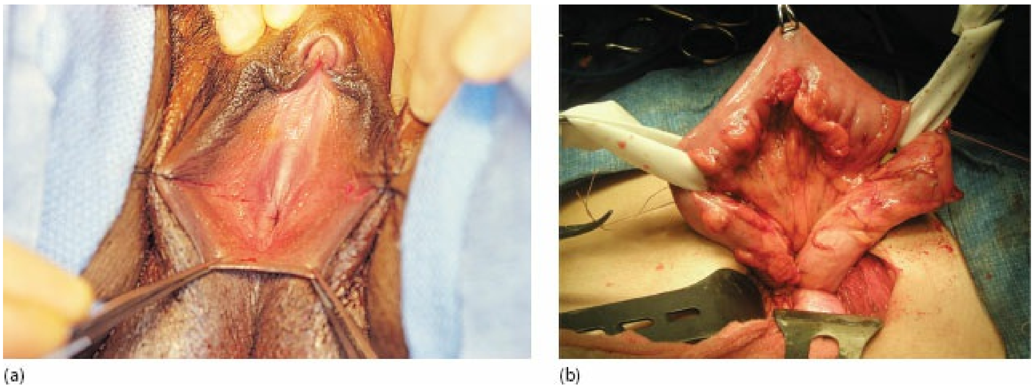

Figure 114.17 (a) Vaginal agenesis in a 16-year-old with Mayer–Rokitansky syndrome. The sexually active patient engaged in urethral coitus. (b) The sigmoid colon (8–10 cm) is isolated on its mesentery and will be mobilized to the vaginal introitus to create a neovagina. The colonic mucus allows for natural lubrication during coitus.

Continent reconstruction of the lower urinary tract is often desired in the face of congenital or acquired anomalies of both the outlet and bladder. The early work of Hendren, Mitrofanoff, and others has led to surgical approaches that produce both better reservoir function and a continent outlet [56]. Continent urinary diversion encompasses three interrelated but independently functioning components. These include a channel by which urine is conducted to the skin, a reservoir or pouch, and a mechanism by which continence is achieved [57]. A host of tissues are available to the reconstructive surgeon (Table 114.4).

The flap valve principle for continence dictates that a portion of the continence channel be fixed on the inner wall of the reservoir. This is the same principle by which ureteral tunneling in the bladder muscle prevents reflux during voiding. In general, a 5:1 length-to-diameter ratio of the continence structure is required.

Table 114.4 Tissues Available for Lower Urinary Tract Reconstruction[a]

External conduit	Urinary reservoir	Continence mechanism
Appendix	Bladder	Anal sphincter
Fallopian tube	Cecum	Artificial urinary sphincter
Ileum	Colon	Benchekroun (hydraulic valve)
Skin tube	Rectum	Koch (nipple valve)
Stomach	Stomach	Mitrofanoff (flap valve)
Urethra		Urethral sphincter

Ureter

[a] In general, three components are required for continent diversion: (1) conduit from the reservoir to the skin, (2) a pouch or reservoir, and (3) a mechanism by which continence is attained.

The Mitrofanoff principle of continent reconstruction describes a supple catheterizable structure (ureter, appendix, etc.) implanted into the inner wall of the reservoir to create a flap valve continence mechanism [58]. The most popular form of flap valve construction for urinary continence is the use of appendix implanted into the bladder or reservoir (appendicovesicostomy). The small stoma may be concealed within the umbilicus (Figure 114.18). Assurance of complete bladder emptying is essential, as this type of continence channel is very effective in its ability to withstand elevated intraluminal pressures. In the noncompliant patient, pouch rupture, or upper tract injury may result from failure to empty the reservoir regularly.

Urinary Tract Reconstruction and Pregnancy

Future pregnancy must be kept in mind when reconstructing the genitourinary tract. Pregnancy may be complicated and requires care by both the obstetrician and urologist. Renal obstruction and incontinence may result as the uterus enlarges. Neobladder reconstruction has a good outcome, but chronic bacteriuria is frequent and occasionally requires an indwelling catheter in the third trimester [59]. Similarly, when suprapubic catheterizable continent stomas have been constructed, indwelling catheterization through the stoma during the third trimester may be required to avoid recurrent urinary tract infections from status [60].

Successful pregnancies and deliveries have been reported after both continent and loop urinary diversions [61–64]. The mode of delivery should be guided by obstetric indications, although vaginal delivery has been successful in the majority of cases. Alternatively, if the bladder neck has been reconstructed, it is usually advisable for delivery to be by cesarean section to avoid damage to the bladder neck reconstruction. The urologist should be available to the obstetric team for consultation if cesarean section is deemed necessary, especially if a bladder augmentation with bowel has been carried out, in order to avoid injury to the vascular pedicle to the bowel segment.

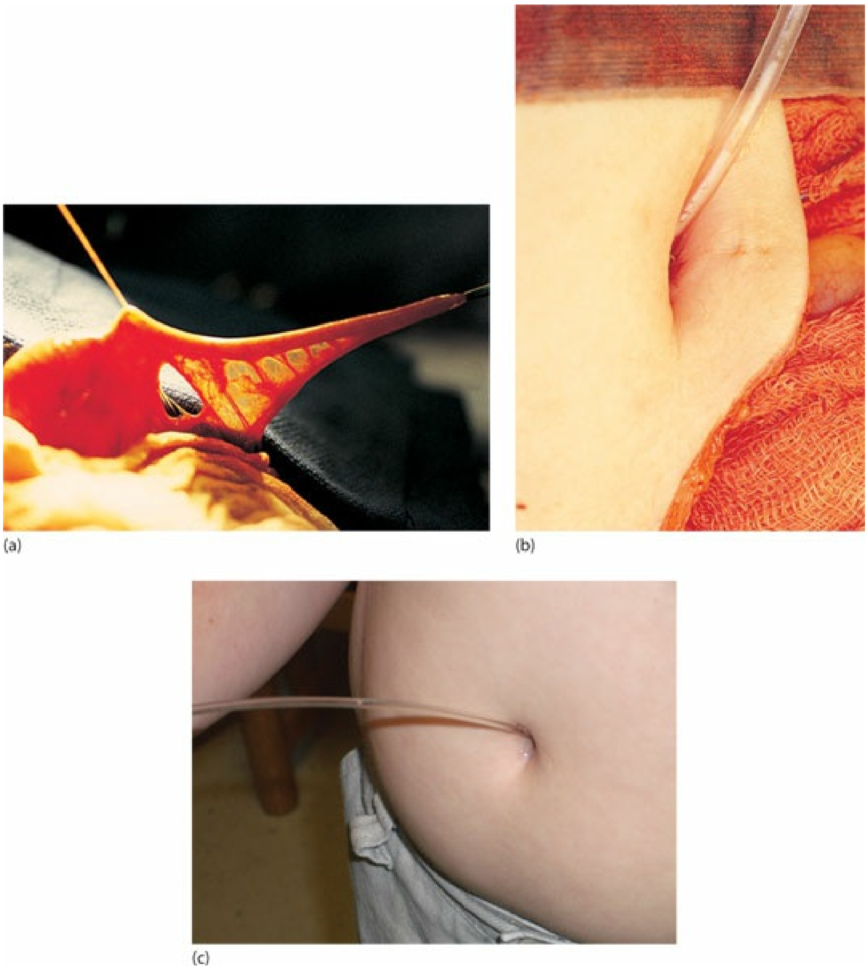

Figure 114.18 In the Mitrofanoff procedure, the appendix is mobilized with its blood supply as illustrated in (a) and reimplanted into the bladder in a tunneled nonrefluxing fashion. The proximal appendix may be brought out to the umbilicus for clean intermittent catheterization (b). Same patient 2 years after appendicovesicostomy performing self-catheterization (c).

115 Female Genital Cosmetic Surgery: From Female Genital Cutting to Vaginal Rejuvenation

Lauri J. Romanzi

OVERVIEW

Genital modification spans the course of recorded history. Mounting attention focused on traditional female genital cutting (FGC) parallels the modern phenomenon of *female genital cosmetic surgery* (FGCS), a.k.a. *vaginal rejuvenation*. Vaginal rejuvenation is a marketing term with no formal medical definition. In its December 2013 policy statement, the Society of Obstetricians and Gynaecologists of Canada (SOGC) recommends that "Non-medical terms, including but not restricted to vaginal rejuvenation, clitoral resurfacing, and G-spot enhancement, should be recognized as marketing terms only, with no medical origin; therefore they cannot be scientifically evaluated" [1,2].

Adopted in response to unprecedented health-care market demands in the industrialized Americas, Europe, Australia, and Asia, the term *vaginal rejuvenation* includes procedures done for (oft overlapping) functional, cosmetic and sexual enhancement client goals. The alternate terms *female genital plastic surgery, cosmetic genital surgery, aesthetic gynecology*, and *genital beautification* are used by plastic surgeons, urologists, gynecologists, and urogynecologists providing these services, which include the most common procedures of labiaplasty in the form of labia minora reduction, labia majora reduction and augmentation, clitoral unhooding, Grafenberg (G)-spot injection, periclitoral injection, perineoplasty, Laser Vaginal Rejuvenation® (LVR), Designer Laser Vaginoplasty® (DLV), *revirgination* through hymenoplasty or hymenorrhaphy, and wrinkle reduction surface radiofrequency therapy applied to labial, vulvar, and groin skin. Arguably, the most widely used marketing term is female genital cosmetic surgery (FGCS). Overall FGCs satisfaction ranges from 89%–100% with complication rates (wound dehiscence, hematoma, dyspareunia) to 5%–9.3% [3,4].

The American College of Obstetrics and Gynecology (ACOG) included vaginal rejuvenation, designer vaginoplasty, revirgination, labiaplasty, and G-spot amplification in the 2007 Committee Opinion 378 "Vaginal rejuvenation and cosmetic vaginal procedures" stating that "Medically indicated surgical procedures may include reversal or repair of female genital cutting (FGC, a.k.a. female genital mutilation, or FGM) and treatment for labial or asymmetrical labial growth secondary to congenital conditions, chronic irritation or excessive androgenic hormones." This committee opinion goes on to list vaginal rejuvenation, designer vaginoplasty, revirgination, and G-spot augmentation as procedures with no medical indication, the safety and efficacy of which have yet to be proved. It ends stating "Women should be informed about the lack of data supporting the efficacy of these procedures and their potential complications, including infection, altered sensation, dyspareunia, adhesions, and scarring" [5].

In response to growing FGCS demand, the International Society for the Study of Women's Sexual Medicine (ISSWSH) sponsored a medical ethics roundtable of six American reproductive health experts in 2007, the results of which were published in the Controversies section of the *Journal of Sexual Medicine*. Conclusions ranged from "FGCS is within the purview of all women, since it is substantively no different than any other cosmetic operation, all of which, by definition, have no purpose other than to alter the appearance of the intended body part without any medical indication" to "women must be informed that normal labial architecture includes a wide variety of labial contours, including asymmetry," thereby deducing that no FGCS is ever indicated for cosmetic purposes.

Another ISSWSH roundtable contributor presciently reminds readers that today's *vaginal rejuvenation* is substantively no different from the centuries-old practice of FGC carried out in traditional societies for "cultural, religious, or nontherapeutic reasons" by a reported 140 million women worldwide, with an estimated incidence of 3 million women and girls per year. Declared a human rights violation in 2012 by the World Health Organization (WHO), FGC has been rendered illegal by almost all governments of the same countries where FGCS services are in demand and readily available. The ISSWSH contributor who included this discrepancy in the debate paradoxically concluded that the answer to this conundrum lies in progressive classification to further distinguish FGC from FGCS [6].

The principles of medical ethics set forth by Beauchamp and Childress (autonomy, nonmaleficence, beneficence, and justice) were applied by three other ISSWSH contributors, two of which chose one of the FGCS target procedures, labiaplasty, as a philosophical exercise pertaining to the entire FGCS phenomenon. They conclude "… the performance of these procedures is not always ethical, nor is it always unethical. Therefore it is the surgeon's burden to …practice well within the boundaries of ethical conduct," ending with an extrapolation to "…other vulvovaginal cosmetic procedures, such as 'vaginal rejuvenation' and 'hymenoplasty.'" Another contributor applied the same medical ethics instrument, deducing "… patient autonomy and technological advancement have been linked together in a business proposition. Does this reflect the true nature of the practice of medicine and… the physician-patient relationship? I would argue no" [6,7]. Others posit the concept of FGCS as none other than genital mutilation, equally deserving of prosecution under antifemale genital mutilation statutes [8].

On these paradoxical conclusions, we endeavor, in this chapter, to review afresh the current state of affairs regarding the traditional practice of FGC and its modern cousin, FGCS.

TRADITIONAL FEMALE GENITAL RITUALS: CUTTING AND ELONGATION

One finds ancient precedents of the modern quest for surgical modification of female genitalia in the traditional practices of FGC in and labial elongation in various African, Arab, and Asian cultures. Both FGC and labial elongation are categorically eschewed by international reproductive health stakeholders and human rights advocates. Both phenomena are in use as asylum-seeking justifications presented on behalf of immigrant and refugee women in the same countries where FGCS is on the rise and where FGC has been rendered illegal. And yet, *many* women of all ages in FGC-practicing cultures readily express pride in their FGC-based traditions, denying oppression or negative sexual or general quality of life impact related to their personal FGC, their voices rising in stark contrast to women with compelling, tragic FGC stories who have achieved international acclaim through the film and book versions of their traumatizing histories [9–11].

The role of enculturation cannot be underestimated. On the other end of the traditional vulvar alteration spectrum comes the regionally popular central African practice of labial elongation, believed to enhance female orgasm, facilitate female ejaculation, and augment sexual satisfaction for both male and female sides of the coital equation [12].

TRADITIONAL FEMALE GENITAL RITUALS: CUTTING OR MUTILATION?

Reflecting ancient traditions often integral to weeklong rites of passage, FGC occurs with variable rates in some countries, such as Senegal, where it is required by a minority of ethnic groups and not ever done in others and at universally high rates (>88%) in Somaliland, Somalia, Egypt, Guinea, Sierra Leone, Djibouti, Mali, and Eritrea and in approximately half of women in Egypt and Ethiopia [13].

Excision of parts of the female vulva dates back to ancient Egypt, where "Phaeronic" circumcision excised the entire clitoris, labia minora, and labia majora with the resulting wound sewn robustly closed in the midline, leaving a 1–2 cm opening anterior to the forchette to permit passage of urine and menses. Upon returning from Egypt (25 BC) a Greek geographer wrote: "One of the customs most zealously observed among the Egyptians is this, that they rear every child that is born, and circumcise the males, and excise the females" [14].

Motivations for this most extreme version of FGC include assuring virginity at marriage and fidelity thereafter, improving the cosmetic appearance of female genitalia, and practice of the female counterpart to male coming-of-age circumcision rituals. Few would debate the mutilating aspect of Phaeronic excision, the results of which may be witnessed in menopausal Somali women even today. One sees an age-related difference, however, among premenopausal teen and adult Somali women who have undergone far lesser excisions, little to no vagina-blocking midline fixation, and minimal to no excision of the clitoral glans, the results of which do indeed appear similar to labiaplasty and clitoral unhooding FGCS results [15].

Now in the well-publicized focus of global efforts to improve the status, health, and well-being of women and girls in developing nations, anti-FGC campaigning first gained momentum in the United States with *The Hosken Report: Genital and Sexual Mutilation of Females* (1979) by Fran Hosken, founder of the Women's International Network and the daughter of a physician [16]. Over the decades, this cultural expose has grown into an international outcry against the forced excision of the genitalia of girls and women. International reproductive health stakeholders united in the effort to abolish this practice range from the WHO and the United Nations (UN) to a growing number of nongovernmental organizations dedicated to the eradication of FGC, further echoed in the laws of numerous industrialized nations alarmed at the genital traditions of FGC-practicing immigrant communities [17–24].

The WHO classifies FGC into four clinical categories [25,26]:

1. *Clitoridectomy*: Partial or total, including instances where only the prepuce (fold of skin over the clitoris) is removed. (NB: This "excision of the prepuce" is the traditional equivalent of "clitoral unhooding" FGCS procedures.)
2. *Excision*: Partial or total removal of the clitoris and labia minora, with or without excision of the labia majora. (*NB*: Partial excision of labia minora is equivalent to FGCS labiaplasty options.)
3. *Infibulation*: Narrowing of the vaginal opening to the creation of a covering seal, formed by cutting and repositioning the inner, or outer, labia, with or without removal of the clitoris. *(NB*: Narrowing of the vaginal opening, albeit involving different genital structures, forms a substantial portion of today's *vaginal rejuvenation* industry.)
4. *Other*: All other harmful procedures to the female genitalia for nonmedical purposes, e.g., pricking, piercing, incising, scraping, or cauterizing the genital area. The WHO includes traditional labial elongation in this category. *(NB*: Genital tattoos and piercings fit these criteria.)

This WHO condemnation is supported by federal laws banning FGC, such as the UK Female Genital Mutilation Act of 2003, the London Safeguarding Children Board's handbook entitled "Safeguarding children at risk of abuse through female genital mutilation," and the U.S. federal legislation involving similar language [27–29].

ANTI-FGC BACKLASH

While modern concerns hinge on the concept of informed consent and realistic concerns about mortality and acute and chronic morbidities related to FGC, this unifaceted, politicized interpretation of the role and (il)legitimacy of FGC is now coming under fire from circumcised African women both proud and pleased to have undergone their culture's FGC process. The apparent leader of this fledgling movement is Fuambai Sia Ahmadu, a medical anthropologist who has served under the UK's medical research council, the U.S. National Institutes of Health, and the office of the vice president of Sierra Leone. She is a cosignatory to the Public Policy Advisory Network on African Female Genital Surgeries (PPAN) published in The Hastings Center Report November/December 2012 issue, the publisher of *SiA*, "a magazine for empowered circumcised women," and founder of *African Women Are Free to Choose*, an organization challenging the notion that FGC is a human rights violation. Her autobiographical synopsis presents cogent counterarguments to the efforts to eradicate genital cutting traditions in developing nations at the same time that FGCS-demanding women in industrialized nations are suffering no such lack of access to all manner of genital cosmetic renovations [30–32]:

> Some 20 odd years ago, when I was just finishing university in the US, I chose to travel to my country of heritage – Sierra Leone – to undergo female initiation. This included female circumcision.
>
> My aunt, mother and grandmother approached me and said they wanted to take me, along with a slightly older aunt, my younger sister and cousin, to "join Bondo". I was excited, recalling memories of my childhood in Africa, watching exuberant women dancing and singing during adolescent girls' initiation ceremonies, called Bondo. These women would take over the town, while men and uninitiated children had to stay in the houses. The women flanked the awesome Bondo masquerade, a powerful representation of our female ancestors, dancing and entertaining the crowds.
>
> We underwent several rites as part of our transition from girlhood to womanhood, the most significant being our excision operation – the reduction of the exposed clitoral hood, glans and labia minorae. My immediate experience was of pain and culture shock, while my eight-year-old sister felt nothing and was

> soon up and about with other young girls playing in the Bondo encampment.
>
> My initial fear – that I would never enjoy sex again and be scarred forever – turned into pride and amazement when I first held a mirror "down there", saw a clean, smooth look, and experienced my first post-operation sexual orgasm with my then boyfriend back in the US.
>
> In December 2012, this practice – now condemned as Female Genital Mutilation – came under an official ban by a UN Resolution, at the same time that the Hastings Centre Report, a leading bioethics journal, published an advisory statement dispelling many of the popular myths about female genital surgeries. Yet, in recent years, all over the internet and in Western women's magazines I see glossy advertisements of white women who have undergone what is now popularised as Female Genital Cosmetic Surgery (FGCS).

LABIAL ELONGATION

A ritual counterpart to FGC is the practice of labial elongation, a tradition found widely in central Africa, particularly Rwanda, Malawi, Uganda, and Zambia [12,34–36]. Labial elongation has been labeled a "WHO type 4 FGM" by some watchdog organizations. In reality, communities practicing labial elongation do so to enhance the sexual pleasure of the man and the woman. In personal, direct conversations with gynecological colleagues, both male and female, from elongating cultures, one is assured that elongation is neither painful, humiliating, nor a tool of oppression. According to female colleagues who have elongated their own labia, they describe it as a rite of passage that acknowledged their own sexual awakening and fostered expectations of sexual pleasure within marriage. To date, the only woman who has ever claimed traumatic memories associated with labial elongation in my experience has been one chronically ill, illegal immigrant undergoing medical evaluation pursuant to an asylum seeking application to the U.S. government.

Labial elongation has its own "Fuambai Sia Ahmadu" in Dr. Sylvia Tamale, feminist, human rights activist, and law professor in Uganda, who argues that elongation enhances female sexual pleasure and is *not* a human rights violation. In 2005, Dr. Tamale published Eroticism, Sensuality, and "Women's Secrets" among the Baganda: A Critical Analysis [37].

In this analysis, Tamale decries the labeling of Okukyalira Ensiko—the practice of labial elongation among Baganda women in Uganda—as a type 4 female genital mutilation by the WHO, a declaration that "completely disregards the ways in which Okukyalira Ensiko enhances women's sexual pleasure." She further points out that cosmetic procedures such as clitoral piercing performed in industrial, Westernized countries are not listed in WHO's type 4 FGM procedures despite meeting criteria. Such double standards in global health turn this African practice of sexual enhancement into a misinterpreted, inaccurate illustration of traditional cultural practices claimed to violate the rights of women and children, when, far from suffering WHO's FGM symptoms of "incompleteness, anxiety, and depression," Baganda women undergoing labial elongation experience none of these symptoms, contradicting this negative characterization. Western researchers lent further academic credibility to the female empowerment and reported benefits of labial elongation in a 2008 peer-reviewed community survey of Rwandan women [38].

MOTIVATIONS FOR CONTEMPORARY FEMALE GENITAL COSMETIC SURGERY

Normal vulvar anatomy varies widely. Waxing of pubic hair and Internet access to genital images appear to have contributed to the rise in numbers of women in industrialized nations seeking modification of their own genitalia to match what they subsequently believe to be "normal" [39]. Grassroots movement to address this genital conundrum exist in online galleries of vulvar images such as "The Labia Library"; Kotex® online platform for teens that reinforces "Well, there is no 'normal' looking vagina; just like your face is different to almost everyone in the world so is your vagina"; and the U.K.'s National Health Service website that explains "Labia vary from woman to woman, so don't judge yours by anyone else's standards" [40–42].

Regardless of the wide range of normal genital anatomy, women continue to seek modification. Physicians addressing such concerns have no meaningful resources in standard medical texts with which to create a reference point for the patient, and for themselves, as most anatomy illustrations of genitalia offer just one morphological image, lacking any acknowledgment or illustration of the wide variations in normal genital architecture [43]. What data exist on genital morphology variability show that normal clitoral size, labial measurements, vaginal, perineal, and clitoral–urethra length vary widely, with no association to age, parity, ethnicity, hormone, or sexual activity status [44]. In addition to cosmetic appearance and body image concerns, client/patient motivations also include chafing, interference with sexual and sporting activities, discomfort in clothing, and improvement in sexual friction and sexual satisfaction. Results show 90%–95% satisfaction overall and 80%–85% sexual satisfaction specifically in one review of FGCS published by a stateside group of FGCS clinicians [4,45].

Further reports of FGCS motivations show a nuanced interplay between body image, genital physical discomfort, and sexuality. In one recent cohort study, 1/3 of women seeking labiaplasty reported being teased about the appearance of their genitals compared to 3% in the control group. The labiaplasty group did not have higher rates of childhood abuse nor any difference on validated measurements of disgust or general appearance compared to controls not seeking labiaplasty [46]. They did not rate higher for anxiety or depression but were more likely to report poor sexual and body image satisfaction and to demonstrate avoidance behaviors regarding these concerns [47]. In a recent prospective comparative trial of women undergoing labiaplasty compared to controls, 91% showed postoperative improvement in long-term follow-up of 11–42 months, and four meeting preoperative criteria for body dysmorphic disorder related to their labia no longer met criteria for this diagnosis post-op (although one did continue to meet criteria, but for her nose, as her vulvar dysmorphia was ameliorated by the labiaplasty operation) [48]. Among peripubertal girls, motivation for labiaplasty is often related to marked asymmetry of the labia minora, anatomic comparison to other girls, normal genital changes associated with puberty, and images on the Internet and in anatomy books [49].

FGCS MARKETING

A multidisciplinary realm inhabited by urologists, gynecologists, urogynecologists, and cosmetic plastic surgeons, FGCS is singular among cosmetic specialties for the practitioners' tendency to publicly seek out "botched" cases for "expert revision," a phenomenon heretofore unknown in the history of cosmetic therapies and surgeries. Online search for "botched *rhinoplasty* or *breast augmentation* or *tummy tuck*, etc.." yields almost exclusively lay-press articles, with no plastic surgeon publicly claiming to be the savior of bad outcomes. When searching "botched labiaplasty," however, one is met with the claims of urological, gynecological, and urogynecological FGCS clinicians exhorting the perils of undergoing FGCS operations at the hands of the grossly unqualified, promising cosmetic rescue for women botched by incompetents, such as "There are only a handful of surgeons who perform these surgeries in adequate volumes to be proficient and adept. Technical skill is of paramount importance but having an artist's eye is of equal value" [50]. Others literally own websites containing the phrases "labiaplasty revision" and "botched labia" in the website domain names, which contain web pages titled "Labiaplasties gone wrong" and "Labiaplasty nightmares," an unprecedented predatory medical marketing phenomenon [51–53].

FGCS: THE MENU

Procedures sought by clients and marketed by FGCS practitioners occur in three overlapping categories: functional, cosmetic, and sexual enhancement.

FGCS for Function

These procedures address discomfort or other morbidity involving congenital or acquired changes in the architecture of the genitalia, perceived as anomalous to the client, often but not always in relation to activities of daily living, sexual activity, or wardrobe discomforts.

Labiaplasty

While labiaplasty is most notorious for associated cosmetic goals, many teen and adult women seeking the operation do so for function reasons, particularly if there is *catching and pinching* of labia during vigorous sporting activities and/or if there is marked asymmetry of the labia minora, or robust, redundant or hypertrophied labia minora that distort body contour in tight clothing or beachwear [4,44,45,54].

Prolapse

Most often marketed as vaginoplasty options, especially in urogynecological FGCS clinics, standard prolapse operations are presented as methods of vaginal rejuvenation. Arguably the most accurate application of this marketing phrase, it has attracted the most criticism from ACOG in the area of medical marketing ethics [5]. The most commonly illustrated of these are anterior and posterior colporrhaphy and perineorrhaphy. Women undergoing anterior and posterior compartment repairs undergone for vaginoplasty to rejuvenate the vagina report 90%–100% satisfaction rates, with 0%–4% regret, and a low rate of complications including wound dehiscence, dyspareunia, rectoperineal fistula, post-op bleeding, and surgical site infection [54].

Hymen Restoration

Hymenoplasty involves careful reconnection of the hymen remnants to recreate a pseudo-virginal state, most commonly requested by women from cultures that place high social significance on virginity and gaining popularity in Europe and the United States from women seeking virginity certificates or hymen restoration surgery [55]. This procedure is under scrutiny due to the inherent cross-cultural and socioethical issues involved. Domestic violence was found with high prevalence in 1 Swiss study of 80 women seeking "revirgination." Of the 19 women who went through with hymen restoration in this series, only 2 of them experienced the desired "virginal bleeding" at first coital episode after surgery [56]. A second Swiss survey of 100 public hospitals addressed this issue present in Switzerland's immigrant communities, most frequently Turkey and Arab nations. Most of the clinics responding revealed that they usually or always provide revirgination hymenoplasty to immigrant women [57]. Another crosssectional survey of Lebanese university students revealed that physical harm and death are considered strongest justification for undergoing hymen restoration, although the majority of students did not endorse revirgination on ethical grounds of honesty between married couples, with no difference in this opinion related to the participants' gender or religious background [58]. A Swedish survey of clinicians showed that while a majority of clinicians would provide virginity certificates or hymen reconstruction to young women undergoing honor-related threat, the remainder have engaged the international zero tolerance policy toward such requests [59]. One Indian website offers a revirgination that guarantees bleeding at first coitus by including prerequisite vaginal tightening, because with hymen reconstruction only "… most patients do not bleed and their husbands complained that vagina was loose. Many … ended up with divorce. One should go for vaginal tightening of muscles (in addition to hymenoplasty)" [60].

A 2010 British Broadcasting Company article investigated hymen reconstruction services available in Paris, performed most often for Arab immigrant women facing ostracism, death, or suicide as the price paid for entering marriage without intact virgin status. The profiled French physician, who performs two to three hymen restorations per week, states "I believe we as doctors have no right to decide for her or judge her" [61].

In the United States, revirgination motives include a desire to improve one's sex life and "the ultimate wedding anniversary gift" for clients' husbands. In one online article, a woman from New York City explains "If a woman isn't a virgin when she gets married, a man can always put her down for that" [62].

Nonsurgical revirgination options may be found at www.hymenshop.com, in the form of an artificial hymen kit guaranteed to give the male partner the sensation of breaking through a membrane. Containing a red dye, it further promises the appearance of virginal blood on the sheets, "… not too much but just the right amount. Add in a few moans and groans and you will pass through undetectable!" Free delivery to any world destination is to be had for the bargain price of $29.95 [63].

FGCS for Cosmetics

These procedures address client desires to alter the cosmetic appearance of external genitalia.

Labia

The goal is to preserve/create symmetry while reducing dependent labial length.

Labia Minora

1. *Linear excision labiaplasty* (Figure 115.1): Linear reduction involves full thickness, full contour, gently sculpted excision of the labia minora. The simplest of all labia minora reduction surgeries, it is marketed under the name “linear reduction” on FGCS websites, though it is often called “amputation” by these same FGCS surgeons who claim to be “botched labiaplasty” experts. This technique completely excises the entire labial edge [54].
2. *Z-plasty wedge labiaplasty* (Figure 115.2): This technique follows plastic surgery Z-plasty principles that facilitate maintenance of the labial edge, a flat excision interface that avoids concave or convex deformation of the revised labia, and low-tension closure of the labial skin, both reducing labial bulk and dependent length [64].
3. *V-wedge labiaplasty*: Central or posterior (Figures 115.3 and 115.4)
   This simple full-thickness wedge also permits maintenance of the labial edge without the complicated staggered excision of a Z-plasty wedge resection. No comparative data exist between wedge resection techniques [53]. Wedge technique involve both central (pie slice) and posterior (anterior edge sewn to incised perineal surface) options [54]. Between various V-wedge and linear excision techniques, cosmetic and sexual satisfaction was similar in one multicenter trial of various FGCS operations [4].
4. *Deepithelialization labiaplasty* (Figures 115.5 and 115.6): An ellipse of dermis is excised from either the lateral or medial aspect of the labum, avoiding fullthickness excision, preserving the labial edge [54].

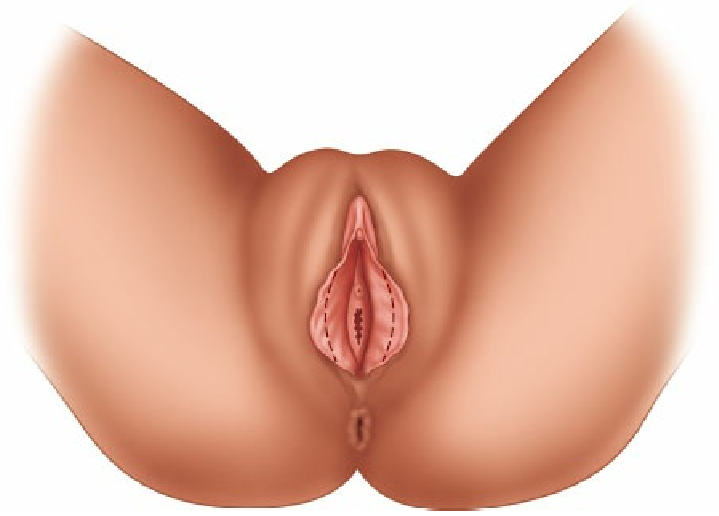

Figure 115.1 Labiaplasty: linear resection. (From Iglesia CB et al., *Int Urogynecol J*, 24, 1997, 2013.)

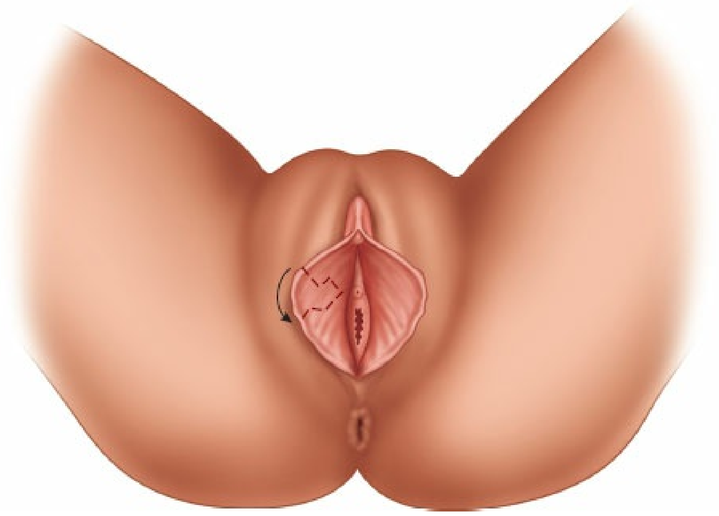

Figure 115.2 Z-wedge labiaplasty. (From Goldstein AT and Romanzi LJ, *J Sex Med*, 4, 550, 2007.)

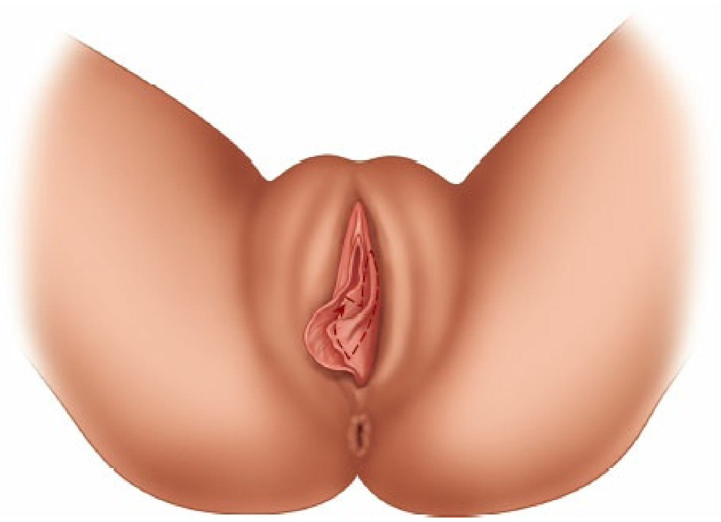

Figure 115.3 V-wedge labiaplasty: central. (From Goodman MP et al., *J Sex Med*, 7(4 Pt 1), 1565, April 2010; Courtesy of Miklos/Moore.)

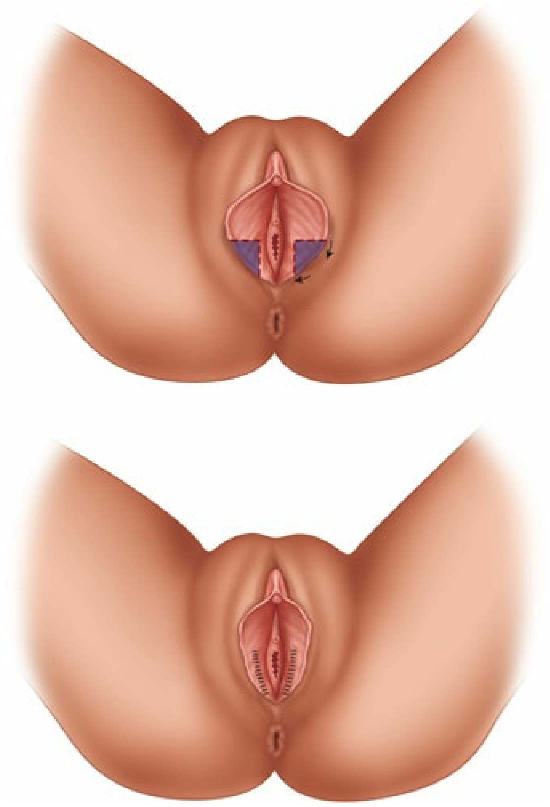

Figure 115.4 V-wedge labiaplasty: posterior.

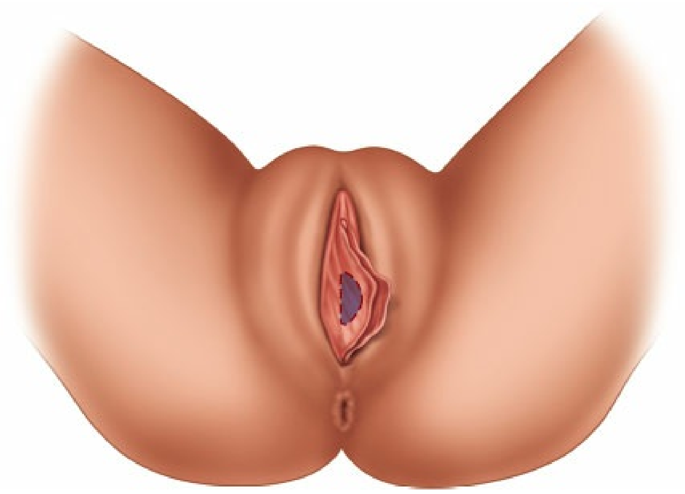

Figure 115.5 Lateral deepithelialization.

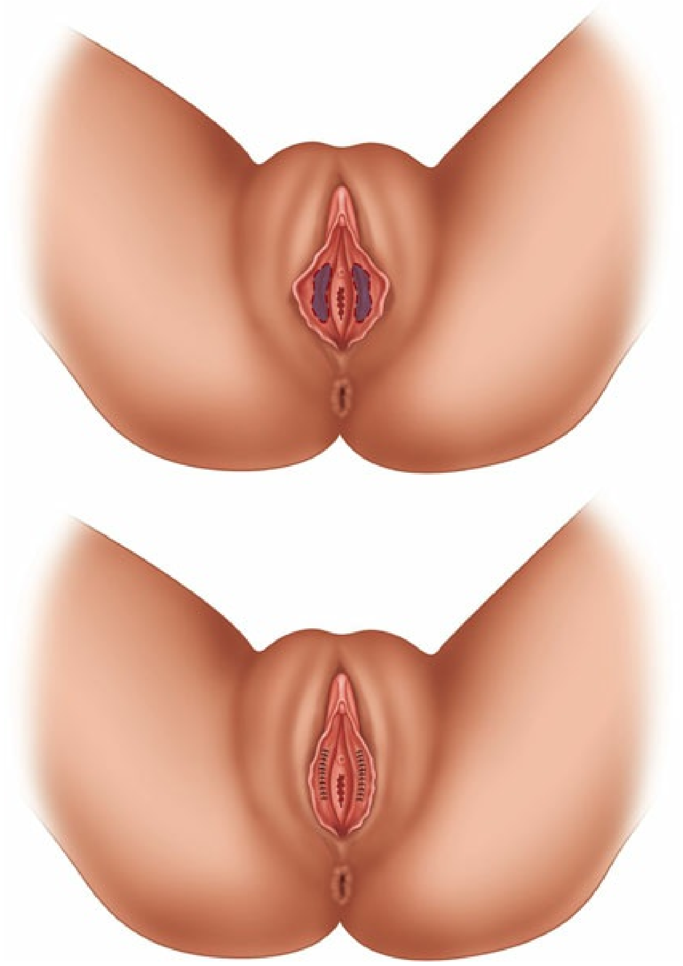

Figure 115.6 Medial deepithelialization.

Labia Majora

1. *Deepithelialization labiaplasty*: The skin overlying the majora is excised in an elliptical dissection, without removing underlying fibromuscular or fat pad structures. The skin edges are reapproximated vertically to achieve smoother labia majora skin, less dependent bulk when standing, and increased dermal turgor [65].
2. *Labial augmentation with injectable filler*: Cosmetic fillers include autologous fat and

synthetics, including hydroxyapatite, polyacrylamide gel, hyaluronic acid, and bovine collagen. Similar to oral labial bulking through injected filler material, cosmetic surgeons now offer injection of filler to restore a youthful fullness and turgor to wrinkled, deflated labia majora. Marketing claims include statements such as "Sagging labia majora can impact your confidence and hinder your sense of youthfulness. This procedure can help you take back the control over your body" [65].

   Cosmetic fillers may be complicated by injection site bruising, temporary swelling, uneven lumpiness of injected material, bacterial wound infection with symptomatic lesions at 5 years (most commonly due to *Staphylococcus epidermidis* and *Propionibacterium acnes),* migratory nodules, granulation, and chronic inflammation [66–68].

3. *Radiofrequency*: Skin tightening using surface application of dermatologic radiofrequency technology is offered in some FGCS centers as a method to reduce wrinkling of labia majora and surrounding skin of the groin and buttocks [65].

Vagina

DLV: "…designer laser vaginoplasty is for (vulvar) aesthetic enhancement" [69]. Patented DLV® has never been described in any gynecological text, surgical atlas, peer review journal, or other publications. DLV and its sexual enhancement cohort LVR are not taught in any surgical or gynecological residency training program, nor in any urogynecology, female urology, female pelvic medicine and reconstructive surgery, plastic surgery, or other reconstructive surgical subspecialty fellowship training programs. Patient choice for LVR® and DLV procedures is confined to doctors who have paid for the LVR DLV franchise, which includes training; certification; participation in an exclusive, robust web marketing network; and contractual obligation forbidding disclosure of the patented techniques. As such, and despite patient satisfaction testimonials on the franchise physician websites, there are no scientific data in any peer-reviewed medical journal for LVR or DLV. Technique details in published interviews in the lay-press disclose that the laser is used to make all incisions and that recovery takes 4–6 weeks [70].

FGCS for Sexual Enhancement (These Procedures Allegedly Increase Sexual Gratification)

1. *Perineoplasty* (Figure 115.7): The majority of websites offering illustrations of FGCS for sexual enhancement commonly include illustrations or descriptions consistent with standard perineoplasty operations, including dissection, suturing, and recuperation estimates found in gynecologic surgery atlases for perineorrhaphy and perineoplasty. The marketing language emphasizes restoration of *coital friction* to improve both female and male sexual satisfaction.
2. *Clitoral unhooding* (Figure 115.8): Amenable to inclusion in the WHO Type 1 FGM category that includes *excision of the clitoral prepuce*, clitoral unhooding is most commonly promoted in the sexual gratification arena of FGCS but does own some territory in the cosmetic FGCS marketplace as well [4,54].
3. *LVR*: LVR is marketed as a method of sexual enhancement by the patent and franchise holders. Descriptions state that incisions are made with the laser with recuperation lasting 4–6 weeks. Website claims state that LVR "help(s) alleviate symptoms of stress urinary incontinence" and "…can enhance vaginal muscle tone, strength and control" [69,70].
4. *G-spot amplification*®: Another patented technique, G-spot enhancement is based on the theory of the Grafenberg spot, an alleged erogenous zone on the anterior vaginal wall in the suburethral area, and the possibility that vaginal orgasm might occur more readily and with greater intensity if this area is made larger/more prominent through temporary filler injection of hyaluronic acid into the urethrovaginal space [71–74]. The founder's research data of "… a pilot study (in which) 87% of women surveyed after receiving the G-shot® reported enhanced sexual arousal/gratification" cannot be verified on literature search of peer-reviewed journals [75]. Results are reportedly temporary, lasting 3–5 months [75,76].

   The existence and function of the G-spot as an anatomic entity continues to spur debate since first described by Grafenberg in 1950. In a 2004 study of genital and sexual function in women, the anterior vaginal wall was not described as an area of erogenous stimulation, though other vaginal parameters, such as depth, did correlate to sexual sensitivity and orgasm intensity [73].

On the G-shot website, the client consent form includes over 50 complications, including dyspareunia, fistula, sexual dysfunction, and permanent numbness [75].

5. O-shot®: O(rgasm)-shot utilizes autologous platelet-rich plasma (PRP) injection therapy to stimulate clitoral function. PRP therapy is derived from patient plasma and allows *release of growth factors from activated platelets in areas where PRP is either injected or applied to the surface in gel form. PRP has many applications in orthopedics for tendon, muscle, and bone injuries, in addition to dermatologic efficacy in optimizing autologous free fat graft uptake, complex wound healing, melasma, alopecia, and depressed facial scars [77–83]. With the O-shot, PRP is harvested and reinjected periclitoral using patented techniques known only to those clinicians trained and certified by the physician who developed and patented the procedure, with alleged significant improvement in female sexual response, orgasm achievement, and orgasm intensity. The O-shot website contains further claims of cure of coincident urinary incontinence.*

SUMMARY

Options for genital modification, be they traditional or nouveau, FGCS, vaginal rejuvenation, or FGC, are increasingly influenced by cross-cultural aspects of immigration, globalization, and the Internet, all of which has spawned a fascinating conundrum in medical ethics and public policy that has turned female genitalia into a modern neosymbol of human rights, female autonomy, and social currency.

Is a Canadian woman with a facelift and breast augmentation (both considered unacceptable and absurd in most developing nations) who requests a "Barbie labiaplasty" under any less disturbing social influences than a Masai woman undergoing ritual genital cutting? Do either one require international monitoring of their genital management issues?

Is traditional genital cutting always traumatic, mutilating, and utterly without personal reward? It appears the answer may well be no.

Is the marketing of standard colporrhaphy techniques as "vaginal rejuvenation" a semantic trick to increase financial yield, or is it a new framework within which women opt to forego the geriatric "prolapse" label for the more youthful concept of "rejuvenation" instead?

Might we successfully introduce the notion of informed consent in ritualistic FGC? Ought we support the apparent trend toward minimal cutting done with local anesthetic carried out by a certified midwife in high-prevalence FGC countries rather than continue the minimal impact zero tolerance policies set forth by international stakeholders? [15].

Why do we accept unilateral labiaplasty in a 15-year-old secondary school elite athlete who claims asymmetry is causing her to lose her races while denying FGC to her 16-year-old immigrant neighbor who needs it in order to be marriageable?

Perhaps the answer lies in labial elongation, the only do-it-yourself option with enticing alleged benefits and minimal apparent risk.

ACKNOWLEDGMENTS

Thanks to Edna Adan, guardian of Somaliland and inexhaustible source of wisdom and inspiration, and to Fuambai Sia Ahmadu and Sylvia Tamale, brave pioneers both whose compelling messages deserve our attention.

116 Cosmetic Vaginal Surgery

Robert D. Moore and John R. Miklos

INTRODUCTION

Vaginal rejuvenation and cosmetic genital vaginal surgery have been performed and popularized increasingly in gynecology, urogynecology, and plastic surgery. However, controversy and debate over the subject remain the most discussed issue in this area, not the in-depth surgical techniques. The line between cosmetic and medically indicated surgical procedures is a gray area, and procedures are performed for both purposes. In the current chapter, we will review the background and history of these procedures, the available data to support them, and the techniques and complications of these procedures. In addition, we will discuss some of the controversies surrounding these topics. Finally, we will also attempt to shed light on what is myth and what is science in this relatively new field of elective genital vaginal surgery for sexual function and cosmesis of the female vagina and vulva.

The current chapter is divided into two sections, the first covering vaginal rejuvenation procedures and the second covering external vaginal/vulvar cosmetic surgery. Many use the term “vaginal rejuvenation” to encompass all elective vaginal/vulvar surgery; however, we feel that it should be used only to refer to functional procedures of the internal vaginal canal and introitus that are designed to enhance sexual function, which includes ensuring adequate support of the pelvic floor and then internal vaginal canal repairs and repair of the introitus. Similarly, cosmetic vaginal surgery to many just means labiaplasty or labial minora reduction; however, one will see in the second section of the chapter that it is much more comprehensive than this. Therefore, we have defined “cosmetic vaginal/vulvar surgery” as cosmetic or aesthetic procedures of the outside of the vagina and/or vulva, including labiaplasty, labia minora reduction, excess or redundant clitoral prepuce reduction, labia majora reduction or augmentation, labia majora divergence repair, perineal skin reduction, and mons pubis reduction. In most instances, to achieve the outcome desired by the woman, a combination of these external cosmetic procedures needs to be done, truly bringing in the “art” of aesthetic surgery.

VAGINAL REJUVENATION

Vaginal rejuvenation has also been defined to include perineoplasty and vaginoplasty, which are techniques to “tighten” the vaginal canal and to elevate and strengthen the perineal body [1]. The purpose of these procedures is not to correct pelvic floor defects, but they are modifications of traditional colporrhaphy designed to repair the damage from childbirth and are frequently performed concomitantly with reconstructive procedures for pelvic organ prolapse. These procedures involve vaginal reconstructive techniques to anatomically modify the vaginal caliber by decreasing the diameter of the vaginal canal while reconstructing the perineal body and the vaginal introitus in an attempt to enhance sexual gratification for the woman [2–4]. Utilizing this definition, one realizes that this is not a new field at all, i.e., gynecologists have been dealing with sexual dysfunction related to vaginal pathology, resulting mostly from vaginal childbirth for hundreds of years. However, the implication of this definition is to actually give credence to women’s complaints of altered sexual function secondary to vaginal relaxation/looseness (Figure 116.1a through c) and possibly to perform vaginal repairs prior to developing signs or symptoms of true prolapse or incontinence. Many women who are candidates for vaginal rejuvenation have symptoms and clinical findings of prolapse. Therefore, a proper repair must involve restoring the foundation of pelvic floor support and encompass some of the newer concepts of vaginal rejuvenation in the repair.

Prolapse and vaginal relaxation occurring after vaginal childbirth is not a new concept. We have clear evidence that vaginal delivery increases the risk of vaginal support problems, vaginal relaxation, prolapse, and incontinence. Various pathophysiological studies have demonstrated marked changes after vaginal delivery to levator muscles [5,6], nerves [7], and pelvic support [8]. It is obvious that parous women are more likely to have pelvic organ prolapse, fecal incontinence, and urinary incontinence than women who have not borne children [9]. There is ample epidemiological evidence that vaginal delivery appears to be the strongest risk factor for pelvic floor disorders [10]. As evident in the Women's Health Initiative [11], women who had borne at least one child were twice as likely to have uterine prolapse, rectocele, and cystocele as nulliparas, after adjusting for age, ethnicity, body mass index, and other factors. The amount of damage at the time of vaginal childbirth has also been shown to be strongly correlated with sexual function. At 6 months postpartum, women with an intact perineum or first-degree perineal tear were less likely to experience sexual dysfunction than those with higher degree of perineal tear [12,13]. Interestingly, 80.4% of urogynecologists stated that they would agree to perform elective primary cesarean section on request [14].

Prolapse and Sexual Function

Female sexual dysfunction is defined as a disorder of sexual desire, arousal, orgasm, and/or sexual pain contributing to personal distress [15]. Sexual dysfunction is a multifactorial disorder; biological, psychosocial, and relational factors can contribute to female sexual dysfunction. Among these factors, the pelvic floor appears to have an important influence. Dysfunction of vaginal support leading to incontinence, prolapse, and sexual dysfunction is highly prevalent [16].

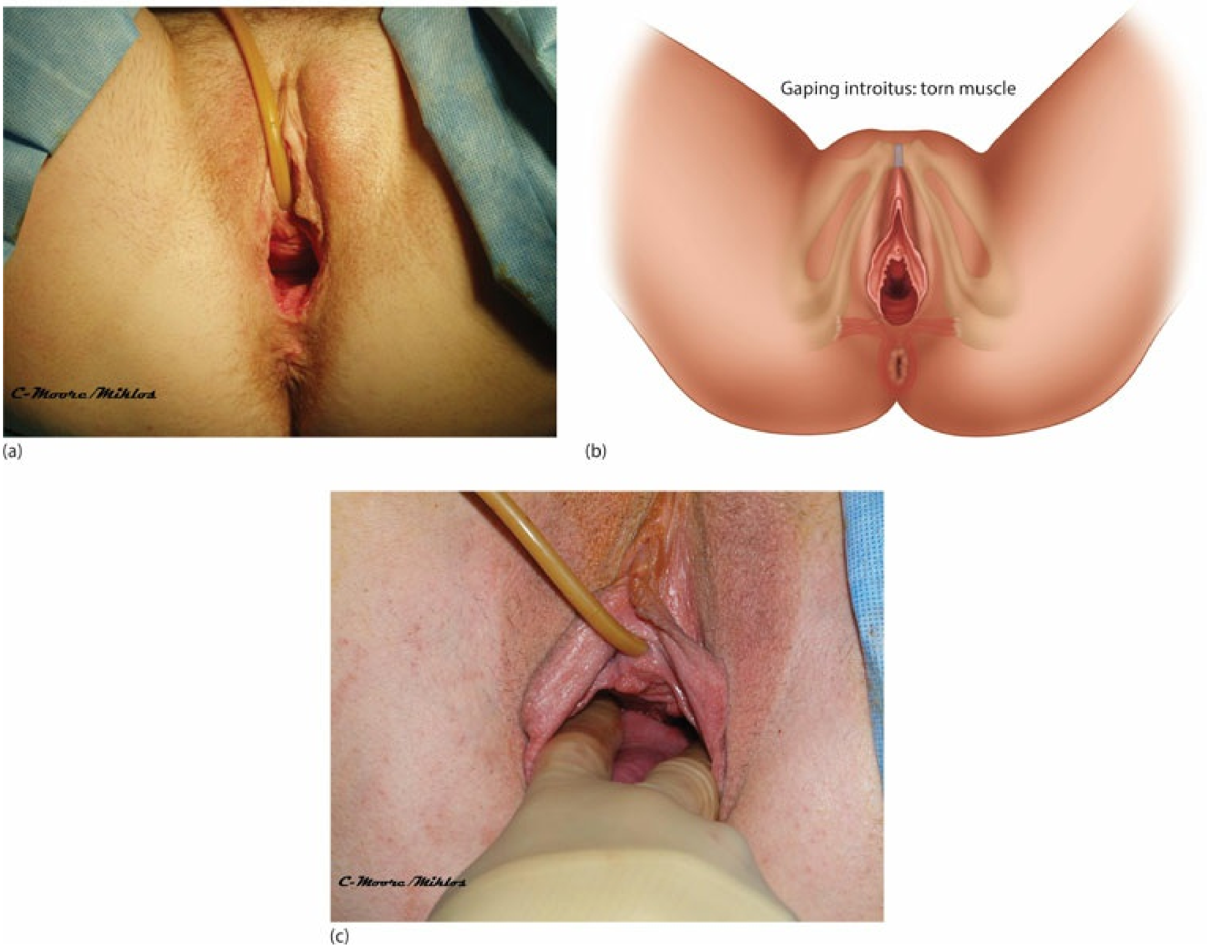

Figure 116.1 (a–c) Vaginal laxity and damaged perineum. (Courtesy of Robert D. Moore and John R. Miklos.

It is beyond the scope of this chapter to review all of the anatomy, neuroanatomy of pelvic floor support, and its relation to sexual function, however, suffice it to say that we do have good evidence that vaginal childbirth, as well as some other environmental and genetic factors, can lead to issues with pelvic floor support, which in turn can affect sexual function. Again, repairs of pelvic floor and vaginal support have been completed for many, many years, and one would not argue that one of the goals of any of these repairs is to "restore sexual function"; therefore, we must make the assumption that vaginal relaxation and prolapse affects sexual function in a negative way.

The literature also supports this theory. There have been many studies published in the literature that confirm, with validated sexual function questionnaires, that prolapse affects sexual function and, when repaired, function improves (Tables 116.1 and 116.2). These studies have confirmed that prolapse, albeit a more severe form of vaginal relaxation, but certainly relaxation, does adversely impact sexual function.

We feel that the posterior vaginal wall anatomically controls most of the vaginal caliber secondary to its relationship to the levator ani and genital hiatus and repair of this wall is a major portion of most rejuvenation-type procedures. Therefore, studies evaluating rectocele repairs may have more of a direct correlation to vaginal caliber and sexual function. Bradner et al. reported that posterior repair had a positive impact on sexual function. They examined the FSFI score before and after surgical rectocele repair in sexually active patients who had symptomatic rectoceles. There were significant improvements of FSFI score in domains of sexual desire, satisfaction, and pain [30]. Tunuguntla and Gousse found that while posterior repair with levatorplasty leads to sexual dysfunction and pain in many women, that actually posterior colporrhaphy completed alone, with the avoidance of levator ani plication, improves sexual function [34]. Komesu et al. investigated the effect of posterior repair on sexual function by using PISQ score. They included a cohort of patients who underwent pelvic floor reconstructive surgery with and without posterior repair and found that both groups significantly improved in sexual function [27]. Paraiso et al. compared three different methods of posterior rectocele repair, including one that utilized a graft and reported that all three approaches resulted in statistically significant improvements in the PISQ score [25].

Table 116.1 Pelvic Organ Prolapse Effects on Sexual Function

Author, year	Study design	*n*	Objective	Population	Sexual function measurement	Results
Ellerkmann et al. [17]	Prospective observational study	237	To compare the symptoms that are related to pelvic floor dysfunction with the location and severity of the coexisting prolapse	Patients with symptomatic pelvic organ prolapse came to Johns Hopkins Medicine.	The Pelvic Floor Dysfunction Questionnaire	Increasing severity of POP is associated with sexual dysfunction.
Barber and Maher [18]	Multiarmed clinical trial	343	To compare sexual function in women with urinary incontinence and pelvic organ prolapse	343 community-dwelling women older than 45 years with urinary incontinence or advanced prolapse.	The condition-specific sexual function questionnaire	33.3% POP group felt that prolapsed or urine leakage affected their ability to have sexual relations compared with 10% of urinary incontinence group ($p = 0.02$).
Novi et al. [19]	Unmatched case control	60	To compare sexual function in women with vs. without POP	30 women with pelvic organ prolapse and it was compared with 30 unmatched controls without evidence of prolapse.	PISQ	Pelvic organ prolapse appears to have a significant negative impact on sexual function compared with control (81.4 ± 7.3 vs. 106.4 ± 15.5, $p < 0.001$).
Botros et al. [20]	Identical twin study	542	To assess the impact of childbirth on sexual function	276 identical, sexually active twins.	PISQ-12	Nulliparous women reported superior sexual satisfaction scores compared with parous women, regardless of age and mode of delivery (102.5 vs. 93.5, $p < 0.001$).
Srikrishna et al. [21]	Prospective observational study	43	To evaluate the expectations and goals of women undergoing surgery for POP	Women with symptomatic POP were recruited from the waiting list for pelvic floor reconstructive surgery.	The prolapse quality-of-life (pQoL) questionnaire	20% women were dissatisfied with their sex lives as a result of their prolapse.

Table 116.2 POP Repair Improved Sexual Function Studies

Author, year	Study design	*n*	Objective	Population	Sexual function measurement	Results
Barber et al. [22]	Multiarmed clinical trial	343	To compare sexual function in women with urinary incontinence and pelvic organ prolapse	343 community-dwelling women older than 45 years with urinary incontinence or advanced prolapse	The condition-specific sexual function questionnaire	Fewer patients with POP reported that their prolapsed affected their ability to have sexual relations 6 months after vaginal reconstructive surgery than at baseline (0% vs. 33%, $p < 0.01$).
Rogers et al. [23]	Prospective observational	269	To assess sexual function in women after surgery for stress urinary incontinence and/or pelvic organ prolapse at 3 and 6 months	Women underwent a variety of anti-incontinence and reconstructive surgeries	PISQ	Sexual function scores improved after surgery (89 vs. 95, $p < 0.001$).
Stoutjesdijk et al. [24]	Prospective observational	67	To compare sexual function in women with POP before and after vaginal reconstructive surgery	Women who underwent vaginal reconstructive surgery	The urogenital distress inventory and incontinence impact questionnaire revisited	There was a significant improvement of dyspareunia after surgery. The ability to have intercourse, the satisfaction, and the frequency of intercourse improved although not significantly.
Paraiso et al. [25]	Randomized controlled trial	106	To compare outcomes of three different rectocele repair techniques (posterior colporrhaphy, site-specific rectocele repair, or site-specific rectocele repair augmented with a porcine small intestinal submucosa graft)	Patients undergoing surgery for stage II or greater posterior vaginal wall prolapse	PISQ-12	PISQ-12 improved significantly in all groups postoperatively ($p < 0.001$), with no differences between groups.
Handa et al. [26]	The CARE trial	224	To describe sexual function before and after sacrocolpopexy	Stress-continent women planning abdominal sacrocolpopexy for stage II–IV prolapse	PISQ-12	Among women who were sexually active before and after surgery, the mean PISQ-12 score improved significantly (34.1 ± 5.2, $p < 0.001$).
Komesu et al. [27]	Multicenter prospective cohort	73	To determine the effect of posterior repair (PR) on sexual function in patients who have undergone incontinence and/or pelvic reconstructive surgery	Sexually active patients who had undergone pelvic reconstructive and/or incontinence procedures	PISQ	Significantly improved their PISQ scores in both PR and non-PR groups, without a difference between groups.

Azar et al. [28]	Prospective observational	60	To evaluate the effect of surgical repair of POP on female sexual function	Women with POP	FSFI	Sexual function was improved 12–16 weeks postoperatively (15.9 ± 10.7 vs. 21.9 ± 11.1, $p < 0.05$).
Kuhn et al. [29]	Prospective observational	70 female, 64 male	To determine the male and female sexual function before and 4 months after surgery for POP	Sexually active heterosexual couples with symptomatic cystocele, rectocele, or vault descent	FSFI	In women, FSFI scores improved significantly in the domains desire, arousal, lubrication, overall satisfaction, and pain. In men, sexual drive, and overall satisfaction improved significantly.
Bradner et al. [30]	Prospective observational	68	To evaluate sexual function before and after surgical rectocele fascial repair in sexually active patients who suffer from symptomatic rectoceles	Sexually active female patients who were to undergo rectocele fascial repair for symptomatic rectoceles	FSFI	Significant improvement for desire ($p < 0.001$), satisfaction ($p < 0.0001$), and pain ($p < 0.0001$).
Lakeman et al. [31]	Prospective observational	29	To evaluate the effects of vaginal prolapse surgery on vaginal vasocongestion, vaginal wall sensibility, and sexual function	Patients scheduled for vaginal prolapse surgery	FSFI	Improvement of sexual function after prolapse surgery (20.5 vs. 23.3, $p = 0.30$).
Thibault et al. [32]	Multicenter prospective	148	To evaluate the impact of laparoscopic sacrocolpopexy on symptoms, health-related quality of life (HRQL), and sexuality among women with symptomatic urogenital prolapse (UGP)	Patients with symptomatic POP who undergo laparoscopic sacrocolpopexy	PISQ-12	Postoperative sexual function had improved significantly (35.42 vs. 32.07, $p < 0.05$).
Kim et al. [33]	Prospective observational	143	To evaluate the effect of surgical repair of POP on female sexual function	Patients scheduled to undergo surgery for POP stages II–IV	FSFI, PISQ-12	Improvement of PISQ score from 25.0 ± 4.95 to 28.33 ± 5.1 postoperatively ($p < 0.001$). No differences of pre- and post-op FSFI ($p = 0.08$); however, only the satisfaction domain score significantly increased ($p = 0.029$).

Vaginal Relaxation and Effect on Sexual Function and Sensation

It is clear from the aforementioned data that prolapse has a role with causing sexual dysfunction. The difficulty with this is that sexual function is multifactorial and can, because of this, be a very difficult area to study. It is also clear from these studies that vaginal repair improves sexual function and sexual quality of life, but is it because of the prolapse creating discomfort causing the woman to avoid intercourse or because of self-image issues regarding the prolapse? Or is it because vaginal relaxation and prolapse may cause decreased sensation leading to sexual dysfunction, i.e., feeling less, having a harder time achieving orgasm, or feeling self-conscious about the fact that she feels her vagina is loose, stretched, or relaxed?

Ozel and White recently published one of the first reports evaluating libido, sexual excitement, vaginal sensation, and ability to orgasm in a group of women with prolapse compared to women without prolapse. They found that women with prolapse and vaginal relaxation were significantly more likely to report an absence of libido, lack of sexual excitement during intercourse, and a much lower frequency of achieving orgasm during intercourse (all statistically significant) compared to women with the same demographics without prolapse (i.e., multiparous, similar age, marital status, etc.) [35]. This is a landmark study as it is one of the first studies evaluating the sensation of the vagina and the changes it may undergo following relaxation of the tissues that causes prolapse.

We have shown that vaginal prolapse can affect sexual function and its repair can improve sexual function and ability to orgasm. It therefore seems to make sense that if women present with an enlarged genital hiatus, or widened vaginal canal without symptomatic prolapse, this may also affect sensation and sexual function. Many women do present with these symptoms and until recently were told that there was nothing wrong and there were no options to improve her sexual sensation or function (Figure 116.2a through d).

Robert D. Moore and John R. Miklos.)

The theory that vaginal size is related to sexual sensation was first confirmed by Pardo et al. [2] in a study of a group of women who presented with symptoms of a wide or relaxed vagina and were interested in vaginal repair for sexual function alone. The women had no symptoms of prolapse or incontinence. Inclusion criteria included a sensation of a wide or loose vagina alone in combination with a decrease or lack of ability to reach orgasm. Exclusion criteria included symptomatic prolapse (cystocele, rectocele, or vault/uterine prolapse), dyspareunia, primary anorgasmia, or psychological impairment (all patients had psychological evaluation). Fifty-three patients were included in the study, and 96% of the patients experienced decreased vaginal sensation, 73% described difficulty achieving orgasm, and 27% could not reach orgasm. All but two patients had previous vaginal deliveries. Following surgical repair of the vaginal caliber and tightening of the vagina itself, 90% of women reported their sexual satisfaction was much or sufficiently improved and 94% of women were able to reach orgasm. This confirmed that vaginal size has a direct impact on sensation and ability to orgasm and when repaired sexual function improves.

Data Supporting Vaginal Rejuvenation and Improved Sexual Function (Table 116.3)

Pardo et al. published an additional follow-up study in a second group of women confirming their initial findings that vaginal size has a direct impact on sensation and ability to orgasm and when repaired sexual function improves [36].

Matlock and Simopoulos also conducted a study to evaluate sexual function in women presenting with subjective symptoms of vaginal relaxation with or without stress urinary incontinence following laser vaginal rejuvenation using PISQ score. Ninety-six patients who underwent the procedure completed PISQ before and 6 months after surgery. All patients presented with chief complaint of relaxed vagina and decreased sensation during intercourse. Of those, 65% had stage II POP-Q. This finding suggests that early pelvic organ prolapse may manifest as vaginal relaxation. The overall sexual function improved after surgery. There were only 13% of women with decreased PISQ score postoperatively. In addition, 53% reported increased intensity of orgasm during sexual intercourse [38].

Goodman et al. led a recent multicenter U.S. study on women undergoing female genital plastic surgery including vaginoplasty/perineoplasty for vaginal relaxation affecting sexual function. This study gathered data from diverse practices and surgical specialties with surgeons who utilize more than a single technique to achieve their desired outcome [39]. Preoperatively, 70% of women reported their sexual function was fair/poor. Postoperatively, it was found that 86% of 81 women following vaginoplasty/perineoplasty for sexual function reported enhanced sexual function following repair with only 1% reporting a negative effect on sexual function, confirming that repair of the vaginal caliber may lead to improved sexual function in women presenting with relaxation. Eighty-three percent of women reported “satisfied” with the outcome of vaginal rejuvenation. The predominate reasons for surgery from the physicians’ and patients’ perspective were feeling of looseness and lack of coital friction and sexual pleasure. A literature review by Goodman indicated that female genital plastic surgery procedures including vaginal rejuvenation appear to fulfill the majority of patient’s desires for cosmetic and functional improvement as well as enhancement of the sexual experience. The majority of patients reported improvement of overall satisfaction and subjective enhancement of sexual function and body image [39].

Most recently, we evaluated sexual function outcomes in a group of women ($n = 78$) presenting for vaginal rejuvenation/vaginoplasty procedure for a chief complaint of vaginal laxity and decreased sensation with intercourse. Outcomes were analyzed utilizing the validated Pelvic Organ Prolapse/Urinary Incontinence Sexual Questionnaire-12 (PISQ-12) before and at least 6 months after repair with vaginal rejuvenation/vaginoplasty procedure (VR). Compared preoperatively and postoperatively, the overall sexual function (total PISQ-12) statistically improved (30.3 ± 6.6 vs. 38.2 ± 5.2, $p < 0.001$). All individual scores statistically improved except in three categories in which there was no change (Q1-desire, Q5-pain, and Q11-partner premature ejaculation). Overall sexual satisfaction improved as well as subcategories of increased sexual excitement during intercourse and overall increase in intensity of orgasms. Pain with intercourse subscores was found to be no different from preoperatively to postoperatively [40].

VAGINAL REJUVENATION: SURGICAL TECHNIQUES

Importance of Proper Evaluation and Diagnosis

Proper preoperative evaluation is a vital process for a patient who presents with an interest in surgery to repair what she conceives is a loose or relaxed vagina and would like it tightened for sexual enhancement or to correct the feeling of having a “wide-open” vagina, i.e., vaginal rejuvenation surgery. This includes proper medical history, psychosocial evaluation for sexual dysfunction, and/or sexual satisfaction prior to any of the anatomical changes she may have noted since childbirth. Marital or relationship issues or concerns and an evaluation of her expectations of surgery and the reasoning why she is interested in the procedure should be discussed as well. Sexual dysfunction is very complex and multifactorial, and of course, a surgical procedure to repair vaginal support and reduce the vaginal caliber will not reverse or change psychological or psychosocial sexual dysfunction arising from previous abuse, primary anorgasmia, relationship issues, depression, or other more complex psychological dysfunctions.

In addition to a medical and psychosocial history, an adequate urogynecology history and physical exam must be completed. Sexual dysfunction related to a sense of a relaxed or loose vagina may be the first sign of the beginning stages of pelvic floor dysfunction and prolapse; therefore, an adequate history must be taken. We have actually found that as many as 50%–75% of patients who present for vaginal rejuvenation, when asked, have symptoms including urinary incontinence, voiding dysfunction such as overactive bladder or difficulty emptying, feelings of pressure or the sense that their organs are falling, defecatory dysfunction, or dyspareunia related to the uterus being hit during intercourse because of prolapse. It is vitally important to have an adequate understanding of the symptoms that prolapse can cause, and we use validated questionnaires such as the UDI-6, IIQ-7, and the PISQ-IR [41] to evaluate patients for these symptoms as well as a general urogynecological history form. If significant symptoms of urogynecological pathology are present, this must be evaluated preoperatively so that it can be addressed properly during surgery. Any prolapse that is present *must* be repaired properly at the time of surgery including uterine/vault prolapse, enterocele, cystocele, or rectocele as vaginal rejuvenation procedures do *not* adequately treat these defects. The foundation of the pelvic floor support must be intact prior to any technique that will tighten the caliber of the vagina or introitus.

Table 116.3 Vaginal Rejuvenation Studies on Female Sexual Function

Author, year	Study design	*n*	Population	Intervention	Outcomes	Results	Follow-up (month)	Complications
Pardo et al. [2]	Prospective observational	53	Women with wide vagina and decrease or lack of ability to reach orgasm	Colpoperineoplasty (dissected with a YAG laser)	Patients' sexual activity, fulfillment of expectations, and vaginal width using a site questionnaire	90% much or sufficiently improved of sexual satisfaction. 4% tighter vagina, able to achieve orgasm. 74% expectation fulfilled completely.	15	4% regretted having procedures.
Pardo et al. [36]	Prospective observational	100	Women with wide vagina and decrease or lack of ability to reach orgasm	Colpoperineoplasty	Patients' sexual activity, fulfillment of expectations, and vaginal width using a site questionnaire	95% tighter vagina during the intercourse. 85% achieve vaginal orgasm. 79% expectation fulfilled completely.	4	4% regretted having the procedures. 2 (0.02%) minor surgical complications
Adamo and Corvi [37]	Prospective observational	40	Women with wide vagina	Lateral colporrhaphy	Sexual sensitivity	95% improvement of vaginal sensation and wide vagina after 6 months. 80% partners noticed improvement.	1.5	5% local infection 2.5% postoperative vaginal bleeding
Matlock and Simopolous [38]	Retrospective	96	Women undergoing laser vaginal rejuvenation	Laser-assisted anterior and posterior repair w/perineorrhaphy	Comparing pre- and postoperative sexual function with PISQ-12 score	53% reported increased intensity orgasm with intercourse. Only 13% had decreased PISQ-12 scores.	6	
Goodman et al. [39]	Multicenter cross-sectional	258	Women undergoing female genital plastic surgery	Vaginoplasty/perineoplasty procedures ($n = 81$)	Preoperative sexual functioning per procedure, overall patient satisfaction per procedure, patient's perception of effect on her partner's sexual enjoyment, per procedure, complications	85% mild/significant enhanced sexual function. 86% satisfaction. Subjective improvement in sexual functioning for both women and their sexual partners ($p = 0.008$).	6–42	4% temporary stricture of vaginal apex 2% wound dehiscence 2% excessive postoperative pain 2% inadequate tightening 2% microtear at 1-year follow-up 2% introital tightening 2% bleeding after first sexual intercourse 2% felt sutures inside vagina 2% introital narrowing
Moore et al. [40]	Prospective observational	78	Women presenting for vaginal rejuvenation/vaginoplasty procedure for a chief complaint of vaginal laxity and decreased vaginal sensation with intercourse	Vaginal rejuvenation	Comparing pre- and postoperative sexual function using PISQ-12 score	Mean PISQ-12 improvement from 30.3 ± 6.6 to 38.2 ± 5.2 ($p < 0.001$).	>6	

Surgical Procedures

The surgical procedure required is determined by the patient's physical exam. Again, many women who present to be interested in vaginal rejuvenation-type surgery, or surgery to correct a feeling of a loose or wide vagina, are found to have prolapse in the form of cystocele, rectocele, or uterine/vault prolapse. In most instances, it is POP-Q stage II or less; however, it is present and should be repaired. This is what determines what surgery will need to be done as *the prolapse must be corrected first*, prior to any rejuvenation procedures being completed, and is really the first step in an overall repair or "rejuvenation" of the vagina and pelvic floor. If significant uterine/vault prolapse and/or anterior compartment (cystocele) defects are encountered, these typically should be repaired abdominally/laparoscopically/robotically prior to addressing the posterior compartment and the caliber of the vagina.

Rejuvenation of the Vaginal Canal and Introitus

Repair of the posterior vaginal wall and the introitus are the key aspects to any vaginal rejuvenation procedure. Vaginal rejuvenation surgeries are alterations and modifications of vaginal repairs for prolapse that focus on the final diameter and caliber of the vagina and attempt to restore it back to its prechildbirth state. They do however go far beyond the simple traditional posterior repairs and perineoplasty of old. The focus of these older procedures is simply to restore and reduce the bulge, whereas the focus of vaginal rejuvenation is to restore the caliber of the vagina and genital hiatus back to prechildbirth state from the introitus all the way up to the apex. They are much more extensive and meticulous procedures. No drop-offs or dips should be felt and there should be no tension placed on the levators that causes lateral banding of the vagina. Additionally, the cosmetic appearance of the introitus and perineal body is also taken into account and requires intricate dissection and repair to not only restore function of the introitus but also obtain an appearance that the woman desires. That look typically is one of the vaginal opening being closed, not gaping or wide open with a normal length perineal body that does not bulge out following the repair. This look is sometimes difficult to obtain, without making the introitus too tight, which will cause pain with intercourse.

Posterior Wall, Introitus, and Rejuvenation

The posterior vaginal wall is the focus of any vaginal rejuvenation procedure. In a woman with a mild cystocele or mild relaxation of the anterior vaginal wall, a small anterior colporrhaphy can be completed to take care of this prior to repair of the posterior wall. However, one needs to be very careful with this as if the repair of the anterior wall is too aggressive, it will lead to lateral banding and constriction of the vagina, before the posterior wall is even started.

An incision is made at the introitus, typically in trapezoid pattern, that will also be used in the perineoplasty portion of the procedure (Figure 116.3a and b). A small incision is then made in a vertical fashion on the posterior wall, and the vaginal epithelium is dissected off the underlying rectovaginal fascia all the way laterally out to the levators (Figure 116.3c and d). The dissection must be taken all the way up to the apex of the vagina, as the repair needs to incorporate the entire posterior wall to restore the caliber of the full length of the vagina (Figure 116.3e). The dissection of the vaginal epithelium may be completed with a laser, as championed by Dr. David Matlock, or completed utilizing more standard techniques with sharp scissors or electrocautery. Care of course needs to be taken with any electrical energy source near the rectum. If a rectocele is present, the fascia is repaired in a site-specific fashion with delayed absorbable suture for the first layer of the repair. This may be a lateral repair of the defects, a midline placation, or a combination (Figure 116.3f). The caliber of the vagina is then addressed by plication of the rectovaginal fascia in the midline with delayed absorbable sutures. Levator plication is avoided; however, the diameter of the vagina is constantly measured, and several layers of plication may be needed to reduce the genital hiatus and reduce the caliber of the vagina to an appropriate level (Figure 116.3g through j). A small amount of vaginal epithelium is then excised and the incision closed in a running fashion.

A perineoplasty is then completed, involving a very meticulous and detailed dissection out laterally to obtain the lacerated edges of the deep and superficial transverse perineal muscles and bringing them back together in the midline to achieve uniformity at the same level of the posterior wall repair. The inferior edges of the labia majora that will make up the posterior forchette of the vaginal opening must be marked at the beginning of the procedure so that these edges match up during the closure to form the vaginal opening. An appropriate amount of skin must also be excised from the perineum and introitus to result in a cosmetically pleasing appearance of the opening of the vagina for the patient. A multilayer (typically this may involve four or five layers) is completed at the perineum and introitus (Figure

116.3k through m).

When a repair is primarily for vaginal relaxation for sexual function, it becomes a much more meticulous dissection and repair as the surgeon has to constantly be judging and measuring vaginal caliber to try to restore the entire vaginal length to its prechildbirth state. If this is not done, then the results will be poor and the patients' sexual function may not change or they will be worse secondary to pain, vaginal shortening, scar tissue formation, and/or constrictions.

Postoperative Care

Routine postoperative care is given to patients undergoing vaginal surgery. Many of the procedures are undertaken on an outpatient basis, and the surgery is completed under spinal or general anesthesia. A pudendal block may also be completed prior to or during the procedure to help decrease postoperative pain. Vaginal packing is left in for a short period of time and removed prior to the patient being discharged. Routine instructions for vaginal surgery are given to the patient and she is seen in follow-up at 4 weeks postoperatively. The vaginal introitus and caliber are assessed, and if felt necessary, the patient will begin perineal massage in warm water bath for 1–2 weeks prior to resuming sexual relations.

Risks/Complications

The potential complications of vaginal rejuvenation are infection, bleeding, wound dehiscence, dyspareunia, inadequate tightening, introital narrowing, and rectoperineal fistula. According to a study of 248 women by Goodman et al., 2% of women had temporary stricture of the vaginal apex, 1% wound dehiscence, 2% excessive postoperative pain, 2% inadequate tightening, 1% microtearing of the perineum with intercourse at 1-year follow-up, 2% introital overtightening, and 2% bleeding after first sexual intercourse [42].

Conclusion

Vaginal rejuvenation surgery is one of the latest trends in elective vaginal surgery for women. It is a repair of the vaginal caliber in women who suffer from decreased vaginal sensation or of feelings of a loose or wide vagina that affects their sexual life. In many instances, women who present with these symptoms are found to have other pelvic pathologies such as prolapse that must also be addressed during any repair contemplated. Sexual dysfunction or decreased sexual sensation may be the first symptoms that women suffer from in the progression of prolapse, and therefore, a proper exam is vital prior to any repair. We have ample evidence that prolapse and vaginal relaxation can create sexual dysfunction and that repair may reverse these changes in many women. It is important to note that when dealing with sexual dysfunction due to vaginal laxity alone, the surgical repair must be very meticulous and exact in order to enhance sensation and function and not impair it. This sums up the statement "The Art of Surgery"!

COSMETIC VAGINAL SURGERY

Aesthetic Surgery of the External Vagina and Vulva

Introduction

There have been many studies and research on the relationship between a woman's body image and her sexual function. However, little research exists on the relationship between a woman's genital image and her sexual function. Realizing one's genital image is part of one's body image; it is easy to understand how many women might feel sexually inhibited if they are not comfortable with the appearance of their vagina, vulva, or external genitalia. A survey of 3627 women found that women with positive body images reported more sexual activity, initiation of sexual activity, orgasm, sex with lights on, and greater comfort undressing in front of their partners, trying new sexual behaviors, and pleasing their partner [43].

Cosmetic vaginal surgery is currently steamrolling its way into mainstream culture. However as with every new trend, there are always those who oppose change. There have been many negative comments and editorials written suggesting that both the doctors and the patients should not be pursuing cosmetic vaginal surgery [44–46]. Many of those who imposingly opine are often ignorant of the patient and their disposition as well as their medical conditions and their associated symptoms [47]. Patients can suffer from a variety of physical and emotional symptoms. Physical symptoms are usually associated with wearing certain types of clothing; engaging in activities such as walking, jogging, exercise, and bicycling; and finally intercourse. Yet, other patients are afflicted with emotional problems such as embarrassment, anxiety, and a loss of self-esteem.

Cosmetic vaginal surgery does not always begin and end with labia minora reduction surgery, i.e., labiaplasty. There are many different techniques that can be applied to enhance a woman's genital cosmetic image. To understand the techniques, a basic understanding of the external genitalia is essential before undertaking surgical procedures.

Anatomy

The vulva is made up of the external genitalia including the mons pubis, clitoris, prepuce or clitoral hood, labia minora, labia majora, urethral meatus, hymen, and vestibule (Figure 116.4). The mons pubis is the adipose-laden area that lies superior to the pubic symphysis. This area is naturally covered with pubic hair and is a natural cushion during the impact of intercourse. The adipose area of the mons is contiguous with that of the hair-bearing labia majora. The labia majora are found bilaterally and converge both anteriorly above the clitoral prepuce and posteriorly at the perineum. The prepuce is actually the clitoral hood and acts like a protective covering over the clitoral gland. Usually, the very distal tip of the clitoris remains uncovered and exposed. The labia minora are bilateral mucosal–cutaneous refolds located between the labia majora and vulvar vestibule. While there is a wide range of normal anatomic variants, in general, the labia minora are semicircular with a 3 cm long base and a free edge extending from the clitoris to the posterior commissure. The medial mucosal surface is derived from the primitive urogenital sinus and is shiny and pink. The free edge and the lateral cutaneous surface that are derived from the urethral folds are more deeply pigmented [48]. However, the deeper pigment tends to be a darker pink initially and then begins to darken with hormonal changes often but not always associated with pregnancy. Obviously, just like any other part of the human body, there are multiple normal variants of this anatomy. Just like a nose, all the structures can be anatomically similar but cosmetically dissimilar. The most common of all described cosmetic vaginal surgery is labia minora reduction or labiaplasty [48–51].

Labia Minora Reduction (Labiaplasty)

Labia minora protruding past the distal edge of the labia majora can be of concern to women. As mentioned earlier, this condition can constitute a functional or cosmetic problem. Such an enlargement can be bilateral or unilateral in nature (Figures 116.5 and 116.6). Labial enlargement can be congenital as described by Caparo [52] and Radman [53] or can also be the result of androgenic hormones, manual stretching, and chronic irritation [52–55].

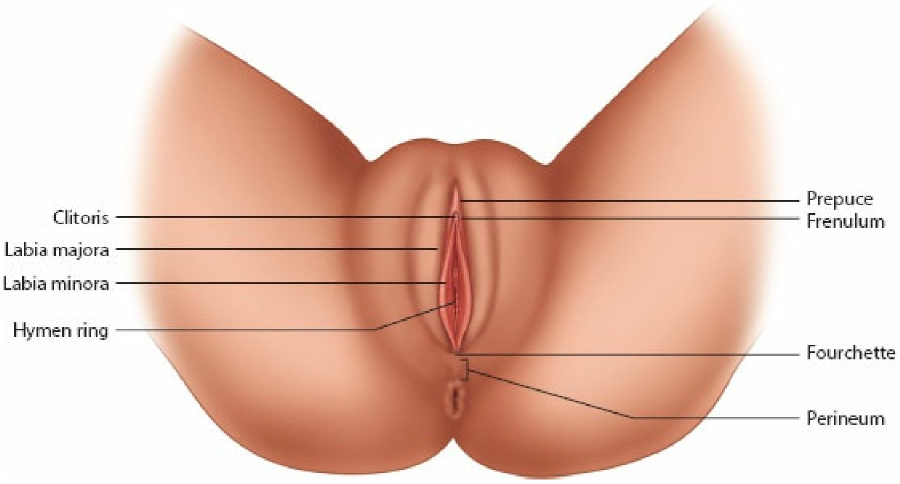

Figure 116.4 Normal external anatomy. (Courtesy of Robert D. Moore and John R. Miklos.)

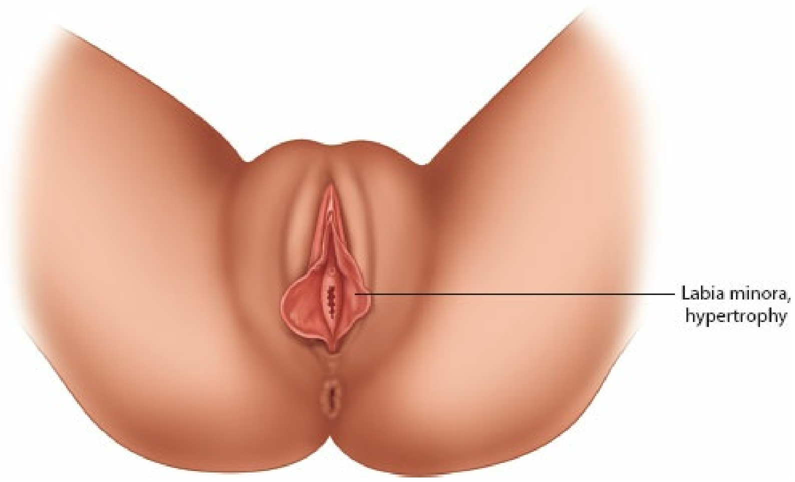

Figure 116.5 Labia minora hypertrophy. (Courtesy of Robert D. Moore and John R. Miklos.)

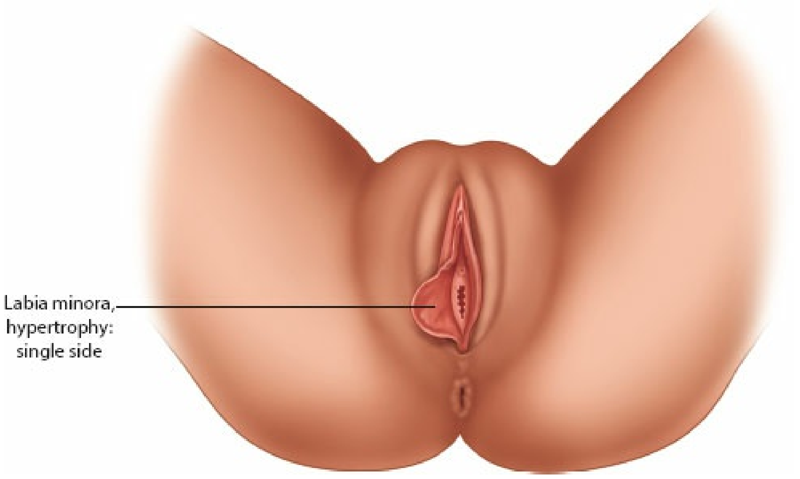

Figure 116.6 Unilateral labia hypertrophy. (Courtesy of Robert D. Moore and John R. Miklos.)

Rouzier et al. reported on 163 women who received labial reduction surgery. The primary reason for patients requesting this surgery was aesthetic dissatisfaction in 87% of cases, discomfort in clothing in 64%, discomfort when taking part in sports in 26%, and entry dyspareunia by invagination of the protuberant tissue in 43% [49]. We reported on a study of 131 patients undergoing labia minora reduction surgery and revealed the patients' indications for having the surgery: 37% strictly cosmetic reasons, 32% strictly for physical symptoms, and 31% a combination of cosmetic reasons and physical symptoms [52].

Although there are still few papers on labial reduction surgery, there are a number of different techniques described in the literature. The two most commonly utilized techniques are known as excision or contouring technique and the wedge resection technique. The authors employ both techniques depending upon the patients' requests and desires. If the patients prefer to keep the darkened pigmented labial border, we tend to utilize the wedge resection technique. However, it has been the authors' experience that most of their patients prefer to have a pinker or lighter look to the edges of their labia. In this situation, in an attempt to fulfill the desires of the patient, we utilize the contouring technique [51].

The contouring or excisional technique is a more time-consuming operation and directly excises the edge of the labia minora (Figure 116.7a through d). Though all surgeries are surgeon dependent, this operation is less reproducible than the wedge technique because it requires more artistic aptitude. There are multiple skin folds that need to be excised, reduced, and brought together to achieve a natural anatomic appearance of the entire external vulvar region. The edges should be contoured or removed in an artistic fashion instead of the commonly described term amputation. The term amputation seems to insinuate the protruding labia should just be "cut off" in a straight vertical fashion, which does not result in aesthetically pleasing results and can cause pain and discomfort. The procedure should not be completed with this type of "amputation" technique. Time and care should be put into the incision and the excision of the protruding aspect of the labia. It should be removed in a curvilinear fashion at the level or below the level of the labia majora. The amount of tissue removed should be in direct correlation to the patient's desire. Aggressive excision can result in complete amputation resulting in an undesirable result (Figure 116.8). The results of a contouring surgery should be aesthetically pleasing yet address any associated physical dysfunction. Most women state that they do not want their labia minora to protrude beyond the majora and are interested in a smooth, sleek appearance of the external vulva. This was confirmed in a recent study of 550 women who presented for labial reduction surgery at our specialty center in Atlanta. Of the 550 women who were presenting for labial reduction, 97.8% of them desired for their labia minora to be reduced to the level of or below the level of the labia majora [56].

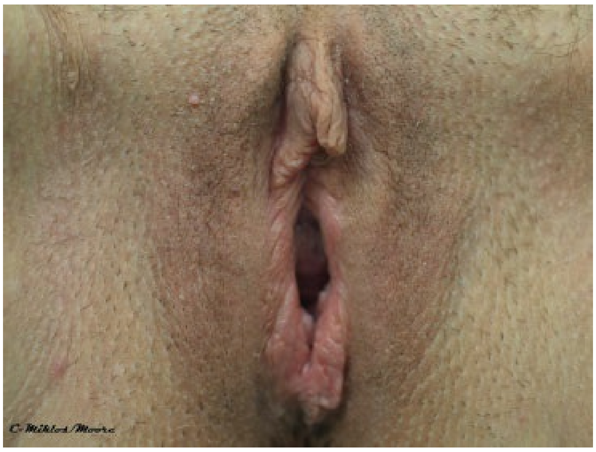

Figure 116.8 Excessive labia minora removed/amputated. (Courtesy of Robert D. Moore and John R. Miklos.)

The authors utilize the wedge resection technique in patients who wish to maintain the darkened skin edges of the labia. The technique was first described in the literature by Alters in 1998, where he utilized the technique on four patients [46]. In this case series, it is suggested that excision or contouring the protuberant edges removes the natural contour and color. Interestingly, many patients do not feel that the darkened skin edges are a normal color but instead the result of aging and hormonal changes. This is no different than the skin discoloration that happens on hands or the areola of the breast. This was also confirmed in a recent study of 550 women presenting for labiaplasty at our center in Atlanta. Of the 238 women, 72% of women felt their skin edges were dark or pigmented and 96% preferred that their skin edges be pink following the procedure [56]. The authors feel the wedge technique is less time consuming and requires less artistic impression; however, it does not address the excess prepuce that is a problem with many women presenting with labial hypertrophy (Figure 116.9).

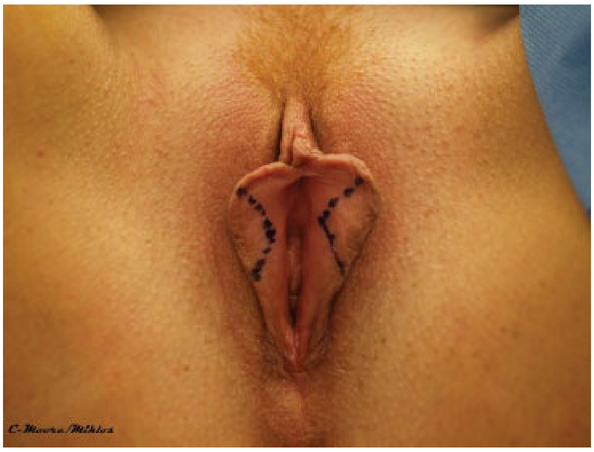

Figure 116.9 Wedge technique. (Courtesy of Robert D. Moore and John R. Miklos.)

Redundant Lateral Prepuce

In our practice, approximately 80% of patients also complain of redundant prepuce when they consult for labia minora reduction (Figure 116.10). This is strictly a cosmetic problem and not a functional problem. We have not had patients complain of symptoms from redundant lateral prepuce except occasionally feeling that it has a negative effect on clitoral sensation. On examination, patients will often point out the lateral excessive tissue, which is adjacent to the clitoral hood bilaterally, or that the clitoral hood is elongated and hangs down a great deal below the majora. If the patient wants to have her labia minora reduced via a contouring technique, often the redundant prepuce will inhibit the surgeon from getting good cosmetic results unless the prepuce redundancy is reduced or removed. The reason why the redundant prepuce becomes an issue is because of its anatomic insertion. The origin of the prepuce starts laterally to the prepuce and then inserts usually at an acute angle into the lateral aspect of the labia minora (Figure 116.10). An excision of the labia minora without addressing the redundant prepuce can result in poor cosmesis (Figure 116.11).

Excess Superior Prepuce Reduction (Clitoral Hood Lift)

As described earlier, we have coined the term “redundant prepuce” in patients who have an extra layer of prepuce *lateral or adjacent* to the clitoral hood. Patients with excess prepuce have excessive prepuce at its normal anatomic position. In other words, the prepuce is in the right spot but there is just an excessive amount of it or an elongation of the clitoral hood itself (Figure 116.12a and b). Excess superior prepuce or clitoral hood elongation may be a purely cosmetic issue, or patients may complain of difficulty accessing the clitoris, thus making clitoral orgasms difficult to achieve. Surgical resection, if done correctly, can bring favorable results for patients with excess prepuce. Performed incorrectly, it can result in hypersensitivity and chronic pain or even severe scar limiting any access to the clitoris.

Labia Majora Reduction

Patients complain of "drooping," "sagging," or "hanging" majora or the majora is just too large and protruding in appearance. Many women state that this skin is very loose and makes the appearance of the external vaginal area appear "old." They are looking for a youthful "plumpness" of the labia majora, without much laxity or wrinkling. The sagging labia majora may be the result of weight gain and weight losses, which seem to be often associated with pregnancy or in patients who have had bariatric surgery. The saggy skin of the labia majora may be the result of stretching during the weight gain, and then with sudden weight loss, the skin hangs because it has lost some of its elasticity. It can also occur due to aging and/or childbearing (Figure 116.13).

Still others complain of enlarged labia majora and on examination do not have sagging skin. These patients tend to have taut skin because it is filled with excessive adipose deposits. This in essence results in lipodystrophy of the labia majora and labia majora hypertrophy. In many cases, women who have had abdominoplasties and/or liposuction of the abdominal region end up with an asymmetrically enlarged mons pubis. This area also in many cases has excess deposits of fatty tissue and, if not reduced at time of abdominoplasty, ends up protruding out or hanging down. These patients often complain they cannot wear tight clothing or they are embarrassed in a swimming garment because they feel as if their vulva and/or mons is protruding. These patients can benefit from liposuction of the mons pubis and labia majora areas (Figure 116.14a and b).

Labia Majora Convergence

Cosmetic surgical patients are very consumer savvy and often are quite specific about their cosmetic desires. Many of our patients will have pictures and/or medical illustrations, which represent their desired cosmetic results. Another common request, we have coined “labia majora convergence” surgery. Patients can have labia majora divergence both anteriorly at the mons pubis or directly anterior to the clitoral hood and posteriorly at the perineum (Figure 116.15a and b). Surgical correction of the divergence results in convergence of both or either the anterior division of posterior aspect of the labia majora.

Combined Vulvar Procedures

Many patients request and ultimately require combined procedures to achieve their desired results. When completing labia majora reduction concomitantly with labia minora reduction, the surgeon needs to be very careful in keeping the incisions separated to prevent the incisions from healing together. Typically, the minora are completed first and then the majora (Figure 116.16a through d).

CONCLUSION

Cosmetic vaginal surgery is a newly emerging frontier in our dynamic and body image–conscious society. Still in its infancy, this discipline will continue to mature and take on a life of its own. Partially spurred by our ever-pervasive process of globalization, the Internet, and the desire to “antiage” and remain youthful in appearance and function, cosmetic vaginal surgery is here to stay. A woman’s desire to enjoy life to its fullest does require a good body image, and *sometimes* a little surgical help might be necessary to help maintain that body image.

117 Urological Complications of Gynecological Surgery

Monica L. Richardson and Craig V. Comiter

During gynecological surgery, the structures of the lower urinary tract are particularly at risk due to the close proximity of the pelvic organs to the ureters and bladder. Therefore, all pelvic surgeons should be familiar with ways to prevent and manage such complications. This chapter focuses on the iatrogenic causes of bladder and ureteral injury, strategies to prevent and recognize them, and management of postoperative repair.

INCIDENCE

The overall rate of urinary tract injury during benign hysterectomy can range between 1% and 4.8% [1–3]. In one large prospective study of more than 830 women, cystotomy at time of total abdominal hysterectomy found with intraoperative cystoscopy occurred in 1.7% of patients [2]. Total vaginal hysterectomy alone had an incidence of 0.4% versus 2.2% if combined with concomitant prolapse procedures [2]. In the same cohort, ureteral injury occurred in 1.7% of total abdominal hysterectomy cases and 2.6% of transvaginal hysterectomy cases [2].

Rates of bladder and ureteral injury are higher with surgery for pelvic organ prolapse and anti-incontinence procedures than benign hysterectomy alone. In patients undergoing benign hysterectomy, Vakili et al. reported a bladder injury rate of 3.6% versus 12.5% in patients undergoing concomitant anti-incontinence procedures [3]. Similarly, the rate of ureteral injury at the time of vaginal surgery for pelvic organ prolapse and anti-incontinence procedures has been reported to be 1.8%–5.1% [3–5].

PREVENTION OF INJURIES

Prior to undergoing gynecological surgery, proper patient selection and preoperative evaluation is vital to minimize the risk of unsuspected anatomic variation and to reduce the risk of surgical injury. Medical history should include obstetric history and records of prior pelvic surgery, radiation, suspected infection, or endometriosis. Any documented anatomic anomalies or urinary tract surgeries should also be reviewed. When indicated, preoperative imaging can be helpful in determining any structural changes secondary to uterine leiomyoma or other potential distorting anatomic conditions. Counseling about the risk of urinary tract injury as well as the sequela of unrecognized injuries should be undertaken prior to surgery and documented in the medical record or consent form.

Universal preplacement of ureteral catheters is not recommended for routine pelvic reconstructive or extirpative surgery. A randomized trial of more than 3000 women without prior pelvic surgery found no difference in the incidences of ureteral injury in those with preplaced ureteral catheters versus not [6]. Ureteral catheters, however, can be helpful in carefully selected women with a history of prior pelvic surgery, known retroperitoneal fibrosis, large uterine leiomyomas, or history of severe endometriosis [7]. Ureteral stents can facilitate identification of the ureters (easier to palpate) and also improve the surgeon’s ability to recognize ureteral injury or transection with obvious visualization of the brightly colored stent.

The surgeon should always identify both ureters throughout the procedure. While familiarity with normal anatomy is vital, it is those cases with abnormal anatomy that pose the highest risk. Intravenous urography or computed tomographic intravenous pyelogram may be considered if a preexisting abnormality is suspected in order to determine the ureteral course. In patients undergoing benign hysterectomy with a normal size uterus, routine utilization of an IVU is not recommended. However, patients with pelvic organ prolapse, especially those with procidentia, may have hydronephrosis prior to prolapse repair. One series of women undergoing surgery for pelvic organ prolapse who had undergone preoperative IVU reported a 7% prevalence of hydronephrosis, 14% of whom had severe dilation [8]. The incidence of hydroureteronephrosis can increase, however, with worsening pelvic prolapse. While ureteral injuries during hysterectomy occur in up to 2.5% of cases [9], routine preoperative IVU has not been shown to reduce the incidence of ureteral injury [8]. Furthermore, some patients may have a significant adverse reaction to the contrast agent, including acute renal injury and anaphylaxis.

Prompt recognition of urinary tract injury aids in the management and prevention of further complications. A properly repaired injury should prevent postoperative ureteral obstruction and ureterovaginal or vesicovaginal fistula formation. The surgeon should be meticulous regarding the inspection of the surgical field, focusing on the bladder base and distal ureters. Routine cystoscopy should always be performed following uterine, bladder, or urethral surgery to rule out associated organ injury and to observe urine efflux per ureteral orifice, thereby ruling out ureteral obstruction. Intravenous indigo carmine can be given to enhance the visualization of ureteral efflux and confirm ureteral patency.

ANATOMY

In order to prevent injury to the lower urinary tract, a surgeon must become very familiar with pelvic anatomy and proximity of the ureter to gynecological structures (Figure 117.1).

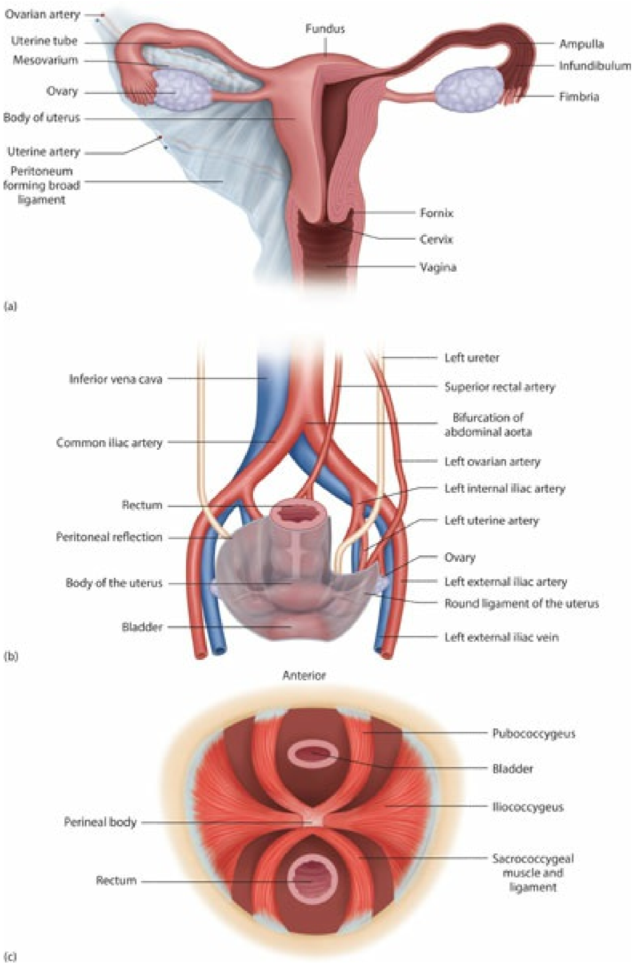

Figure 117.1 Pelvic and vreteral anatony. (a) Uterus. (b) Vaseculature. (c) Pelvic Floor.

The Ureters

Ureters are retroperitoneal tubular structures posterior to the renal artery and vein and run from the renal pelvis to the trigone of the bladder [10]. They are approximately 22–30 cm long and can be injured anywhere along this path [10–12]. The ureter courses anterior to the psoas muscle then anterior to the iliac vessels. The right ureter descends anteriorly over the duodenum and runs lateral to the inferior vena cava [10]. The left ureter travels lateral to the aorta and runs close to the descending and sigmoid colon. As the ureters approach the pelvis, they are crossed anteriorly by the ovarian vessels [10]. The right ureter enters the pelvis by crossing over the external iliac artery, while the left ureter crosses over the common iliac artery. In the middle of the pelvis, the ureter is crossed anteriorly by the uterine artery [13]. Here, it tunnels into the cardinal ligament approximately 1.5–2 cm lateral to the cervix near the internal cervical os and vaginal fornices as it enters in the trigone of the bladder [14]. It is in this area that the ureters are mostly likely to be injured during hysterectomy.

Histologically, the ureter is made of three layers that include an inner layer of transitional epithelium; a middle layer of longitudinal, circular, and smooth muscle; and an outer layer of adventitia [10]. The adventitial layer contains the blood and nerve supply as well as lymphatic drainage from the ureter [10]. The renal, ovarian, and common iliac arteries as well as the aorta all contribute to the blood supply of the ureter [12]. In the abdomen, the ureter derives its blood supply from all small arteries approaching it medially (from the aorta), where the pelvic ureter receives its blood supply from vessels approaching laterally (from the iliac arteries) [12].

The Bladder

The bladder is positioned anterior to the vagina, cervix, and lower uterine segment. The vesicouterine fold/pouch is a reflection of the anterior peritoneum that lies between the dome of the bladder and the lower uterine segment. The bladder base is opposed to the cervix and vagina with the vesicocervical and vesicovaginal fascia. The bladder is typically described as consisting of the dome superior to the trigonal ridge and the base inferiorly [12]. The base contains the trigone, including the ureters, which enter posteriorly, and the urethra, which exits at the most inferior aspect of the bladder [12].

MECHANISMS OF INJURY

The lower urinary tract can be injured in several ways. Direct trauma may include injury to the ureter by transection or clamping. It can also be devascularized or denervated by sharp or blunt dissection, typically when the dissection is carried out (unintentionally) in a subadventitial plane. Thermal injury via electrocautery or other sources of energy such as a harmonic scalpel or laser can also compromise the ureteral vascular supply. Such injuries are more likely to happen during laparoscopic surgery for hysterectomy [15–17] than with transvaginal extirpative surgery or prolapse repair. As bladder or ureteral urinary leakage secondary to thermal injury typically occurs secondary to ureteral wall necrosis, the presentation is usually delayed until several days after surgery. On the other hand, direct injury to the bladder, on the other hand, usually occurs with either laceration to the bladder wall or accidental placement of a suture or staple [18,19]. Unrecognized placement of a permanent suture or metal staple into the bladder wall may initial be asymptomatic. Over time, however, exposure of the foreign body to urine typically leads to stone formation [20]. Presentation can relate secondarily to pain, recurrent urinary tract infection, or even obstructive uropathy. Following surgery, an unrecognized lower urinary tract injury can lead to infection, abscess or hematoma formation, or edema and even frank ureteral obstruction [21]. Injury to the bladder that communicates with a vaginal incision often presents as "extraurethral" urinary leakage in the form of a genitourinary fistula [22].

SLING SURGERY

Midurethral synthetic sling surgery is currently recognized as the gold standard surgery for the treatment of female stress urinary incontinence [23]. The most common complication related to operative technique is bladder perforation during needle passage through the endopelvic fascia (from below) or through the retropubic space (from above). Reported rates of bladder perforation during midurethral sling placement range from 4% to 9% [24]. If recognized intraoperatively, bladder perforation is usually inconsequential as long as the trocar is removed and replaced outside the bladder. Urethral injury is much less common than is bladder puncture, with a recent case series documenting less than 1.0% risk [25]. Transobturator slings have been reported to have lower rates of bladder (0%–1%) and urethral injury (0.1%) [26–28] than do retropubic slings. Bladder injuries occur more often in women undergoing concomitant vaginal surgery [29].

Injury of the urethra or bladder during the vaginal dissection is best avoided by placing a urethral catheter (which drains the bladder and also allows for easy palpation of the urethra and bladder neck) by infiltrating the anterior vaginal wall with lidocaine or saline with 1:100,000 epinephrine solution (which elevated the vaginal wall from the underlying periurethral and perivesical fasciae) and by using sharp dissection rather than electrocautery or blunt dissection. The surgeon should strive to always stay superficial to the perivesical and periurethral fasciae in order to avoid injury to the urethra and bladder. Bladder perforation during needle passage is best avoided by emptying the bladder and providing finger guidance during needle passage through the retropubic space (which is not routinely done with percutaneous vaginal tape procedures for stress urinary incontinence). Following needle passage, the surgeon must always perform cystourethroscopy. If bladder perforation is appreciated, the needles should be withdrawn and then repassed more laterally. Care must be taken not to pass the needles too far laterally, which can risk injury to the external iliac vein. Following accidental bladder puncture with a small midurethral sling trocar, prolonged catheter drainage is not necessary.

If the bladder is injured during the dissection between the vaginal epithelium and pubocervical fascia, it should be immediately repaired. Transvaginal repair should be attempted if possible, closing the bladder in two layers using self-absorbing suture. If exposure is suboptimal, it may be necessary to approach the bladder transabdominally, and it may even be necessary to approach the posterior bladder wall through an intentional anterior cystotomy. Following repair of the incidental and the intentional cystotomies, catheter drainage is recommended for 1–2 weeks. Cystography is the most definitive method to determine adequate healing prior to catheter removal.

Bleeding may occur during the vaginal dissection, during perforation of the retropubic space, or during needle passage. Blood loss exceeding 500 cc or the need for blood transfusion has been reported to range from 1.4% to 2.5% [30,31]. Bleeding upon entry into the retropubic space can be difficult to manage, as it can be quite difficult to expose and ligate the perivesical venous plexus. An attempt at suture ligation is indicated, followed by packing with a laparotomy pad, or transvaginal insertion of a sponge-wrapped catheter with a 30 cc balloon into the retropubic space [32]. If bleeding is adequately controlled, then the surgery should be completed by releasing the sling from its plastic sheaths and positioned under the midurethra in a tension-free manner. The vaginal epithelium should be closed in watertight fashion and the vagina packed with gauze. Ultimately, persistent heavy bleeding may require abdominal incision and an open retropubic exploration and suture ligation. Major bleeding during needle passage may signify external iliac or femoral vessel injury, which is usually caused by exaggerated flexion of the thigh and excessively lateral passage of the needle. Symptomatic retropubic hematoma and vaginal or labial hematoma occurs with a frequency of 1%–5% [33]. Management is typically conservative, with ice packs, rest, and observation.

PROLAPSE SURGERY

During surgery for pelvic organ prolapse, the bladder can be difficult to differentiate among other prolapsed organs (such as uterine prolapse, enterocele, or even high rectocele) due to distorted anatomy. Cystotomy can be avoided by infiltrating the anterior vaginal wall with 1:100,000 epinephrine solution, using sharp dissection superficial to the pubocervical fascia, and keeping the bladder empty. Bleeding during vaginal dissection should be managed with temporary packing or with suture ligation rather than electrocautery in order to minimize the risk of vesicovaginal fistula formation. An additional way to aid in distinguishing the bladder from an enterocele or high rectocele in the setting of high-grade multicompartment pelvic organ prolapse is the “cystoscopic light test” that illuminates the urinary bladder, differentiating a large cystocele from a high rectocele or enterocele [34] (see Figure 117.2).

The bladder can be injured at the dome or above or below the trigone. If cystotomy is suspected, the bladder should be filled with blue-colored fluid to visualize any extravasation or leakage. Specific surgical management depends on the size of the injury. An injury that is less than 2 mm typically can be followed by Foley catheter drainage for 1 week and expectant management. Injuries that are greater than 2 mm but less than 1 cm either can be managed expectantly with a Foley catheter for 7 days or can be repaired. Bladder lacerations or defects greater than 1 cm should be surgically repaired in two layers—a mucosal and separate detrusor layer, performed in a watertight fashion using a self-absorbing suture. Repair should be attempted only after adequate tissue mobilization and debridement has been accomplished [35] in order to allow a watertight and tension-free repair. If more than one bladder wall injury is found, it is often easier to connect the lacerations into one large defect. It is vital to document the integrity of both ureters after cystotomy repair via direct or cystoscopic visualization of urinary efflux, as the risk of concomitant ureteral injury is as high as 10% in cases of bladder injury [36]. Extension of the cystotomy anteriorly may be necessary in order to properly visualize the bladder trigone. This allows for visualization of urinary efflux from the ureteral orifices. Intravenous indigo carmine or methylene blue should be given in order to properly visualize ureteral efflux. If efflux is not demonstrated, or if high suspicion remains, retrograde ureteral stents should be passed over a floppy-tipped wire, ideally with fluoroscopic guidance. The patient should be transferred to a fluoroscopy-ready table prior to attempting passage of a guidewire, ureteral stent, or ureteroscope, thereby minimizing the risk of additional iatrogenic ureteral injury.

A repair should only be performed after all surgery is complete, since other injuries may occur in the setting of abnormal anatomy. The cystotomy should be closed in two layers with self-absorbing suture. When the repair is completed, the closure should be tested to see if it is watertight by instilling colored fluid into the bladder catheter.

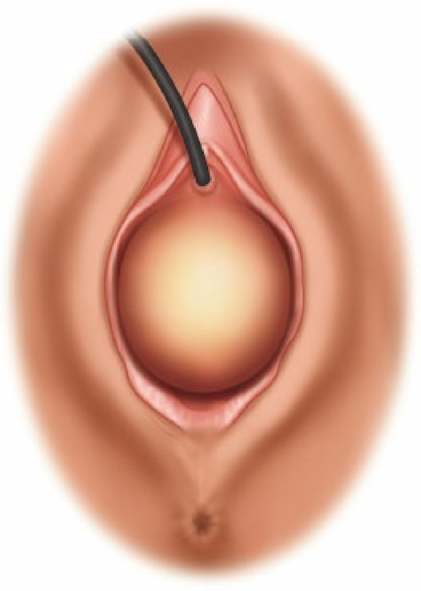

Figure 117.2 The “cystoscopic light test.”

With significant anterior wall prolapse, the trigone of the bladder can be displaced inferiorly and anteriorly, increasing the risk of ureteral occlusion during anterior wall repair. Ureteral injury can happen in prolapse repair such as cystocele repair, enterocele repair, and vaginal vault suspensions. In prolapse repairs, ureteral injury should always be recognized and remedied intraoperatively. Rates of ureteral injury have been reported to range from 1% to 11% during vaginal vault suspensions, with highest rates during uterosacral ligament suspensions [37]. Therefore, cystourethroscopy is absolutely indicated and visualization of urine efflux should be observed from both ureteral orifices. Difficulty visualizing efflux may be overcome by administration of intravenous indigo carmine and fluid challenge. If there is no efflux from the ureter, the surgeon should consider removing suspension sutures on that side as ureteral kinking is the most common cause of obstruction. Alternatively, the surgeon can attempt passage (and then removal) of a ureteral stent. Inability to pass a stent implies ureteral ligation and requires removal of the offending sutures, typically those sutures involving the cardinal ligament or posterior pubocervical fascia. Subsequent confirmation of urinary efflux should suffice, without the need for further evaluation or treatment. If a ureteral jet is not visualized, a surgeon with experience with urinary tract injury should be consulted intraoperatively. Retrograde pyelography and attempted retrograde placement of a ureteral stent are indicated. If there is doubt regarding the integrity of the ureter, an indwelling double-J ureteral stent should be left in place for 2 weeks.

If the closure is tenuous, interposition of adjacent vascularized tissue such as a labial fat pad (omental flap in abdominal surgery) between the cystotomy repair and the vagina is recommended to reduce the risk of fistulization [38]. The purpose of this flap often called a Martius flap is to introduce a new blood supply and separate the bladder and vaginal suture lines to obliterate dead space and protect from vesicovaginal fistula formation. The bladder can reepithelialize as early as 72 hours and regains its normal strength in approximately 21 days [39,40].

The bladder should be drained continuously for 2 weeks, with catheter removal following cystographic confirmation of complete healing. A proper cystogram should include retrograde filling of the bladder to at least 300 mL, as studies have shown false-negative results at lower volumes. While CT cystogram includes a multiplanar view, plain cystography must include a scout film prior to filling, an anterior/posterior film with a full bladder, and postdrainage view that can visualize any posteriorly directed extravasation that can be hidden by the full bladder.

HYSTERECTOMY

Injury to the bladder can occur at any time during vaginal or abdominal hysterectomy, but is particularly at risk while dissecting the bladder away from the lower uterus, cervix, and upper vagina during hysterectomy. This tissue plane can be straightforward to find in the absence of prior surgery, but becomes more challenging with a history of previous surgery such as cesarean section. Filling the bladder with normal saline can facilitate identification of the vesicouterine plane and help to minimize the risk of injury to the bladder wall during dissection. Sharp dissection is preferred, with avoidance of electrocautery near the bladder, thereby eliminating the risk of thermal injury.

If a bladder injury is suspected, an intraoperative test may be helpful, which includes instillation of saline or methylene blue, diluted in 200–300 cc on normal saline into the bladder. Extravasation of saline or urine into the abdomen confirms the presence of a cystotomy. Another useful sign is gas distention of the urinary drainage bag due to insufflation of CO_2 into the injured bladder during laparoscopy [21].

During benign gynecological surgery, the ureter can be injured along its path from the renal pelvis to the trigone of the bladder. A common site of ureteral injury during abdominal hysterectomy is at the pelvic brim where the ureter lies beneath the infundibulopelvic ligament [13]. Here, the surgeon should make a conscious decision to visualize the course of the ureter and ensure that it is not included in the infundibulopelvic pedicle. A second common site of injury (at risk during uterosacral ligament suspension) is the lateral pelvic side wall next to the uterosacral ligaments, often thickened in cases of endometriosis [41]. A third location (injury can occur during total hysterectomy) is at the level of the cervical internal os, where the uterine artery crosses the ureter over the iliac arteries, also known as the cardinal ligament [13,14]. Additionally, the ureter can be compromised (during excision of the cervix and vaginal cuff or even during closure of the vaginal cuff) where it passes anteriorly and lateral to the fornix of the vagina just as it enters the trigone of the bladder [13].

In order to best avoid ureteral injury during hysterectomy, the surgeon should identify the ureter at each step in the procedure. Common sites of injury that merit extra caution include ligation of ovarian vessels and uterine vessels and with closure of the vaginal cuff. Isolating the uterine vessels with meticulous dissection aids in excluding the ureter from the vascular clamp. When placing any clamp, the surgeons should only include vessels and must check that the ureter is excluded before applying the clamp. Once the uterine vessels are ligated, the ureter should then fall inferior and lateral to the pedicle. Subsequent bites should only be taken medial to this pedicle to avoid any ureteral injury. In addition, care should be taken to mobilize the bladder off the anterior cervix allowing the ureters to descend with the bladder.

If urinary tract injury is recognized intraoperatively, it should be immediately repaired in order to prevent infection, urinary leakage, or risk of fistula formation. If the surgeon is not comfortable repairing the injury, consultation with an experienced female pelvic medicine and reconstructive surgeon is recommended. All patients undergoing gynecological surgery should have sterile urine and should receive surgical site infection prophylaxis. Additional postoperative antibiotics are not indicated, even if an injury has occurred. There is a general lack of data to suggest any advantage to additional antibiotic coverage following repair of intraoperative lower urinary tract injury. During the postoperative period, fever, chemical peritonitis, abdominal or flank pain, leukocytosis, anuria, urinary leakage from wound, hydronephrosis, or hematuria may signify bladder or ureteral injury.

URETERAL REPAIR

If ureteral ligation or injury is found, and retrograde stent placement is not successful, intraoperative repair will be necessary. With injuries to the distal ureter, ureteroneocystostomy is typically favored over end-to-end ureteroureterostomy repair. Ureteroneocystostomy bypasses the site of injury and allows for straightforward proximal dissection and excision of any devascularized segment, eliminating any need for difficult dissection of the distal ureter [42]. Success rates are close to 100% with ureteral reimplantation [43–45], and the risk of ureteral obstruction is minimized by avoiding an antirefluxing anastomosis. On the other hand, ureteroureterostomy has an unacceptably high rate of stricture, due to embarrassment of the distal ureteral blood supply that typically occurs with the injury.

The location of the injury and the degree of ureteral and bladder mobility will dictate the method of implantation. While a distal ureteral injury is amenable to simple ureteral reimplantation, in the setting of a more proximal injury, a ureteroneocystostomy may be aided by a psoas bladder hitch to minimize anastomotic tension [44]. A Boari flap replacement of the distal ureter is indicated when the obstructive segment lies even more proximally [45,46]. With high or long ureteral strictures, a more complex reconstruction such as transureteroureterostomy, renal descensus, renal autotransplantation, or ileoureterocystoplasty may be necessary. Nephrectomy should be undertaken as a last resort and only in the setting of a normal contralateral renal unit [45,46]. In the rare instance of a midureteral or proximal ureteral transection, ureteroureterostomy would be preferred, but only if the anastomosis can be widely spatulated and tension-free.

Indwelling double pigtail stents are placed and usually left in place for a minimum of 6 weeks. Closed suction drains should be left in place after repairs and monitored for urine leakage. Suprapubic catheter placement is not necessary, in most cases. Foley catheter placement is indicated for 1–2 weeks if a cystotomy is necessary. Postoperative antibiotics are typically not indicated if the preoperative urinalysis was negative. Anticholinergic medication may help to reduce complaints of painful bladder spasm.

REPAIR OF URETEROVAGINAL FISTULA

The most common cause of uterovaginal fistula is total abdominal hysterectomy for either benign or malignant disease [47]. Fistulization occurs when a ureteral leak persists and the urinoma establishes a communication with the vaginal cuff. Any unexplained abdominal or flank pain or findings of costovertebral angle tenderness should alert the surgeon to the possibility of a ureteral injury. However, if there is no significant ureteral obstruction, and just extravasation, there may be no symptoms before urinary incontinence occurs. The typical presentation is one of sudden onset leakage from the vagina 1 to 4 weeks postoperatively. The patient additionally voids per urethra since there is otherwise normal filling of the bladder from the intact contralateral ureter.

In a female with vaginal leakage after pelvic surgery, a double dye test may differentiate between vesicovaginal and ureterovaginal fistulae [48]. The vagina is packed and methylene blue is given intravenously, while red carmine is instilled intravesically. The vaginal pack will stain red if a vesicovaginal fistula is present and blue if a ureterovaginal fistula is present. Alternatively, oral pyridium can be given several hours prior to bladder instillation with methylene blue, with orange staining or blue staining confirming a ureterovaginal or vesicovaginal fistula, respectively. An IVU may demonstrate varying degrees of hydronephrosis, or even a silent kidney [49]. If IVU or CT urogram is nondiagnostic, a retrograde ureterogram should demonstrate the location and magnitude of the fistula as well as any ureteral obstruction.

Management should urgently treat any ureteral obstruction with an internal ureteral stent if possible, or a percutaneous nephrostomy, with definitive repair via open or laparoscopic surgical repair, or even nephrectomy. Controversy exists regarding timing of repair, with some surgeons performing immediate, while others advocate early upper tract drainage followed be delayed ureteral repair [50–55]. While the surgery may be somewhat less cumbersome by waiting several months for inflammation to subside, the results for early versus delayed repair are comparable [56].

Retrograde ureteropyelography is recommended and may be diagnostic and therapeutic if a stent can be passed. If a ureteral catheter cannot be passed, the diagnosis of a distal obstruction remains and spontaneous healing is unlikely. Should a stent be placed to bypass the fistula, spontaneous healing is likely, but may still require further intervention [57,58].

If retrograde ureteral stenting is unsuccessful, antegrade percutaneous nephrostomy is recommended. With decompression of the kidney, the obstruction is relieved, and access for antegrade ureteral stenting is achieved. If spontaneous healing does not occur, an attempt at anterograde stenting is recommended. Once a stent is placed, there is a 50%–70% chance that the ureterovaginal fistula will heal without the need for open surgical intervention [57,58]. Because of the chance of ureteral structuring, close follow-up is needed.

If neither anterograde nor retrograde ureteral access is successful, open surgical repair is indicated.

Early surgical repair may be undertaken if there is no significant urosepsis and if renal function is relatively preserved. See Chapter 10.3 for description of ureteral reimplantation techniques.

CONCLUSIONS

Lower urinary tract injury during gynecological surgery is a well-known complication but, with careful preparation and attention to proper surgical technique, can be prevented in the vast majority of cases. Meticulous surgical technique and familiarity with pelvic anatomy are essential for every gynecological surgery. Intraoperative discovery of bladder or ureteral injury can be accomplished with careful inspection, cystoscopy, or from concern due to proximity of suture, ligation, or thermal use. Repair should always be attempted at time of recognition to decrease any future morbidity, complications, and urogenital fistula. If an injury is found, a urologist or urogynecologist with experience in FPMRS procedures should be consulted for repair. Patients who present postoperatively with fever, abdominal or flank pain, vomiting, ileus, low urine output or leakage of urine from the vagina, or incision raise concern for lower urinary tract injury. Repair of ureteral injuries should start with an attempt at retrograde or antegrade stenting, and if that fails, advanced surgical repair or reconstruction may be necessary.

Standardization of Terminology

Dirk De Ridder and Marcus J. Drake

INTRODUCTION

We could not imagine a scientific world without standards and definitions. Clearly, this applies in the clinical sciences, where widely accepted definitions of signs, conditions, and diagnosis are essential. Worldwide agreement on standards is needed to allow exchange of data, ideas, and patient information. Although we might think that definitions cannot be changed anymore once they have been defined, we must realize that making or updating of definitions and standards at regular intervals is necessary to refine our understanding of the underlying concepts. With scientific progress, our understanding improves steadily and our definitions can be refined. Even seemingly "unvariable" standard units are subject to change, as is illustrated by this story by J.R. Chong on the definition of the kilogram [1]:

> 40 feet underground, in a secured and temperature and humidity controlled vault lies kilogram number 20. It consists of a platinum and iridium cylinder that is the perfect embodiment of the kilogram. The enlightenment and French revolution in the late 18th century spurred to the idea of standardization. People could only be free if they could calculate for themselves the weight and cost of things they bought. The French government created the kilogram in 1795 defining it as the mass of a liter of distilled water at a temperature of melting ice. A century later the treaty of the meter established the kilogram as an international standard. The foundation of the standard was a cylinder of 90% platinum and 10% iridium created in 1878 that became known as Le Grand K. Forty copies are made and distributed to governments around the world. Another 50 were made later. About every 50 years, the national prototypes are returned to the headquarters of the international bureau of weights and measures in France to be compared with the international prototype. During the first major comparison about 1950, scientists noticed discrepancies between the average mass of Le Grand K and its copies. At the last major kilogram comparison about 1990, some of the copies had gained as much as 132 mcg. A few had lost up to 665 mcg. There was no way to tell what was changing Le Grand K or its copies. This variability has impact on the world of precision physics which uses the kilogram as the basis for their standard measurements, from the force of gravity to the Ampere or Planck's constant, the omnipresent figure of quantum mechanics.
>
> In essence no one really knows today what the kilogram is. The kilogram has kicked off an international race to redefine the measure. Instead of using an object, scientists are searching for some property of nature or scientific constant, such as the vibrations of the cesium atom to define the second. The kilogram is the last of seven base units in international system of units that are still based on a physical object; a remnant of the era before relativity and quantum mechanics transformed the understanding of the universe. In fact at least 6 kg copies have been lost or damaged over the years. Two ideas have emerged as the leading contenders to redefine the kilogram. One involves counting the trillion trillion atoms in the most perfect silicon sphere ever made. The other idea was to measure the electrical current necessary to balance a 1 kg weight against earth's gravity. But serious complications have occurred in both approaches.

This story illustrates the relativity of so-called fixed standards and definitions. They should rather be seen as concepts under continuous evaluation and refinement.

Applying this to the terminology of the lower urinary tract, it becomes obvious that clinical definitions will potentially require modification as well. When the International Continence Society (ICS) produced the 2002 report on definitions of lower urinary tract function, some criticisms were expressed, despite the fact that these definitions were a product of an intensive consensus process [2]. Over subsequent years, it was increasingly clear that the 2002 definition of overactive bladder (OAB) has advanced our understanding and clinical effectiveness considerably. Nonetheless, a point will come where this terminology will benefit from review on the basis of increasing evidence from the literature

[3–5].

The selection of a good standard to compare new standards or definitions against is of utmost importance. While in the past, urodynamic findings were seen as the gold standard, recently, patient-centered or clinical observations have become the more evident yardstick [6]. This is illustrated by a study by Irwin et al., where the current ICS definitions of the lower urinary tract symptoms (LUTS) and currently used alternative definitions of these LUTS were compared [7]. This study noted that the ICS definitions for increased daytime frequency (the subject's perception of urinating too often by day) and for nocturia adequately described bladder symptoms within the OAB population when assessed by the level of symptom bother. In this population, the predominant manifestation of OAB was a combination of urgency with one or more other OAB symptoms. The nocturia definition adequately described the bladder symptoms in the OAB population. However, bother increased dramatically when nocturia was defined as two or more episodes per night. Also, voiding and postmicturition LUTS are common in those with the OAB, which contrasts with the prevailing perception that individuals with OAB symptoms predominantly experience storage LUTS. This study suggests that conclusions drawn from the ICS definitions from 2002 and assumptions based on these definitions might not be entirely true in a real-life world. Care must be taken with the interpretation of definitions.

In addition, the evidence base can provide important developments that can affect the appropriateness of established definitions. For example, the definition of nocturnal polyuria may better be based on nocturnal urine production or nocturnal voided volumes rather than on a diurnal urine production pattern [8].

In a study by Brubaker et al. including 655 participants, the proportion of women with mixed urinary incontinence (MUI) varied from 8.3% to 93.3%, depending on the MUI definition [9].

The current definitions may not adequately categorize clinically relevant urinary incontinence subgroups. For research reporting, MUI subcomponents of stress and urge urinary incontinence should be described separately rather than as a single dimension.

Another example is the ICS definition on painful bladder. Depending on the comparator standard, the outcome may vary considerably. Warren et al. showed that the ICS definition categorized 66% of 138 patients whom study investigators and caregivers had diagnosed as having interstitial cystitis/painful bladder syndrome (IC/PBS) [10]. Furthermore, those who met the ICS definition did not differ in important ways from those who did not. These findings were taken to suggest that the ICS definition may not be sufficiently sensitive. The definition of PBS/IC or bladder pain syndrome (PBS) is now subject to vigorous debate [11]. The ICS will issue a new standardization on terminology for chronic pelvic pain in 2015.

Thus, defining and standardizing are very important to allow exchange of clinical and scientific data. Given their central importance, the development of such standards needs to follow rigorous standards of evidence-based medicine and governance.

THE MAKING OF DEFINITIONS AND STANDARDS

Several processes exist to create standards or definitions, ranging from a simple expert consensus meeting to a structured Delphi process. When an international standard is produced, the process by which this was done should be transparent and explicitly mentioned in the publication.

The international standardization office is a well-known international organization that creates standards for many industrial applications. Recently, their methodology has also been implemented in hospital logistic processes and even in clinical settings. Their guidelines for creating a new standard include some key steps:

1. *Proposal stage*: The first step in the development of a new standard is to confirm the clinical need. This could be done by a working or interest group that submits a proposal to a relevant committee. If the committee accepts this proposal and if a sufficient number of people declare their commitment to participate, the next steps can follow.
2. *Preparatory stage*: A working group of experts is set up under the leadership of a chairperson. This group will prepare a working draft. Successive iterations of the draft may be considered until the working group is satisfied that it has developed the best technical solution for the problem being addressed.
3. *Committee stage*: As soon as a first draft is available, it will be registered by the central office. It

is then forwarded to independent external and internal experts. Successive working drafts may be considered until consensus is reached on the technical content. Once consensus has been attained, the text is presented as a draft standard.

4. *Enquiry stage*: The draft standard document is circulated to all members for commenting within a defined time period. Criteria for acceptation can be set, e.g., a proportion of votes needed. If the approval criteria are not met, the text is returned to the committee for further study and revision. The revised version can then again be circulated until consensus is reached.
5. *Approval stage*: The final draft is circulated to all members for a final yes or no vote. Criteria for acceptance or rejection can be defined. If technical comments are received during this period, they are no longer considered at this stage, but registered for consideration during a future revision of the standard text.
6. *Publication stage*: Once the final draft has been approved, only minor editorial changes, if and where necessary, are introduced into the final text. The final text is sent to the international peer-reviewed journal of choice and can then be referred to as the new standard.
7. *Review of international standards*: Standardization documents need to be reviewed over time to ensure they remain contemporaneous and consistent with the evidence base.

This cycle of standardization is widely accepted within industry and quality control organizations, but has only recently been adopted into clinical medicine. It has now been adapted for use as the basis of ICS standardizations [12].

WHAT IS CONSENSUS?

Currently, most clinical standards are based on consensus processes, usually governed by experts in the field of interest. The selection of the experts is not always transparent, and the way meetings are held is likewise usually not transparent and not really described in resulting publications. Several types of bias might affect the outcome of this type of approach.

There are several types of consensus methods that can be used to explicate the judgmental approach that is often needed in clinical and diagnostic situations where no definitive standard exists [13]:

1. *Interactive or consensus groups*: These techniques are the most informal. They are unstructured, with little direction coming from a group leader. As such, this technique is highly dependent on the motivation and personalities of the involved participants. Participants generate their own discussions around the issues of interest and proceed as they see fit. This process is particularly at risk of being dominated or steered by one or two opinion leaders or strong personalities within the group. Group dynamics are sometimes difficult to control and they may influence the outcome of the discussion.
2. *Nominal group techniques*: Participants in the group privately generate a list of their own ideas about the topic or questions of interest. In the next phase, participants share their ideas with the rest of the group, with ideas being recorded for the whole group to refer back to at a later point. After everyone's ideas are presented, a focused discussion is led by the facilitator to clarify issues and ideas. The final phase is for participants to rank or rate each item that was generated. This step is again done individually, without further group discussion. This method allows for each individual to have the same degree of input into the outcome, while still allowing for a face-to-face discussion.
3. *Delphi technique*: The Delphi technique was originally developed in the 1950s by the RAND Corporation as a research technique to gather expert opinion in a systematic way. This process has the following four attributes: (i) anonymity, (ii) iteration with control feedback, (iii) statistical group response, and (iv) expert input. Using this process, experts are polled individually and anonymously by a self-administered questionnaire completed by mail or e-mail. The Delphi technique progresses iteratively, with repeated questionnaire administration after feedback from the preceding round. After each round, information and responses from the questionnaire are tabulated at the coordinating center and anonymously provided as feedback to the entire group as part of the subsequent round's questionnaire. The Delphi is complete after there has been a convergence of opinion to a predefined level of agreement or after a certain number of iterations have been completed (usually 3 or 4). Cronbach's α can be used to assess

the variability among the responders.
4. *NIH process*: In this method, the members of the consensus panel act as a jury and debate on facts presented to them by a group of content experts.

After the formal presentation phase is over, members of the jury meet to discuss a topic of interest and draft a consensus document, often addressing a number of predefined questions put to them by the scientific organizing committee of the conference.

After this document is drafted, the findings of the jury are presented, and often further discussion with experts occurs, either in person or by e-mail after the symposium. The final phase of this process is a publication of the final consensus statement.

This process attempts to avoid the biases inherent to experts in the many fields where controversies exist. The disadvantage of this process, however, also lies in the lack of content expertise among the panel. Because of this, the validity of the recommendations may suffer and the acceptance by opinion leaders in the scientific committee community may be diminished.

There have been no studies comparing the results of using different consensus methods to address a particular question. In fact, it is probably not the choice of an individual technique but the way in which any of these techniques is applied that matters most. Key principles are as follows:

1. An explicit and transparent method for recruiting expert participants with disclosure of conflicts of interest
2. A comprehensive data-driven approach to inform item generation and production
3. Limiting the opportunity for strong personalities with firmly held convictions to have undue influence
4. The use of thresholds for the agreement or consensus
5. A process for facilitating ongoing iterative improvements in the consensus results

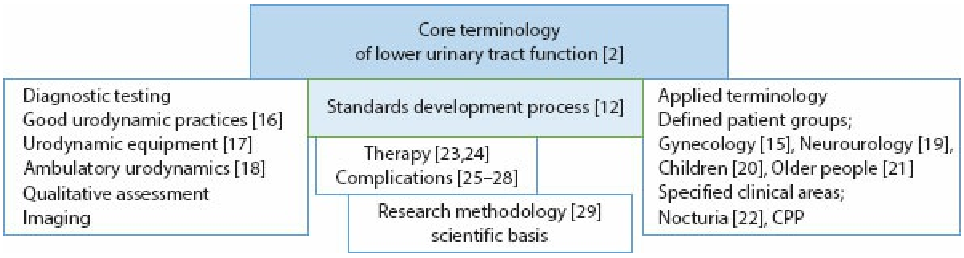
CONFOUNDING FACTORS

Many collective decision-making processes must balance individual preferences and incentives with the need for collective unity. Psychological research has established certain patterns of behavior in this context [14]. Behavior such as stubbornness, the presence of outlying individuals, or the awareness of opposing incentives apparently improved the collective performance of the entire group. The preferences of minorities seemed to win consistently in these experiments. The results of this kind of experiment may help us to avoid or control biases induced by group dynamics. Approaches to managing group dynamics derived from these experiments are potentially very beneficial.

UPDATING STANDARDS

Progressive advances in knowledge and clinical practice and the necessary adaptations of health economies to cope with new developments mean that standards have to respond to remain relevant. In the field of gynecology, the revision of the standardization of terminology of lower urinary tract function [15] is just such a development.

A modular approach is a realistic way forward, where the “core terminology” is the backbone for several related modules (Figure A.1). This core terminology should define the key concepts, while the modules should define or standardize specific applications of the core terminology. Applied to the lower urinary tract, the core terminology could exist of definitions of incontinence and symptoms, pelvic organ anatomy, etc., while modules could apply this to patient groups (neurological disease, children, the elderly) or could apply this to technical examinations (e.g., urodynamics, imaging techniques) and the relevant basic science models. This approach allows for a dynamic set of standards and is central to the ICS approach (http://www.ics.org/Documents/Documents.aspx?FolderID=189).



Core terminology
of lower urinary tract function [2]
Diagnostic testing
Good urodynamic practices [16]
Urodynamic equipment [17]
Ambulatory urodynamics [18]
Qualitative assessment
Imaging
Standards development process [12]
Therapy [23,24]
Complications [25–28]
Research methodology [29]
scientific basis
Applied terminology
Defined patient groups;
Gynecology [15], Neurourology [19],
Children [20], Older people [21]
Specified clinical areas;
Nocturia [22], CPP

Figure A.1 A modular approach to terminology in the clinical and scientific field of urinary tract function and dysfunction espoused by the International Continence Society. CPP, chronic pelvic pain.

CONCLUSION

At this point in time, standardization and terminology definitions in clinical medicine are often designed by some form of consensus process. Scientific societies should invest in further professionalization of these processes within their society. In other words, “standardization should be standardized.”

Appendix B

The Standardization of Terminology of Lower Urinary Tract Function: Report from the Standardization Subcommittee of the International Continence Society*

Paul Abrams, Linda Cardozo, Magnus Fall, Derek Griffiths, Peter F.W.M. Rosier, Ulf Ulmsten, Philip van Kerrebroeck, Arne Victor, and Alan J. Wein

INTRODUCTION

This report presents definitions of the symptoms, signs, urodynamic observations, and conditions associated with lower urinary tract dysfunction (LUTD) and urodynamic studies (UDS) for use in all patient groups from children to the elderly.

The definitions restate or update those presented in previous International Continence Society (ICS) Standardisation of Terminology reports [1–18] and those recently published on urethral function [10] and nocturia [16]. The published ICS report on the technical aspects of urodynamic equipment [13] is complemented by the new ICS report on urodynamic practice [15]. In addition, there are four published ICS outcome reports [5,9,11,12].

New or changed definitions are all indicated; however, recommendations concerning technique are not included in the main text of this report.

The definitions have been written to be compatible with the WHO publication International Classification of Functioning, Disability and Health-2 (ICIDH-2) published in 2001, and the International Classification of Diseases-10 (ICD-10). As far as possible, the definitions are descriptive of observations, without implying underlying assumptions that may later prove to be incorrect or incomplete. By following this principle, the ICS aims to facilitate comparison of results and enable effective communication by investigators who use urodynamic methods. This report restates the ICS principle that symptoms, signs, and conditions are separate categories and adds a category of urodynamic observations. In addition, terminology related to therapies is included [3].

When a reference is made to the whole anatomic organ the vesica urinaria, the correct term is the bladder. When the smooth muscle structure known as the m. detrusor urinae is being discussed, then the correct term is detrusor.

It is suggested that acknowledgment of these standards in written publications be indicated by a footnote to the section “Methods and Materials” or its equivalent, to read as follows:

> Methods, definitions, and units conform to the standards recommended by the ICS, except where specifically noted.

The report covers the following areas.

LOWER URINARY TRACT SYMPTOMS

Symptoms are the subjective indicator of a disease or change in condition as perceived by the patient, carrier, or partner and may lead him or her to seek help from health-care professionals. (NEW)

Symptoms may either be volunteered or described during the patient interview. They are usually qualitative. In general, LUTS cannot be used to make a definitive diagnosis. LUTS can also indicate pathologies other than LUTD, such as urinary infection.

SIGNS SUGGESTIVE OF LUTD

Signs are observed by the physician, including simple means to verify symptoms and quantify them.

(NEW)

For example, a classic sign is the observation of leakage on coughing. Observations from frequency volume charts, pad tests, and validated symptom and quality of life questionnaires are examples of other instruments that can be used to verify and quantify symptoms.

URODYNAMIC OBSERVATIONS

Urodynamic observations are observations made during UDS. (NEW)

For example, an involuntary detrusor contraction (detrusor overactivity) is a urodynamic observation. In general, a urodynamic observation may have a number of possible underlying causes and does not represent a definitive diagnosis of a disease or condition and may occur with a variety of symptoms and signs or in the absence of any symptoms or signs.

CONDITIONS

Conditions are defined by the presence of urodynamic observations associated with characteristic symptoms or signs and/or nonurodynamic evidence of relevant pathological processes. (NEW)

TREATMENT

Treatment for LUTD: These definitions are from the 7th ICS report on lower urinary tract rehabilitation techniques [3].

LOWER URINARY TRACT SYMPTOMS

LUTSs are defined from the individual's perspective, who is usually, but not necessarily, a patient within the healthcare system. Symptoms are either volunteered by, or elicited from, the individual or may be described by the individual's caregiver.

LUTSs are divided into three groups: storage, voiding, and postmicturition symptoms.

Storage Symptoms

Storage symptoms are experienced during the storage phase of the bladder and include daytime frequency and nocturia: (NEW)

- *Increased daytime frequency* is the complaint by the patient who considers that he or she voids too often by day. (NEW) This term is equivalent to pollakisuria used in many countries.
- *Nocturia* is the complaint that the individual has to wake at night one or more times to void. (NEW)[*]
- *Urgency* is the complaint of a sudden compelling desire to pass urine, which is difficult to defer. (CHANGED)
- *Urinary incontinence* is the complaint of any involuntary leakage of urine. (NEW)[†]

In each specific circumstance, urinary incontinence should be further described by specifying relevant factors such as type, frequency, severity, precipitating factors, social impact, effect on hygiene and quality of life, the measures used to contain the leakage, and whether or not the individual seeks or desires help because of urinary incontinence.[‡]

Urinary leakage may need to be distinguished from sweating or vaginal discharge:

- *Stress urinary incontinence* is the complaint of involuntary leakage on effort or exertion or on sneezing or coughing. (CHANGED)[§]
- *Urge urinary incontinence* is the complaint of involuntary leakage accompanied by or immediately preceded by urgency. (CHANGED)[¶]
- *Mixed urinary incontinence* is the complaint of involuntary leakage associated with urgency and also with exertion, effort, sneezing, or coughing. (NEW)
- *Enuresis* means any involuntary loss of urine. (ORIGINAL) If it is used to denote incontinence during sleep, it should always be qualified with the adjective "nocturnal."
- *Nocturnal enuresis* is the complaint of loss of urine occurring during sleep. (NEW)

- *Continuous urinary incontinence* is the complaint of continuous leakage. (NEW)
- *Other types of urinary incontinence* may be situational, for example, the report of incontinence during sexual intercourse, or giggle incontinence.
- *Bladder sensation* can be defined, during history taking, by five categories:
  - *Normal*: The individual is aware of bladder filling and increasing sensation up to a strong desire to void. (NEW)
  - *Increased*: The individual feels an early and persistent desire to void. (NEW) *Reduced: The individual is aware of bladder filling but does not feel a definite desire to void. (NEW)*
  - *Absent*: The individual reports no sensation of bladder filling or desire to void. (NEW)
  - *Nonspecific*: The individual reports no specific bladder sensation, but may perceive bladder filling as abdominal fullness, vegetative symptoms, or spasticity. (NEW)[**]

Voiding Symptoms

Voiding symptoms are experienced during the voiding phase: (NEW)

- *Slow stream* is reported by the individual as his or her perception of reduced urine flow, usually compared to previous performance or in comparison to others. (NEW)
- *Splitting or spraying* of the urine stream may be reported. (NEW)
- *Intermittent stream (intermittency)* is the term used when the individual describes urine flow that stops and starts, on one or more occasions, during micturition. (NEW)
- *Hesitancy* is the term used when an individual describes difficulty in initiating micturition resulting in a delay in the onset of voiding after the individual is ready to pass urine. (NEW)
- *Straining* to void describes the muscular effort used to initiate, maintain, or improve the urinary stream. (NEW)[*]
- *Terminal dribble* is the term used when an individual describes a prolonged final part of micturition, when the flow has slowed to a trickle/dribble. (NEW)

Postmicturition Symptoms

Postmicturition symptoms are experienced immediately after micturition: (NEW)

- *Feeling of incomplete emptying* is a self-explanatory term for a feeling experienced by the individual after passing urine. (NEW)
- *Postmicturition dribble* is the term used when an individual describes the involuntary loss of urine immediately after he or she has finished passing urine, usually after leaving the toilet in men or after rising from the toilet in women. (NEW)

Symptoms associated with Sexual Intercourse

Dyspareunia, vaginal dryness, and incontinence are among the symptoms women may describe during or after intercourse. These symptoms should be described as fully as possible. It is helpful to define urine leakage as during penetration, during intercourse, or at orgasm.

Symptoms Associated with Pelvic Organ Prolapse

The feeling of a lump (“something coming down”), low backache, heaviness, dragging sensation, and the need to digitally replace the prolapse in order to defecate or micturate are among the symptoms that women with a prolapse may describe.

Genital and Lower Urinary Tract Pain[†]

Pain, discomfort, and pressure are part of a spectrum of abnormal sensations felt by the individual. Pain produces the greatest impact on the patient and may be related to bladder filling or voiding, may be felt after micturition, or may be continuous. Pain should also be characterized by type, frequency, duration, precipitating and relieving factors, and location as defined in the following:

- *Bladder pain* is felt suprapubically or retropubically, usually increases with bladder filling, and

may persist after voiding. (NEW)
- *Urethral pain* is felt in the urethra and the individual indicates the urethra as the site. (NEW)
- *Vulval pain* is felt in and around the external genitalia. (NEW)
- *Vaginal pain* is felt internally above the introitus. (NEW)
- *Scrotal pain* may or may not be localized, for example, to the testis, epididymis, cord structures, or scrotal skin. (NEW)
- *Perineal pain* is felt, in the female, between the posterior fourchette (posterior lip of the introitus) and the anus and, in the male, between the scrotum and the anus. (NEW)
- *Pelvic pain* is less well defined than, for example, bladder, urethral, or perineal pain, is less clearly related to the micturition cycle or to bowel function, and is not localized to any single pelvic organ. (NEW)

Genitourinary Pain Syndromes and Symptom Syndromes Suggestive of LUTD

Syndromes describe constellations, or varying combinations of symptoms, but cannot be used for precise diagnosis. The use of the word syndrome can only be justified if there is at least one other symptom in addition to the symptom used to describe the syndrome. In scientific communications, the incidence of individual symptoms within the syndrome should be stated, in addition to the number or individuals with the syndrome.

The syndromes described are functional abnormalities for which a precise cause has not been defined. It is presumed that routine assessment (history taking, physical examination, and other appropriate investigations) has excluded obvious local pathologies, such as those that are infective, neoplastic, metabolic, or hormonal in nature.

Genitourinary Pain Syndromes

These syndromes are all chronic in their nature. Pain is the major complaint but concomitant complaints are of lower urinary tract, bowel, sexual, or gynecologic nature:

- *Painful bladder syndrome* is the complaint of suprapubic pain related to bladder filling, accompanied by other symptoms such as increased daytime and nighttime frequency, in the absence of proven urinary infection or other obvious pathologies. (NEW)[‡]
- *Urethral pain syndrome* is the occurrence of recurrent episodic urethral pain, usually on voiding, with daytime frequency and nocturia, in the absence of proven infection or other obvious pathologies. (NEW)
- *Vulval pain syndrome* is the occurrence of persistent or recurrent episodic vaginal pain, which is either related to the micturition cycle or associated with symptoms suggestive of urinary tract or sexual dysfunction. There is no proven infection or other obvious pathologies. (NEW)[*]
- *Vaginal pain syndrome* is the occurrence of persistent or recurrent episodic vaginal pain that is associated with symptoms suggestive of urinary tract or sexual dysfunction. There is no proven vaginal infection or other obvious pathologies.
- *Scrotal pain syndrome* is the occurrence of persistent or recurrent episodic scrotal pain that is associated with symptoms suggestive of urinary tract or sexual dysfunction. There is no proven epididymo-orchitis or other obvious pathologies.
- *Perineal pain syndrome* is the occurrence of persistent or recurrent episodic perineal pain, which is either related to the micturition cycle or associated with symptoms suggestive of urinary tract or sexual dysfunction. There is no proven infection or other obvious pathologies. (NEW)[†]
- *Pelvic pain syndrome* is the occurrence of persistent or recurrent episodic pelvic pain associated with symptoms suggestive of lower urinary tract, sexual, bowel, or gynecological dysfunction. There is no proven infection or other obvious pathologies. (NEW)

Symptom Syndromes Suggestive of LUTD

In clinical practice, empirical diagnoses are often used as the basis for initial management after assessing the individual’s lower urinary tract symptoms, physical findings, and the results of urinalysis and other indicated investigations.

- *Urgency*, with or without urge incontinence, usually with frequency and nocturia, can be described as the *overactive bladder syndrome*, *urge syndrome*, or *urgency–frequency syndrome*. (NEW)

These symptom combinations are suggestive of urodynamically demonstrable detrusor overactivity, but can be due to other forms of urethrovesical dysfunction. These terms can be used if there is no proven infection or other obvious pathologies.

- *Lower urinary symptom suggestive of bladder outlet obstruction* is a term used when a man complains predominantly of voiding symptoms in the absence of infection or obvious pathology other than possible causes of outlet obstruction. (NEW)[‡]

SIGNS SUGGESTIVE OF LUTD

Measuring the Frequency, Severity, and Impact of LUTS

Asking the patient to record micturitions and symptoms[§] for a period of days provides invaluable information. The recording of micturition events can be in three main forms:

- *Micturition time chart*: This records only the times of micturitions, day and night, for at least 24 hours. (NEW)
- *Frequency volume chart*: This records the volumes voided as well as the time of each micturition, day and night, for at least 24 hours. (CHANGED)
- *Bladder diary*: This records the times of micturitions and voided volumes, incontinence episodes, pad usage, and other information such as fluid intake, the degree of urgency, and the degree of incontinence. (NEW)[¶]

The following measurements can be abstracted from frequency volume charts and bladder diaries:

- *Daytime frequency* is the number of voids recorded during waking hours and includes the last void before sleep and the first void after waking and rising in the morning. (NEW)
- *Nocturia* is the number of voids recorded during a night's sleep: Each void is preceded and followed by sleep. (NEW)
- *24-hour frequency* is the total number of daytime voids and episodes of nocturia during a specified 24-hour period. (NEW)
- *24-hour production* is measured by collecting all urine for 24 hours. (NEW)

This is usually commenced *after* the first void produced after rising in the morning and is completed by including the first void on rising the following morning.

- *Polyuria* is defined as the measured production of more than 2.8 L of urine in 24 hours in adults. It may be useful to look at output over shorter time frames [16]. (NEW) [**]
- *Nocturnal urine volume* is defined as the total volume of urine passed between the times the individual goes to bed with the intention of sleeping and the time of waking with the intention of rising. (NEW) Therefore, it excludes the last void before going to bed but includes the first void after rising in the morning.
- *Nocturnal polyuria* is present when an increased proportion of the 24-hour output occurs at night (normally during the 8 hours while the patient is in bed). (NEW) The nighttime urine output excludes the last void before sleep but includes the first void in the morning.[*]
- *Maximum voided volume* is the largest volume of urine voided during a single micturition and is determined either from the frequency/volume chart or bladder diary. (NEW)

The maximum, mean, and minimum voided volumes over the period of recording may be stated.[†]

Physical Examination

Physical examination is essential in the assessment of all patients with LUTD. It should include abdominal, pelvic, perineal, and a focused neurological examination. For patients with possible neurogenic LUTD, a more extensive neurologic examination is needed.

Abdominal

The bladder may be felt by abdominal palpation or by suprapubic percussion. Pressure suprapubically or during bimanual vaginal examination may induce a desire to pass urine.

Perineal/Genital Inspection

This allows the description of the skin (e.g., the presence of atrophy or excoriation), any abnormal anatomic features, and the observation of incontinence.

- *Urinary incontinence (the sign)* is defined as urine leakage seen during examination; this may be urethral or extraurethral.
- *Stress urinary incontinence* is the observation of involuntary leakage from the urethra, synchronous with exertion/effort, or sneezing or coughing. (CHANGED)‡

Stress leakage is presumed to be due to raised abdominal pressure.

- *Extraurethral incontinence* is defined as the observation of urine leakage through channels other than the urethra. (ORIGINAL)
- *Uncategorized incontinence* is the observation of involuntary leakage that cannot be classified into one of the above categories on the basis of signs and symptoms. (NEW)

Vaginal Examination

Vaginal examination allows the description of observed and palpable anatomic abnormalities and the assessment of pelvic floor muscle function, as described in the ICS report on pelvic organ prolapse. The definitions given are simplified versions of the definitions in that report [4]:

- *Pelvic organ prolapse* is defined as the descent of one or more of the anterior vaginal wall, the posterior vaginal wall, and the apex of the vagina (cervix/uterus) or vault (cuff) after hysterectomy. Absence of prolapse is defined as stage 0 support; prolapse can be staged from stage I to stage IV. (NEW)

Pelvic organ prolapse can occur in association with urinary incontinence and other LUTD and may on occasion mask incontinence.

- *Anterior vaginal wall prolapse* is defined as descent of the anterior vagina so that the urethrovesical junction (a point 3 cm proximal to the external urinary meatus) or any anterior point proximal to this is <3 cm above the plane of the hymen. (CHANGED)
- *Prolapse of the apical segment of the vagina* is defined as any descent of the vaginal cuff scar (after hysterectomy) or cervix below a point that is 2 cm less than the total vaginal length above the plane of the hymen. (CHANGED)
- *Posterior vaginal wall prolapse* is defined as any descent of the posterior vaginal wall so that a midline point on the posterior vaginal wall 3 cm above the level of the hymen, or any posterior point proximal to this, is <3 cm above the plane of the hymen. (CHANGED)

Pelvic Floor Muscle Function

This can be qualitatively defined by the tone at rest and the strength of a voluntary or reflex contraction as strong, weak, or absent or by a validated grading system (e.g., Oxford 1–5). A pelvic muscle contraction may be assessed by visual inspection, palpation, electromyography, or perineometry. Factors to be assessed include strength, duration, displacement, and repeatability.

Rectal Examination

Rectal examination allows the description of observed and palpable anatomic abnormalities and is the easiest method of assessing pelvic floor muscle function in children and men. In addition, rectal examination is essential in children with urinary incontinence to rule out fecal impaction.

- *Pelvic floor muscle function* can be qualitatively defined, during rectal examination, by the tone at rest and the strength of a voluntary contraction, as strong, weak, or absent. (NEW)

Pad Testing

Pad testing may be used to quantify the amount of urine lost during incontinence episodes, and methods range from a short provocative test to a 24-hour pad test.

URODYNAMIC OBSERVATIONS AND CONDITIONS

Urodynamic Techniques

There are two principal methods of urodynamic investigation:

1. *Conventional UDS* normally take place in the urodynamic laboratory and usually involve artificial bladder filling. (NEW)
   a. *Artificial bladder filling* is defined as filling the bladder, via a catheter, with a specified liquid at a specified rate. (NEW)
2. *Ambulatory UDS* are defined as a functional test of the lower urinary tract, utilizing natural filling and reproducing the subject's everyday activities.*
   a. *Natural filling* means that the bladder is filled by the production of urine rather than by an artificial medium.

Both filling cystometry and pressure flow studies (PFS) of voiding require the following measurements:

- *Intravesical pressure* is the pressure within the bladder. (ORIGINAL)
- *Abdominal pressure* is taken to be the pressure surrounding the bladder. In current practice, it is estimated from rectal, vaginal, or, less commonly, extraperitoneal pressure or a bowel stoma. The simultaneous measurement of abdominal pressure is essential for the interpretation of the intravesical pressure trace. (ORIGINAL)
- *Detrusor pressure* is that component of intravesical pressure that is created by forces in the bladder wall (passive and active). It is estimated by subtracting abdominal pressure from intravesical pressure. (ORIGINAL)

Filling Cystometry

The word "cystometry" is commonly used to describe the urodynamic investigation of the filling phase of the micturition cycle. To eliminate confusion, the following definitions are proposed:

- *Filling cystometry* is the method by which the pressure/volume relationship of the bladder is measured during bladder filling. (ORIGINAL)

The filling phase starts when filling commences and ends when the patient and urodynamicist decide that "permission to void" has been given.†

Bladder and urethral function, during filling, need to be defined separately.

The rate at which the bladder is filled is divided into the following:

- *Physiological filling rate* is defined as a filling rate less than the predicted maximum—predicted maximum body weight in kilogram divided by four, expressed as milliliter per minutes [17]. (CHANGED)
- *Nonphysiological filling rate* is defined as a filling rate greater than the predicted maximum—predicted maximum body weight in kilogram divided by four expressed as milliliter per minutes [8]. (CHANGED)

Bladder storage function should be described according to bladder sensation, detrusor activity, bladder compliance, and bladder capacity.[‡]

Bladder Sensation during Filling Cystometry

- *Normal bladder sensation* can be judged by three defined points noted during filling cystometry and evaluated in relation to the bladder volume at that moment and in relation to the patient's symptomatic complaints.
- *First sensation of bladder filling* is the feeling the patient has, during filling cystometry, when he or she first becomes aware of the bladder filling. (NEW)
- *First desire to void* is defined as the feeling, during filling cystometry, that would lead the patient to pass urine at the next convenient moment, but voiding can be delayed if necessary. (CHANGED)
- *Strong desire to void* is defined, during filling cystometry, as a persistent desire to void without the fear of leakage. (ORIGINAL)
- *Increased bladder sensation* is defined, during filling cystometry, as an early first sensation of bladder filling (or an early desire to void) and/or an early strong desire to void, which occurs at low bladder volume and which persists. (NEW)[*]
- *Reduced bladder sensation* is defined, during filling cystometry, as diminished sensation throughout bladder filling. (NEW)
- *Absent bladder sensation* means that, during filling cystometry, the individual has no bladder sensation. (NEW)
- *Nonspecific bladder sensations*, during filling cystometry, may make the individual aware of bladder filling, for example, abdominal fullness or vegetative symptoms. (NEW)
- *Bladder pain*, during filling cystometry, is a self-explanatory term and is an abnormal finding. (NEW)
- *Urgency*, during filling cystometry, is a sudden compelling desire to void. (NEW)[†]
- *The vesical/urethral sensory threshold* is defined as the least current that consistently produces a sensation, perceived by the subject during stimulation at the site under investigation [3]. (ORIGINAL)

Detrusor Function during Filling Cystometry

In everyday life, the individual attempts to inhibit detrusor activity until he or she is in a position to void. Therefore, when the aims of the filling study have been achieved, and when the patient has a desire to void, normally the "permission to void" is given (see "filling cystometry" earlier). That by the change in detrusor moment is indicated on the urodynamic trace and all detrusor activity before this "permission" is defined as "involuntary detrusor activity."

- *Normal detrusor function* allows bladder filling with little or no change in pressure. No involuntary phasic contractions occur despite provocation. (ORIGINAL)
- *Detrusor overactivity* is a urodynamic observation characterized by involuntary detrusor contractions during the filling phase, which may be spontaneous or provoked. (CHANGED)[‡]

There are certain patterns of detrusor overactivity:

- *Phasic detrusor overactivity* is defined by a characteristic waveform and may or may not lead to urinary incontinence. (NEW)[§]
- *Terminal detrusor overactivity* is defined as a single involuntary detrusor contraction occurring at cystometric capacity, which cannot be suppressed, and results in incontinence, usually resulting in bladder emptying (voiding). (NEW)[¶]
- *Detrusor overactivity incontinence* is incontinence due to an involuntary detrusor contraction. (NEW)

In a patient with normal sensation, urgency is likely to be experienced just before the leakage episode.[**]

Detrusor overactivity may also be qualified, when possible, according to cause, for example,

- *Neurogenic detrusor overactivity* when there is a relevant neurologic condition.

This term replaces the term “detrusor hyperreflexia.” (NEW)

- *Idiopathic detrusor overactivity* when there is no defined cause. (NEW)

This term replaces “detrusor instability.”[††]

In clinical and research practice, the extent of neurologic examination/investigation varies. It is likely that the proportion of neurogenic to idiopathic detrusor overactivity will increase if a more complete neurologic assessment is carried out.

Other patterns of detrusor overactivity are seen; for example, the combination of phasic and terminal detrusor overactivity and the sustained high-pressure detrusor contractions seen in spinal cord injury patients when attempted voiding occurs against a dyssynergic sphincter.

- *Provocative maneuvers* are defined as techniques used during urodynamics in an effort to provoke detrusor overactivity, for example, rapid filling, use of cooled or acid medium, postural changes, and hand washing. (NEW)

Bladder Compliance during Filling Cystometry

- *Bladder compliance* describes the relationship between change in bladder volume and change in detrusor pressure. (CHANGED)[*]

Compliance is calculated by dividing the volume change (DV) by the change in detrusor pressure (Dp_{det}) during that change in bladder volume ($C = V.Dp_{det}$). It is expressed in mL/cmH_2O.

A variety of means of calculating bladder compliance has been described. The ICS recommends that two standard points should be used for compliance calculations: the investigator may wish to define additional points. The standards points are as follows:

1. The detrusor pressure at the start of bladder filling and the corresponding bladder volume (usually zero).
2. The detrusor pressure (and corresponding bladder volume) at cystometric capacity or immediately before the start of any detrusor contraction that causes significant leakage (and therefore causes the bladder volume to decrease, affecting compliance calculation). Both points are measured excluding any detrusor contraction.

Bladder Capacity during Filling Cystometry

- *Cystometric capacity* is the bladder volume at the end of the filling cystometrogram, when “permission to void” is usually given. The end point should be specified, for example, if filling is stopped when the patient has a normal desire to void. The cystometric capacity is the volume voided together with any residual urine. (CHANGED)[†]
- *Maximum cystometric capacity*, in patients with normal sensation, is the volume at which the patient feels he or she can no longer delay micturition (has a strong desire to void). (ORIGINAL)
- *Maximum anesthetic bladder capacity* is the volume to which the bladder can be filled under deep general or spinal anesthetic and should be qualified according to the type of anesthesia used, the speed of filling, the length of time of filling, and the pressure at which the bladder is filled. (CHANGED)

Urethral Function during Filling Cystometry

The urethral closure mechanism during storage may be competent or incompetent:

- *Normal urethral closure mechanism* maintains a positive urethral closure pressure during

bladder filling even in the presence of increased abdominal pressure, although it may be overcome by detrusor overactivity. (CHANGED)
- *Incompetent urethral closure mechanism* is defined as one that allows **leakage of urine in the absence of a detrusor contraction**. (ORIGINAL)
- *Urethral relaxation incontinence* is defined as leakage due to urethral relaxation in the absence of raised abdominal pressure or detrusor overactivity. (NEW)[‡]
- *Urodynamic stress incontinence* is noted during filling cystometry and is defined as the involuntary leakage of urine during increased abdominal pressure, in the absence of a detrusor contraction. (CHANGED)

Urodynamic stress incontinence is now the preferred term to "genuine stress incontinence."[¶]

Assessment of Urethral Function during Filling Cystometry

- *Urethral pressure measurement*
    - *Urethral pressure* is defined as the fluid pressure needed to just open a closed urethra. (ORIGINAL) *The urethral pressure profile* is a graph indicating the intraluminal pressure along the length of the urethra. (ORIGINAL)
    - *The urethral closure pressure profile* is given by the subtraction of intravesical pressure from urethral pressure. (ORIGINAL)
    - *Maximum urethral pressure* is the maximum pressure of the measured profile. (ORIGINAL)
    - *Maximum urethral closure pressure* is the maximum difference between the urethral pressure and the intravesical pressure. (ORIGINAL)
    - *Functional profile length* is the length of the urethra along which the urethral pressure exceeds intravesical pressure in women.
    - *Pressure "transmission" ratio* is the increment in urethral pressure on stress as a percentage of the simultaneously recorded increment in intravesical pressure.

- *Abdominal leak point pressure* is the intravesical pressure at which urine leakage occurs due to increased abdominal pressure in the absence of a detrusor contraction. (NEW)[*]
- *Detrusor leak point pressure* is defined as the lowest detrusor pressure at which urine leakage occurs in the absence of either a detrusor contraction or increased abdominal pressure. (NEW)[†]

Pressure Flow Studies

Voiding is described in terms of detrusor and urethral function and assessed by measuring urine flow rate and voiding pressures.

- *PFS* of voiding are the methods by which the relationship between pressure in the bladder and urine flow rate is measured during bladder emptying. (ORIGINAL)

The voiding phase starts when "permission to void" is given or when uncontrollable voiding begins and ends when the patient considers voiding has finished.

Measurement of Urine Flow

Urine flow is defined either as *continuous*, that is, without interruption, or as *intermittent*, when an individual states that the flow stops and starts during a single visit to the bathroom in order to void. The continuous flow curve is defined as a *smooth*, arc-shaped curve, or *fluctuating* when there are multiple peaks during a period of continuous urine flow:[‡]

- *Flow rate* is defined as the volume of fluid expelled via the urethra per unit time. It is expressed in milliliter per second. (ORIGINAL)
- *Voided volume* is the total volume expelled via the urethra. (ORIGINAL)
- *Maximum flow rate* is the maximum measured value of the flow rate after correction for artifacts. (CHANGED)

- *Voiding time* is total duration of micturition, i.e., includes interruptions. When voiding is completed without interruption, voiding time is equal to flow time. (ORIGINAL)
- *Flow time* is the time over which measurable flow actually occurs. (ORIGINAL)
- *Average flow rate* is voided volume divided by flow time. The average flow should be interpreted with caution if flow is interrupted or there is a terminal dribble. (CHANGED)
- *Time to maximum flow* is the elapsed time from onset of flow to maximum flow. (ORIGINAL)

Pressure Measurements during PFS

The following measurements are applicable to each of the pressure curves: intravesical, abdominal, and detrusor pressure.

- *Premicturition pressure* is the pressure recorded immediately before the initial isovolumetric contraction. (ORIGINAL)
- *Opening pressure* is the pressure recorded at the onset of urine flow (consider time delay). (ORIGINAL)
- *Opening time* is the elapsed time from initial rise in detrusor pressure to onset of flow. (ORIGINAL)

This is the initial isovolumetric contraction period of micturition. Flow measurement delay should be taken into account when measuring opening time.

- *Maximum pressure* is the maximum value of the measured pressure. (ORIGINAL)
- *Pressure at maximum flow rate* is the lowest pressure recorded at maximum measured flow rate. (ORIGINAL)
- *Closing pressure* is the pressure measured at the end of measured flow. (ORIGINAL)
- *Minimum voiding pressure* is the minimum pressure during measurable flow. This is not necessarily equal to either the opening or closing pressures.
- *Flow delay* is the time delay between a change in bladder pressure and the corresponding change in measured flow rate.

Detrusor Function during Voiding

- *Normal detrusor function*

Normal voiding is achieved by a voluntarily initiated continuous detrusor contraction that leads to complete bladder emptying within a normal time span and in the absence of obstruction. For a given detrusor contraction, the magnitude of the recorded pressure rise will depend on the degree of outlet resistance. (ORIGINAL)

- *Abnormal detrusor activity* can be subdivided:
    - *Detrusor underactivity* is defined as a contraction of reduced strength and/or duration, resulting in prolonged bladder emptying and/or a failure to achieve complete bladder emptying within a normal time span. (ORIGINAL)
    - *Acontractile detrusor* is one that cannot be demonstrated to contract during UDS. (ORIGINAL)[*]
    - *Postvoid residual* is defined as the volume of urine left in the bladder at the end of micturition. (ORIGINAL)[†]

Urethral Function during Voiding

Normal urethral function during voiding is defined as a urethra that opens and is continuously relaxed to allow the bladder to be emptied at a normal pressure. (CHANGED)

Abnormal urethral function may be due to either obstruction to urethral overactivity or a urethra that cannot open due to anatomic abnormality, such as an enlarged prostate or a urethral stricture.

- *Bladder outlet obstruction* is the generic term for obstruction during voiding and is characterized by increased detrusor pressure and reduced urine flow rate. It is usually diagnosed by studying the synchronous values of flow rate and detrusor pressure. (CHANGED)[‡]

- *Dysfunctional voiding* is defined as an intermittent and/or fluctuating flow rate due to involuntary intermittent contractions of the periurethral striated muscle during voiding, in neurologically normal individuals. (CHANGED)[§]
- *Detrusor sphincter dyssynergia* is defined as a detrusor contraction concurrent with an involuntary contraction of the urethral and/or periurethral striated muscle. Occasionally, flow may be prevented altogether. (ORIGINAL)[¶]
- *Nonrelaxing urethral sphincter obstruction* usually occurs in individuals with a neurological lesion and is characterized by a nonrelaxing, obstructing urethra, resulting in reduced urine flow. (NEW)[**]

CONDITIONS

- *Acute retention of urine* is defined as a painful, palpable, or percussable bladder, when the patient is unable to pass any urine. (NEW)[††]
- *Chronic retention of urine* is defined as a nonpainful bladder, which remains palpable or percussable after the patient has passed urine. such patients may be incontinent. (NEW)[‡‡]
- *Benign prostatic obstruction* is a form of bladder outlet obstruction; it may be diagnosed when the cause of outlet obstruction is known to be benign prostatic enlargement, due to histological benign prostatic hyperplasia. (NEW)
- *Benign prostatic hyperplasia* is a term used (and reserved) for the typical histological pattern, which defines the disease. (NEW)
- *Benign prostatic enlargement* is defined as prostatic enlargement due to histological benign prostatic hyperplasia. The term “prostatic enlargement” should be used in the absence of prostatic histology. (NEW)

TREATMENT

The following definitions were published in the 7th ICS report on lower urinary tract rehabilitation techniques [3] and remain in their original form.

Lower Urinary Tract Rehabilitation

This is defined as a nonsurgical, nonpharmacological treatment for lower urinary tract function and includes the following:

- *Pelvic floor training* is defined as repetitive selective voluntary contraction and relaxation of specific pelvic floor muscles.
- *Biofeedback* is the technique by which information about a normally unconscious physiological process is presented to the patient and/or the therapist as a visual, auditory, or tactile signal.
- *Behavioral modification* is defined as the analysis and alteration of the relationship between the patient’s symptoms and his or her environment for the treatment of maladaptive voiding patterns.

This may be achieved by modification of the behavior and/or environment of the patient.

Electrical Stimulation

This is the application of electrical current to stimulate the pelvic viscera or their nerve supply.

The aim of electrical stimulation may be to directly induce a therapeutic response or to modulate lower urinary tract, bowel, or sexual dysfunction.

Catheterization

Catheterization is a technique for bladder emptying employing a catheter to drain the bladder or a urinary reservoir.

Intermittent (In/Out) Catheterization

This is defined as drainage or aspiration of the bladder or a urinary reservoir with subsequent removal of the catheter.

The following types of intermittent catheterization are defined:

- *Intermittent self-catheterization* is performed by the patient himself or herself.
- *Intermittent catheterization* is performed by an attendant (e.g., doctor, nurse, or relative).
- *Clean intermittent catheterization*: Use of a clean technique. This implies ordinary washing techniques and use of disposable or cleansed reusable catheters.
- *Aseptic intermittent catheterization*: Use of a sterile technique. This implies genital disinfection and the use of sterile catheters and instruments/gloves.

Indwelling Catheterization

This describes an indwelling catheter that remains in the bladder, urinary reservoir, or urinary conduit for a period of time longer than one emptying.

Bladder Reflex Triggering

This comprises various maneuvers performed by the patient or the therapist in order to elicit reflex detrusor contraction by exteroceptive stimuli.

The most commonly used maneuvers are suprapubic tapping, thigh scratching, and anal/rectal manipulation.

Bladder Expression

This comprises various maneuvers aimed at increasing intravesical pressure in order to facilitate bladder emptying.

The most commonly used maneuvers are abdominal straining, Valsalva maneuver, and Credé maneuver.

ACKNOWLEDGMENTS

The authors of this report are very grateful to Vicky Rees, administrator of the ICS, for her typing and editing of numerous drafts of this document.

ADDENDUM

Formation of the ICS Terminology Committee

The Terminology Committee was announced at the ICS meeting in Denver in 1999 and expressions of interest were invited from those who wished to be active members of the committee, and they were asked to comment in detail on the preliminary draft (the discussion paper published in *Neurourology and Urodynamics*). These are the nine authors who replied with a detailed critique by April 1, 2000, and constitute the committee: Paul Abrams, Linda Cardozo, Magnus Fall, Derek Griffiths, Peter Rosier, Ulf Ulmsten, Philip van Kerrebroeck, Arne Victor, and Alan Wein.

We thank other individuals who later offered their written comments: Jens Thorup Andersen, Walter Artibani, Jerry Blaivas, Linda Brubaker, Rick Bump, Emmanuel Chartier-Kastler, Grace Dorey, Clare Fowler, Kelm Hjalmas, Gordon Hosker, Vik Khullar, Guus Kramer, Gunnar Lose, Joseph Macaluso, Anders Mattiasson, Richard Millard, Rien Nijman, Arwin Ridder, Werner Schäfer, David Vodusek, and Jean Jacques Wyndaele.

A half-day workshop was held at the ICS Annual Meeting in Tampere (August 2000) and a 2-day meeting in London (January 2001), which produced draft 5 of the report, which was then placed on the ICS website (www.icsoffice.org). Discussions on draft 6 took place at the ICS meeting in Korea (September 2001), and draft 7 then remained on the ICS website until final submission to journals in November 2001.

[*] Published by kind permission of the International Continence Society, John Wiley & Sons, and Neurourology and Urodynamics 2002;21:167–178.

[**] These nonspecific symptoms are most frequently seen in neurologic patients, particularly those with spinal cord trauma, and in children and adults with malformations of the spinal cord.

[*] The term “nighttime frequency” differs from that for nocturia, as it includes voids that occur after the individual has gone to bed, but before he or she has gone to sleep, and voids that occur in the early morning that prevent the individual from getting back to sleep as he or she wishes. These voids before and after sleep may need to be considered in research studies, for example, in nocturnal polyuria. If this definition were used, then an adapted definition of daytime frequency would need to be used with it.

[†] In infants and small children, the definition of urinary incontinence is not applicable. In scientific communications, the definition of incontinence in children would need further explanation.

[**] The causes of polyuria are various and reviewed elsewhere but include habitual excess fluid intake. The figure of 2.8 is based on a 70 kg person voiding SPiGR40 mL/kg.

[*] The normal range of nocturnal urine production differs with age and the normal ranges remain to be defined. Therefore, nocturnal polyuria is present when sPiGR20% (young adults) to 33% (over 65 years) is produced at night. Hence, the precise definition is dependent on age.

[†] The term “functional bladder capacity” is no longer recommended as “voided volume” is a clearer and less confusing term, particularly if qualified (e.g., “maximum voided volume”). If the term bladder capacity is used, in any situation, it implies that this has been measured in some way, if only by abdominal ultrasound. In adults, voided volumes vary considerably. In children, the “expected volume” may be calculated from the formula (30 + [age in years x 30] in mL). Assuming no residual urine, this will be equal to the “expected bladder capacity.”

[‡] The original ICS definition of incontinence, “Urinary incontinence is the involuntary loss of urine that is a social or hygienic problem,” relates the complaint to quality of life (QoL) issues. Some QoL instruments have been, and are being, developed in order to assess the impact of both incontinence and other LUTS on QoL.

[§] The committee considers the term “stress incontinence” to be unsatisfactory in the English language because of its mental connotations. The Swedish, French, and Italian expression “effort incontinence” is preferable; however, words such as “effort” or “exertion” still do not capture some of the common precipitating factors for stress incontinence such as coughing or sneezing. For this reason, the term is left unchanged.

¶ Urge incontinence can present in different symptomatic forms, for example, as frequent small losses between micturitions, or as a catastrophic leak with complete bladder emptying.

* Suprapubic pressure may be used to initiate or maintain urine flow. The Credé maneuver is used by some spinal cord injury patients, and girls with detrusor underactivity sometimes press suprapubically to help empty the bladder.

† The terms “strangury,” “bladder spasm,” and “dysuria” are difficult to define and of uncertain meaning and should not be used in relation to lower urinary tract dysfunction, unless a precise meaning is stated. Dysuria literally means “abnormal urination” and is used correctly in some European countries. However, it is often used to describe the stinging/burning sensation characteristic of urinary infection. It is suggested that these descriptive words should not be used in the future.

† The ICS believes this to be a preferable term to “interstitial cystitis.” Interstitial cystitis is a specific diagnosis and requires confirmation by typical cystoscopic and histological features. In the investigation of bladder pain, it may be necessary to exclude conditions such as carcinoma in situ and endometriosis.

* The ICS suggests that the term vulvodynia (vulva pain) should not be used, as it leads to confusion between single symptom and a syndrome.

† The ICS suggests that, in men, the term prostatodynia (prostate pain) should not be used as it leads to confusion between a single symptom and a syndrome.

‡ In women, voiding symptoms are usually thought to suggest detrusor underactivity rather than bladder outlet obstruction.

§ Validated questionnaires are useful for recording symptoms, their frequency, severity, and both and the impact of LUTS on QoL. The instrument used should be specified.

¶ It is useful to ask the individual to make an estimate of liquid intake. This may be done precisely by measuring the volume of each drink or crudely by asking how many drinks are taken in a 24-hour period. If the individual eats significant quantities of water-containing foods (vegetables, fruit, salads), then an appreciable effect on urine production will result. The time that diuretic therapy is taken should be marked on a chart or diary.

‡ Coughing may induce a detrusor contraction; hence, the sign of stress incontinence is only a reliable indication of urodynamic stress incontinence when leakage occurs synchronously with the first proper cough and stops at the end of that cough.

* The term ambulatory urodynamics is used to indicate that monitoring usually takes place outside the urodynamic laboratory rather than the subject’s mobility using natural filling.

† The ICS no longer wishes to divide filling rates into slow, medium, and fast. In practice, almost all investigations are performed using medium filling rates, which have a wide range. It may be more important during investigations to consider whether or not the filling rate used during conventional urodynamic studies (UDS) can be considered physiologic.

‡ While bladder sensation is assessed during filling cystometry, the assumption that it is sensation from the bladder alone, without urethral or pelvic components, may be false.

* The assessment of the subject’s bladder sensation is subjective, and it is not, for example, possible to quantify “low bladder volume” in the definition of “increased bladder sensation.”

† The ICS no longer recommends the terms “motor urgency” and “sensory urgency.” These terms are often misused and have little intuitive meaning. Furthermore, it may be simplistic to relate urgency just to the presence or absence of detrusor overactivity when there is usually a concomitant fall in urethral pressure.

‡ There is no lower limit for the amplitude of an involuntary detrusor contraction, but confident interpretation of low-pressure waves (amplitude smaller than 5 cm H2O) depends on “high-quality” urodynamic technique. The phrase “which the patient cannot completely suppress” has been deleted from the old definition.

§ Phasic detrusor contractions are not always accompanied by any sensation, or may be interpreted as a first sensation of bladder filling, or as a normal desire to void.

¶ “Terminal detrusor overactivity” is a new ICS term: It is typically associated with reduced bladder sensation, for example, in the elderly stroke patient when urgency may be felt as the voiding contraction occurs. However, in complete spinal cord injury patients, there may be no sensation whatsoever.

** ICS recommends that the terms “motor urge incontinence” and “reflex incontinence” should no longer be used as they have no intuitive meaning and are often misused.

†† The terms “detrusor instability” and “detrusor hyperreflexia” were both used as generic terms, in the English-speaking world and in Scandinavia, prior to the first ICS report in 1976. As a compromise, they were allocated to idiopathic and neurogenic overactivity, respectively. As there is no real logic or intuitive meaning to the terms, the ICS believes they should be abandoned.

* The observation of reduced bladder compliance during conventional filling cystometry is often related to relatively fast bladder filling: the incidence of reduced compliance is markedly lower if the bladder is filled at physiologic rates, as in ambulatory urodynamics.

† In certain types of dysfunction, the cystometric capacity cannot be defined in the same terms. In the absence of sensation, the cystometric capacity is the volume at which the clinician decides to terminate filling. The reason(s) for terminating filling should be defined, for example, high detrusor filling pressure, large infused volume, or pain. If there is uncontrollable voiding, it is the volume at which this begins. In the presence of sphincter incompetence, the cystometric capacity may be significantly increased by occlusion of the urethra, for example, by Foley catheter.

‡ Fluctuations in urethral pressure have been defined as the “unstable ure-thra.” However, the significance of the fluctuations and the term itself lack clarity, and the term is not recommended by the ICS. If symptoms are seen in association with a decrease in urethral pressure, a full description should be given.

§ In patients with stress incontinence, there is a spectrum of urethral characteristics ranging from a highly mobile urethra with good intrinsic function to an immobile urethra with poor intrinsic function. Any delineation into categories such as “urethral hypermobility” and “intrinsic sphincter deficiency” may be simplistic and arbitrary and requires further research.

* The leak pressure point should be qualified according to the site of pressure measurement (rectal, vaginal, or intravesical) and the method by which pressure is generated (cough or Valsalva). Leak point pressures may be calculated in three ways from the three different baseline values that are in common use: zero (the true zero of intravesical pressure), the value of pves measured at zero bladder volume, or the value of pves immediately before the cough or Valsalva (usually at 200 or 300 mL bladder capacity). The baseline used and the baseline pressure should be specified.

† Detrusor leak point pressure has been used most frequently to predict upper tract problems in neurologic patients with reduced bladder compliance. ICS has defined it “in the absence of a detrusor contraction” although others will measure DLPP during involuntary detrusor contractions.

‡ The precise shape of the flow curve is decided by detrusor contractility, by the presence of any abdominal straining, and by the bladder outlet [11].

* A normal detrusor contraction will be recorded as a high pressure if there is high outlet resistance, normal pressure if there is normal outlet resistance, or low pressure if urethral resistance is low.

† If after repeated free flowmetry no residual urine is demonstrated, then the finding of residual urine during UDS should be considered an artifact, due to the circumstances of the test.

‡ Bladder outlet obstruction has been defined for men but, as yet, not ade-quately in women and children.

§ Although dysfunctional voiding is not a very specific term, it is preferred to terms such as “nonneurogenic neurogenic bladder.” Other terms such as “idiopathic detrusor sphincter dyssynergia,” or “sphincter overactivity voiding dysfunction” may be preferable. However, the term “dysfunctional voiding” is very well established. The condition occurs most frequently in children. While it is felt that pelvic floor contractions are responsible, it is possible that the intraurethral striated muscle may be important.

¶ Detrusor sphincter dyssynergia typically occurs in patients with a supra-sacral lesion, for example, after high spinal cord injury, and is uncommon in lesions of the lower cord. Although the urethral and periurethral striated muscles are usually held responsible, the smooth muscle of the bladder neck or urethra may also be responsible.

** Nonrelaxing sphincter obstruction is found in sacral and infrasacral lesions such as meningomyelocele and after radical pelvic surgery. In addition, there is often urodynamic stress incontinence during bladder filling. This term replaces “isolated distal sphincter obstruction.”

†† Although acute retention is usually thought of as painful, in certain cir-cumstances, pain may not be a presenting feature, for example, when due to prolapsed intervertebral disk, postpartum, or after regional anesthesia such as an epidural anesthetic. The retention volume should be significantly greater than the expected normal bladder capacity. In patients after surgery, due to bandaging of the lower abdomen or abdominal wall pain, it may be difficult to detect a painful, palpable, or percussable bladder.

‡‡ The ICS no longer recommends the term “overflow incontinence.” This term is considered confusing and lacking a convincing definition. If used, a precise definition and any associated pathophysiology, such as reduced urethral function, or detrusor overactivity/low bladder compliance, should be stated. The term chronic retention excludes transient voiding difficulty, for example, after surgery for stress incontinence, and implies significant residual urine; a minimum figure of300 mL has been previously mentioned.

Appendix C

International Urogynecological Association/International Continence Society Joint Report on the Terminology for Female Pelvic Floor Dysfunction*

Bernard T. Haylen, Dirk De Ridder, Robert M. Freeman, Steven E. Swift, Bary Berghmans, Joseph Lee, Ash Monga, Eckhard Petri, Diaa E.E. Rizk, Peter K. Sand, and Gabriel N. Schaer

INTRODUCTION

There is currently no single document addressing all elements required for diagnoses in the area of female pelvic floor dysfunction in a comprehensive way. Indeed, the diagnoses themselves have not been all completely defined. The term "diagnosis" is defined as "the determination of the nature of a disease: *clinical,* made from a study of the symptoms and signs of a disease; and *laboratory*," multiple options mentioned [1]. Such a specific report would require a full outline of the terminology for all symptoms, signs, urodynamic investigations for female pelvic floor dysfunction, the imaging associated with those investigations, and the most common diagnoses.

It may have been possible in the past to combine all the terminology for lower urinary tract function in men, women, and children into one report. The International Continence Society (ICS) has provided leadership in terminology for lower urinary tract dysfunction over decades employing combined or generic reports. The 1988 report by the Committee on the Standardization of Terminology [2] is one such example. With the increasing specificity and complexity of female diagnoses, a combined report may now be an anachronism. The 2002 report [3] still provided the traditional core terminology and some useful modifications, many of which are repeated in this document. However, it also revealed evidence that (1) a coherent and user-friendly combined report may be starting to become too difficult and (2) the terminology for women, due to the absence of specific diagnoses as well as other female-specific terminology, may not have been advantaged by this approach [4]. The need for standardized terminology in female pelvic floor dysfunction to enable accurate communication for clinical and research purposes has been highlighted for some time [5]. There is indeed the need for a general terminology, forming a "backbone" or "core" terminology to which more specific terminologies can be attached.

A female-specific terminology report should be as follows:

1. *As user-friendly as possible*: It should be able to be understood by all clinical and research users.
2. *Clinically based*: Symptoms, signs, and validated investigations should be presented for use in forming workable diagnoses. Sections 1 through 3 will address symptoms, signs, urodynamic investigations, and current associated pelvic imaging modalities routinely used in the office or urodynamic laboratory to make those diagnoses. A number of related radiological investigations as well as magnetic resonance imaging (MRI) have also been included. The detailed description of electromyography (EMG) and related nerve conduction, reflex latency, and other sensory studies contained in reference [2] will again [3] not be reinstated here. This report does not specifically address terminology for neurogenic pelvic floor dysfunction.

Section 4 will address the most common diagnoses of pelvic floor dysfunction. The terms [3] "urodynamic observation" and "condition" (nonmedical) have not been used in this report. The scope of the report will exclude (1) more invasive investigations requiring anesthetic and (2) evidence-based treatments for each diagnosis.

3. *Able to indicate origin and to provide explanations*: Where a term's existing definition (from one of multiple sources used) is deemed appropriate, that definition will be included and duly referenced. A large number of terms in female pelvic floor function and dysfunction, because of their longterm use, have now become generic, as apparent by their listing in medical dictionaries.

Where a specific explanation is deemed appropriate to explain a change from earlier definitions or to qualify the current definition, this will be included as a note to this appendix (superscript numbers 1, 2, 3, etc.). Wherever possible, evidence-based medical principles will be followed.

As in earlier ICS reports [2,3], when a reference is made to the whole anatomical organ, the vesica urinaria, the correct term is the bladder. When the smooth muscle structure known as the m. detrusor urinae is being discussed, then the correct term is detrusor.

It is suggested that acknowledgment of these standards in written publications related to female pelvic floor dysfunction be indicated by a footnote to the section "Methods and Materials," or its equivalent, to read as follows: "Methods, definitions, and units conform to the standards jointly recommended by the International Continence Society and the International Urogynecological Association, except where specifically noted."

SECTION 1: SYMPTOMS

Symptom: Any morbid phenomenon or departure from the normal in structure, function, or sensation experienced by the woman and indicative of disease [1] or a health problem. Symptoms are either volunteered by, or elicited from the individual, or may be described by the individual's caregiver [2,3].

1A: Urinary Incontinence Symptoms[*]

1. *Urinary incontinence (symptom)*: Complaint of involuntary loss of urine.
2. *Stress (urinary) incontinence*: Complaint of involuntary loss of urine on effort or physical exertion (e.g., sporting activities) or on sneezing or coughing. NB: "*activity-related incontinence*" might be preferred in some languages to avoid confusion with psychological stress.
3. *Urgency (urinary) incontinence*: Complaint of involuntary loss of urine associated with urgency.[†]
4. *Postural (urinary) incontinence: (NEW)* Complaint of involuntary loss of urine associated with change of body position, e.g., rising from a seated or lying position.[‡]
5. *Nocturnal enuresis*: Complaint of involuntary urinary loss of urine that occurs during sleep [3].
6. *Mixed (urinary) incontinence*: Complaint of involuntary loss of urine associated with urgency and also with effort or physical exertion or on sneezing or coughing.
7. *Continuous (urinary) incontinence*: Complaint of continuous involuntary loss of urine [3,6].
8. *Insensible (urinary) incontinence: (NEW)* Complaint of urinary incontinence where the woman has been unaware of how it occurred.
9. *Coital incontinence: (NEW)* Complaint of involuntary loss of urine with coitus. This symptom might be further divided into that occurring with penetration and that occurring at orgasm.

1B: Bladder Storage Symptoms

1. *Increased daytime urinary frequency*: Complaint that micturition occurs more frequently during waking hours than previously deemed normal by the woman [7].[§]
2. *Nocturia*: Complaint of interruption of sleep one or more times because of the need to micturate [3].[¶]
3. *Urgency*: Complaint of a sudden, compelling desire to pass urine that is difficult to defer.[**]
4. *Overactive bladder (OAB, urgency) syndrome*: Urinary urgency, usually accompanied by frequency and nocturia, with or without urgency urinary incontinence, in the absence of urinary

tract infection (UTI) or other obvious pathologies.

1C: Sensory Symptoms

Sensory symptoms: A departure from normal sensation or function, experienced by the woman during bladder filling [1]. Normally, the individual is aware of increasing sensation with bladder filling up to a strong desire to void [3].

1. *Increased bladder sensation*: Complaint that the desire to void during bladder filling occurs earlier or is more persistent to that previous experienced. NB: This differs from urgency by the fact that micturition can be postponed despite the desire to void.
2. *Reduced bladder sensation*: Complaint that the definite desire to void occurs later to that previously experienced despite an awareness that the bladder is filling.
3. *Absent bladder sensation*: Complaint of both the absence of the sensation of bladder filling and a definite desire to void [3].

1D: Voiding and Postmicturition Symptoms

Voiding symptoms: A departure from normal sensation or function, experienced by the woman during or following the act of micturition [1].

1. *Hesitancy*: Complaint of a delay in initiating micturition.
2. *Slow stream*: Complaint of a urinary stream perceived as slower compared to previous performance or in comparison with others.
3. *Intermittency*: Complaint of urine flow that stops and starts on one or more occasions during voiding.
4. *Straining to void*: Complaint of the need to make an intensive effort (by abdominal straining, Valsalva, or suprapubic pressure) to either initiate, maintain, or improve the urinary stream.
5. *Spraying (splitting) of urinary stream*: Complaint that the urine passage is a spray or split rather than a single discrete stream.
6. *Feeling of incomplete (bladder) emptying*: Complaint that the bladder does not feel empty after micturition.
7. *Need to immediately revoid*: Complaint that further micturition is necessary soon after passing urine.
8. *Postmicturition leakage*: Complaint of a further involuntary passage of urine following the completion of micturition.
9. *Position-dependent micturition: (NEW)* Complaint of having to take specific positions to be able to micturate spontaneously or to improve bladder emptying, for example, leaning forward or backward on the toilet seat or voiding in the semistanding position.
10. *Dysuria*: Complaint of burning or other discomfort during micturition. Discomfort may be intrinsic to the lower urinary tract or external (vulvar dysuria).
11. *(Urinary) retention: (NEW)* Complaint of the inability to pass urine despite persistent effort.

1E: POP Symptoms

Prolapse symptoms: A departure from normal sensation, structure, or function, experienced by the woman in reference to the position of her pelvic organs. Symptoms are generally worse at the times when gravity might make the prolapse worse (e.g., after long periods of standing or exercise) and better when gravity is not a factor, for example, lying supine. Prolapse may be more prominent at times of abdominal straining, for example, defecation.

1. *Vaginal bulging*: Complaint of a “bulge” or “something coming down” through the vaginal introitus. The woman may state she can either feel the bulge by direct palpation or see it aided with a mirror.
2. *Pelvic pressure*: Complaint of increased heaviness or dragging in the suprapubic area and/or pelvis.
3. *Bleeding, discharge, infection*: Complaint of vaginal bleeding, discharge, or infection related to

dependent ulceration of the prolapse.

4. *Splinting/digitation*: Complaint of the need to digitally replace the prolapse or to otherwise apply manual pressure, for example, to the vagina or perineum (splinting), or rectally (digitation) to assist voiding or defecation.
5. *Low backache*: Complaint of low, sacral (or "periodlike") backache associated temporally with pelvic organ prolapse (POP).

1F: Symptoms of Sexual Dysfunction

A departure from normal sensation and/or function experienced by a woman during sexual activity.

1. *Dyspareunia*: Complaint of persistent or recurrent pain or discomfort associated with attempted or complete vaginal penetration[*]
2. *Superficial dyspareunia*: Complaint of pain or discomfort on vaginal entry or at the vaginal introitus
3. *Deep dyspareunia*: Complaint of pain or discomfort on deeper penetration (mid- or upper vagina)
4. *Obstructed intercourse*: Complaint that vaginal penetration is not possible due to obstruction
5. *Vaginal laxity*: Complaint of excessive vaginal laxity
6. *Other symptoms* [9,10][†]

1G: Symptoms of Anorectal Dysfunction[‡]

1. *Anal incontinence (symptom)*: Complaint of involuntary loss of feces or flatus
2. *Fecal incontinence*: Complaint of involuntary loss of feces [11]
   a. Solid
   b. Liquid
   c. Passive fecal incontinence (such as soiling without sensation or warning or difficulty wiping clean)
   d. Coital fecal incontinence (occurring with vaginal intercourse)
3. *Flatal incontinence*: Complaint of involuntary loss of flatus [11]
4. *Fecal (rectal) urgency*: Sudden, compelling desire to defecate that is difficult to defer
5. *Fecal (flatal) urgency incontinence*: Involuntary loss of feces (flatus) associated with urgency
6. *Straining to defecate*: Complaint of the need to make an intensive effort (by abdominal straining or Valsalva) to either initiate, maintain, or improve defecation
7. *Feeling of incomplete (bowel) evacuation*: Complaint that the rectum does not feel empty after defecation
8. *Diminished rectal sensation*: Complaint of diminished or absent sensation in the rectum [11]
9. *Constipation*: Complaint that bowel movements are infrequent and/or incomplete and/or there is a need for frequent straining or manual assistance to defecate (Rome II criteria)[*]
10. *Rectal prolapse*: Complaint of external protrusion of the rectum
11. *Rectal bleeding/mucus*: Complaint of the loss of blood or mucus per rectum

1H: Lower Urinary Tract Pain and/or Other Pelvic Pain[†]

1. *Bladder pain*: Complaint of suprapubic or retropubic pain, pressure, or discomfort, related to the bladder, and usually increasing with bladder filling. It may persist or be relieved after voiding [3].
2. *Urethral pain*: Complaint of pain felt in the urethra and the woman indicates the urethra as the site [3].
3. *Vulval pain*: Complaint of pain felt in and around the vulva [3].
4. *Vaginal pain*: Complaint of pain felt internally within the vagina, above the introitus [3].
5. *Perineal pain*: Complaint of pain felt between the posterior fourchette (posterior lip of the introitus) and the anus [3].
6. *Pelvic pain*: The complaint of pain perceived to arise in the pelvis, not associated with

symptoms suggestive of lower urinary tract, sexual, bowel, or gynecological dysfunction. It is less well defined than the aforementioned types of localized pain.
7. *Cyclical (menstrual) pelvic pain*: Cyclical pelvic pain related to menses that raises the possibility of a gynecological cause.
8. *Pudendal neuralgia*: Burning vaginal or vulval (anywhere between the anus and clitoris) pain associated with tenderness over the course of the pudendal nerves. Recently, five essential criteria (Nantes criteria) have been proposed for the diagnosis of pudendal neuropathy [13]: (1) pain in the anatomical region of pudendal innervation, (2) pain that is worse with sitting, (3) no waking at night with pain, (4) no sensory deficit on examination, and (5) relief of symptoms with a pudendal block.
9. *Chronic lower urinary tract and/or other pelvic pain syndromes*.[‡]

1I: Lower UTI

1. *UTI*: Scientific diagnosis of a UTI is the finding of microbiological evidence of significant bacteriuria and pyuria[§]
2. *Recurrent UTIs*: At least three symptomatic and medically diagnosed UTI in the previous 12 months.[¶]
3. *Other related history*: For example, hematuria and catheterization.

SECTION 2: SIGNS

Sign: Any abnormality indicative of disease or a health problem, discoverable on examination of the patient; an objective indication of disease [1] or a health problem.

2A: Urinary Incontinence Signs

All examinations for urinary incontinence are best performed with the woman's bladder comfortably full.

1. *Urinary incontinence*: Observation of involuntary loss of urine on examination; this may be urethral or extraurethral [3].
2. *Stress (urinary) incontinence (clinical stress leakage)*: Observation of involuntary leakage from the urethra synchronous with effort or physical exertion or on sneezing or coughing [3].
3. *Urgency (urinary) incontinence*: Observation of involuntary leakage from the urethra synchronous with the sensation of a sudden, compelling desire to void that is difficult to defer.
4. *Extraurethral incontinence*: Observation of urine leakage through channels other than the urethral meatus, for example, fistula.
5. *Stress incontinence on prolapse reduction (occult or latent stress incontinence)*: (*NEW*) Stress incontinence only observed after the reduction of coexistent prolapse.[**]

2B: Signs of POP

All examinations for POP should be performed with the woman's bladder empty (and if possible an empty rectum). An increasing bladder volume has been shown to restrict the degree of descent of the prolapse [14]. The choice of the woman's position during examination, for example, left lateral (Sims), supine, standing, or lithotomy, is that which can best demonstrate POP in that patient and which the woman can confirm, for example, by use of a mirror or digital palpation. The degree of prolapse may be worse later in the day (after a lengthy time in the erect position) than it is earlier in the day. The hymen remains the fixed point of reference for prolapse description [15].

1. *POP (definition)*: The descent of one or more of the anterior vaginal wall, posterior vaginal wall, the uterus (cervix), or the apex of the vagina (vaginal vault or cuff scar after hysterectomy). The presence of any such sign should be correlated with relevant POP symptoms. More commonly, this correlation would occur at the level of the hymen or beyond.
2. *POP—(POPQ)—(staging [3,15,16])*
   Stage 0: No prolapse is demonstrated.

Stage I: Most distal portion of the prolapse is more than 1 cm above the level of the hymen.
Stage II: Most distal portion of the prolapse is 1 cm or less proximal to or distal to the plane of the hymen.
Stage III: The most distal portion of the prolapse is more than 1 cm below the plane of the hymen.
Stage IV: Complete eversion of the total length of the lower genital tract is demonstrated.*

3. *Uterine/cervical prolapse*: Observation of descent of the uterus or uterine cervix.
4. *Vaginal vault (cuff scar) prolapse*: Observation of descent of the vaginal vault (cuff scar after hysterectomy) [19].†
5. *Anterior vaginal wall prolapse*: Observation of descent of the anterior vaginal wall. Most commonly this would be due to bladder prolapse (cystocele, either central, paravaginal, or a combination). Higher stage anterior vaginal wall prolapse will generally involve uterine or vaginal vault (if uterus is absent) descent. Occasionally, there might be anterior enterocele (hernia of peritoneum and possibly abdominal contents) formation after prior reconstructive surgery [19] (Figure C.1).‡
6. *Posterior vaginal wall prolapse*: Observation of descent of the posterior vaginal wall. Most commonly, this would be due to rectal protrusion into the vagina (rectocele). Higher-stage posterior vaginal wall prolapse after prior hysterectomy will generally involve some vaginal vault (cuff scar) descent and possible enterocele formation [19].§

2C: Other Pelvic Examinations/Signs [2,3,20]

The internal examinations are generally best performed with the woman's bladder empty.

1. *Vulval examination*: Abnormalities include cysts, other tumors, atrophic changes, or lichen sclerosis.
2. *Urethral inspection/palpation*
   a. *Urethral mucosal prolapse*: Prolapse, generally circumferential and larger, of the distal urethral urothelium.
   b. *Urethral caruncle*: Smaller eversion of the urethral urothelium, generally involving the posterior lip.
   c. *Urethral diverticulum*: The presence of a sac opening from the urethra. It might be suspected by a lump or tenderness along the line of the urethra or external urethral discharge on urethral massage.
3. *Vaginal examination*: Examination for vaginal length and mobility, presence of scarring and/or pain, and estrogenization. The location of any vaginal pain should be noted. Included here is any tenderness over the course of the pudendal nerve (see 1H[8] pudendal neuralgia).
4. *Bimanual pelvic examination*: Observations for any pelvic mass or unusual tenderness by vaginal examination together with suprapubic palpation.

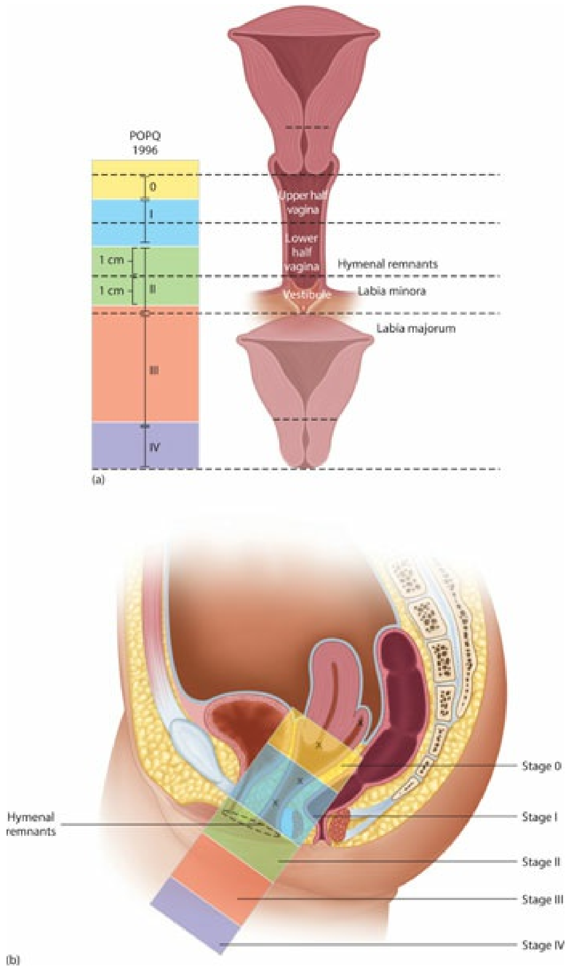

Figure C.1 (a, b) Prolapse staging—0, I, II, III, IV. (Uterine—by the position of the leading edge of the cervix.)

5. *Pelvic floor muscle function [3,20]*: Can be qualitatively defined by the tone at rest and the strength of a voluntary or reflex contraction as strong, normal, weak, or absent, or by a validated grading symptom. Voluntary pelvic floor muscle contraction and relaxation may be assessed by visual inspection, digital palpation (circumferentially), EMG dynamometry, perineometry, or ultrasound. Factors to be assessed include muscle strength (static and dynamic), voluntary muscle relaxation (absent, partial, complete), muscular endurance (ability to sustain maximal or near maximal force), repeatability (the number of times a contraction to maximal or near maximal force can be performed), duration, coordination, and displacement. It is desirable to document findings for each side of the pelvic floor separately to allow for any unilateral defects and asymmetry. The ICS Report into the standardization of terminology of pelvic floor muscle function and dysfunction [20] provides a fuller description of the assessment of pelvic floor muscle function including the following:
    a. *Normal pelvic floor muscles*: Pelvic floor muscles that can voluntarily and involuntarily contract and relax.
    b. *Overactive pelvic floor muscles*: Pelvic floor muscles that do not relax or may even contract when relaxation is functionally needed, for example, during micturition or defecation.
    c. *Underactive pelvic floor muscles*: Pelvic floor muscles that cannot voluntarily contract when this is appropriate.
    d. *Nonfunctioning pelvic floor muscles*: Pelvic floor muscles where there is no action palpable.
6. *Examination for levator (puborectalis) injury*: The puborectalis muscle may be assessed for the presence of major morphological abnormalities by palpating its insertion on the inferior aspect of the os pubis. If the muscle is absent 2–3 cm lateral to the urethra, that is, if the bony surface of the os pubis can be palpated as devoid of muscle, an “avulsion injury” of the puborectalis

muscle is likely [21].

7. *Perineal examination* [20]: When the patient is asked to cough or Valsalva, the perineum should show no downward movement; ventral movement may occur because of the guarding actions of the pelvic floor muscles.
   a. *Perineal elevation*: This is the inward (cephalad) movement of the vulva, perineum, and anus.
   b. *Perineal descent*: This is the outward (caudal) movement of the vulva, perineum, and anus.
8. *Rectal examination*: Observations can include the following:
   a. *Anal sphincter tone and strength*: Assessment on digital examination as good or poor in the absence of any quantitative assessment.
   b. *Anal sphincter tear*: May be recognized as a clear "gap" in the anal sphincter on digital examination.
   c. *Confirm presence or absence of rectocele*: And if possible, differentiate from enterocele. Diagnose perineal body deficiency.
   d. *Confirm presence or absence of fecal impaction*.
   e. *Other rectal lesions*: Intussusception, rectovaginal fistula, or tumor.
   f. *Anal lesions*: Hemorrhoids, fissure.
   g. *Other perianal lesions*: Anocutaneous fistula.

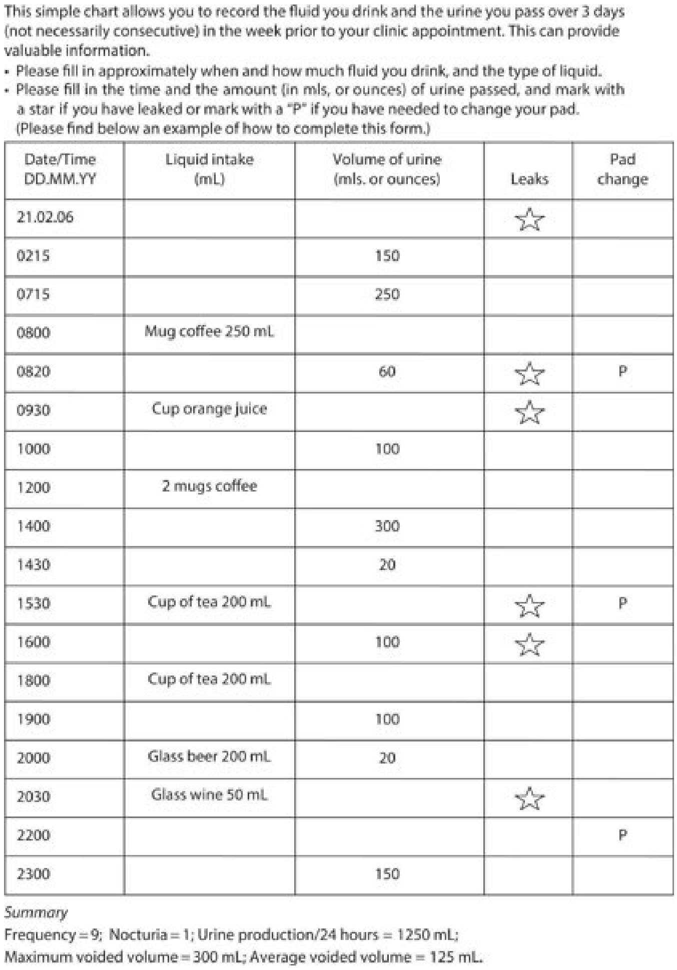
2D: Other Relevant Examinations/Signs [2]

The following general examinations and signs may be relevant:

1. *Neurological signs*: For patients with possible neurogenic lower urinary tract or pelvic floor dysfunction, there should be particular note of those neurological signs related to S2–S4, but these should be complemented by a more general neurological examination as indicated.
2. *Abdominal signs*: Among numerous possible abdominal signs are the following:
   a. *Bladder fullness/retention*: The bladder may be felt by abdominal palpation or suprapubic percussion.
   b. *Other abdominal masses*: Or distension (e.g., ascites).
   c. *Scars*: Indicating previous relevant surgery or traumas.
   d. *Renal area*: Examination for tenderness and masses.

2E: Frequency Volume Chart/Bladder Diary

1. *Frequency volume chart (FVC)*: The recording of the time of each micturition and the volume voided for at least 24 hours. Two or three days of recording (not necessarily consecutive) will generally provide more useful clinical data.
   Information obtained will confirm the following:
   a. *Daytime urinary frequency*: Number of voids by day (wakeful hours including last void before sleep and first void after waking and rising).
   b. *Nocturnal frequency/nocturia*: Number of times sleep is interrupted by the need to micturate. Each void is preceded and followed by sleep.
   c. *24-hour frequency*: Total number of daytime voids and episodes of nocturia during a specified 24-hour period.
   d. *24-hour urine production*: Summation of all urine volumes voided in 24 hours.
   e. *Maximum voided volume*: Highest voided volume recorded.
   f. *Average voided volume*: Summation of volumes voided divided by the number of voids.
   g. *Median functional bladder capacity*: Median maximum voided volume in everyday activities.



This simple chart allows you to record the fluid you drink and the urine you pass over 3 days (not necessarily consecutive) in the week prior to your clinic appointment. This can provide valuable information.

- Please fill in approximately when and how much fluid you drink, and the type of liquid.
- Please fill in the time and the amount (in mls, or ounces) of urine passed, and mark with a star if you have leaked or mark with a "P" if you have needed to change your pad. (Please find below an example of how to complete this form.)

Date/Time DD.MM.YY	Liquid intake (mL)	Volume of urine (mls. or ounces)	Leaks	Pad change
21.02.06			☆	
0215		150		
0715		250		
0800	Mug coffee 250 mL			
0820		60	☆	P
0930	Cup orange juice		☆	
1000		100		
1200	2 mugs coffee			
1400		300		
1430		20		
1530	Cup of tea 200 mL		☆	P
1600		100	☆	
1800	Cup of tea 200 mL			
1900		100		
2000	Glass beer 200 mL	20		
2030	Glass wine 50 mL		☆	
2200				P
2300		150		

Summary
Frequency = 9; Nocturia = 1; Urine production/24 hours = 1250 mL;
Maximum voided volume = 300 mL; Average voided volume = 125 mL.

Figure C.2 Example of a bladder diary.

   h. *Polyuria*: Excessive excretion of urine resulting in profuse and frequent micturition [3]. It has been defined as over 40 mL/kg body weight during 24 hours or 2.8 L urine for a woman weighing 70 kg [22].
   i. *Nocturnal urine volume*: Cumulative urine volume from voids after going to bed with the intention of sleeping to include the first void at the time of waking with the intention of rising (excludes last void before sleep).
   j. *Nocturnal polyuria*: Excess (over 20%–30%—age dependent) proportion of urine excretion (nocturnal voided volume/total 24-hour voided volume · 100%) occurs at night (or when patient is sleeping).[*]

2. *Bladder diary*: Adds to the FVC mentioned earlier, the fluid intake, pad usage, incontinence episodes, and the degree of incontinence. Episodes of urgency and sensation might also be recorded, as might be the activities performed during or immediately preceding the involuntary loss of urine. Additional information obtained from the bladder diary involves *severity of incontinence in terms of leakage episodes and pad usage* (Figure C.2).

2F: Pad Testing

Pad testing is the quantification of the amount of urine lost over the duration of testing, by measuring the increase in the weight of the perineal pads (weighed pre- and posttesting) used. This may give a guide to the severity of incontinence. Different durations from a short (1 hour) test to a 24- and 48-hour tests have been used with provocation varying from normal everyday activities to defined regimens.

SECTION 3: URODYNAMIC INVESTIGATIONS AND ASSOCIATED PELVIC IMAGING

Urodynamics: Functional study of the lower urinary tract.

Clinical sequence of testing: Urodynamic investigations generally involve a woman attending with a comfortably full bladder for free (no catheter) uroflowmetry and postvoid residual urine volume (PVR) measurement prior to filling and voiding (with catheter) cystometry.

3A: Uroflowmetry

1. *Ideal conditions for free (or spontaneous—no catheter) uroflowmetry*: Ideally, all free uroflowmetry studies should be performed in a completely private uroflowmetry room. Most modern uroflowmeters have a high degree of accuracy (±5%) though regular calibration is important [23].
2. *Urine flow*: Voluntary urethral passage of urine that may be
   a. *Continuous*: No interruption to flow.
   b. *Intermittent*: Flow is interrupted.
3. *Flow rate*: Volume of urine expelled via the urethra per unit time. It is expressed in milliliter per second [2,3].
4. *Voided volume (mL)*: Total volume of urine expelled via the urethra [2,3].
5. *Maximum (urine) flow rate (MUFR–mL/s)–*Q_{max}: Maximum measured value of the flow rate [2,3] correcting for artifacts [3].
6. *Flow time (s)*: The time over which measurable flow actually occurs [2,3].
7. *Average (urine) flow rate (AUFR–mL/s)–*Q_{ave}: Voided volume divided by the flow time [2,3] (Figure C.3).
8. *Voiding time (s)*: This is the total duration of micturition, that is, includes interruptions. When voiding is completed without interruption, voiding time is equal to flow time [2,3].
9. *Time to maximum flow (s)*: This is the elapsed time from the onset of urine flow to maximum urine flow [2,3].
10. *Interpretation of the normality of free uroflowmetry*: Because of the strong dependency of urine flow rates on voided volume [24], they are best referenced to nomograms where the cutoff for abnormally slow MUFR and AUFR has been determined and validated [23,25,26] as under the 10th centile of the respective Liverpool nomogram [26]. References to a specific urine flow rate as the lower limit of normal provided a specific volume has been voided require further validation studies [27] (Figure C.4).

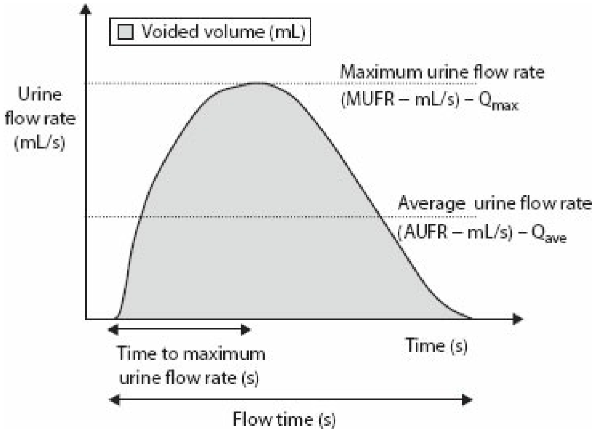


Figure C.3 A schematic representation of urine flow over time.

3B: PVR (Urine Volume)

1. *PVR*: Volume of urine left in the bladder at the completion of micturition [1,3].
2. *Conditions for PVR measurement*: PVR reading is erroneously elevated by delayed measurement due to additional renal input (1–14 mL/min) into bladder volume [28]. Ultrasonic techniques (transvaginal, abdominal, Doppler planimetry) allow immediate (within 60 seconds of micturition) measurement [28]. A short plastic female catheter provides the most effective

bladder drainage for PVR measurement [28].

3. *Assessment of normality of PVR*: Quoted upper limits of normal may reflect the accuracy of measurement. Studies using "immediate" PVR measurement (e.g., transvaginal ultrasound) suggest an upper limit of normal of 30 mL [29]. Studies using urethral catheterization (up to 10 minute delay) quote higher upper limits of normal of 50 mL [27] or 100 mL [29]. An isolated finding of a raised PVR requires confirmation before being considered significant.

3C: Cystometry: General [2,3,29]

1. *Cystometry*: Measurement of the pressure/volume relationship of the bladder during filling and/or pressure–flow study during voiding [2,30].
2. *Cystometrogram*: Graphical recording of the bladder pressure(s) and volume(s) over time [2,30].
3. *Urodynamic studies*: These usually take place in a special clinical room (urodynamic laboratory) and involve (artificial) bladder filling with a specified liquid at a specified rate [3,30].

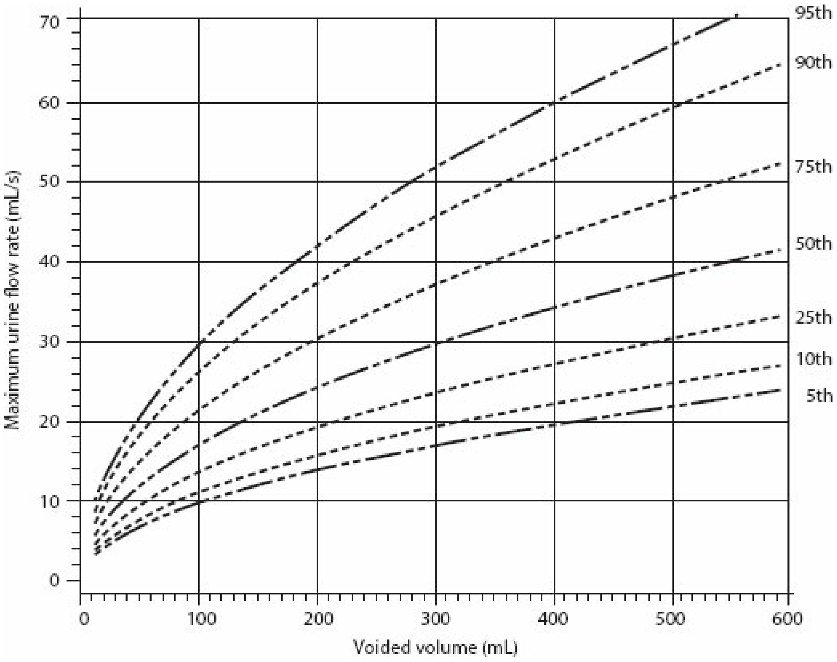

Figure C.4 Liverpool nomogram for maximum urine flow rate in women. Equation: Ln (maximum urine flow rate) = 0.511 + 0.505 · Ln (voided volume), root mean square error = 0.340. (From Van Kerrebroeck P et al., *Neurourol Urodyn*, 21, 179, 2002; Fantl JA et al., *Am J Obstet Gynecol*, 145, 1017, 1982.)

4. *Conditions for cystometry [2,3,30]*
   a. *Pressures*: All systems are zeroed at atmospheric pressure.
   b. *External pressure transducers*: Reference point is the superior edge of the pubic symphysis.
   c. *Catheter-mounted transducers*: Reference point is the transducer itself.
   d. *Initial bladder volume*: Bladder should be empty.
   e. *Fluid medium*: Usually water or saline (or contrast if radiology involved).
   f. *Temperature of fluid*: Should ideally be warmed to body temperature.
   g. *Position of patient*: Sitting position is more provocative for abnormal detrusor activity than the supine position. At some point in the test, filling might desirably take place with the patient standing.
   h. *Filling rate*: The filling rate, including any changes during testing, should be noted on the urodynamic report.
5. *Intravesical pressure (P_{ves})*: The pressure within the bladder [1–3].

6. *Abdominal pressure (P_{abd})*: The pressure surrounding the bladder. It is usually estimated from measuring the rectal pressure, though vaginal and infrequently the pressure though a bowel stoma can be measured as an alternative. The simultaneous measurement of P_{abd} is essential for the interpretation of the P_{ves} trace [2,3]. Artifacts on the detrusor pressure (P_{det}) trace may be produced by an intrinsic rectal contraction.
7. *Detrusor pressure*: The component of intravesical pressure that is created by forces in the bladder wall (passive and active). It is estimated by subtracting P_{abd} from P_{ves} [3].
8. *Ambulatory urodynamics*: These investigations are a functional test of the lower urinary tract, performed outside the clinical setting, involving natural filling and reproducing the woman’s everyday activities.

3D: Filling Cystometry [2,3,30]

1. *Filling cystometry*: This is the pressure/volume relationship of the bladder during bladder filling [1,2]. It begins with the commencement of filling and ends when a “permission to void” is given by the urodynamicist [3].
2. *Aims of filling cystometry*: These are to assess bladder sensation, bladder capacity, detrusor activity, and bladder compliance [2,3].
3. *Bladder sensation during filling cystometry*: This is usually assessed by questioning the woman in relation to the fullness of the bladder during cystometry [2].
   a. *First sensation of bladder filling*: The feeling when the woman first becomes aware of bladder filling [3].
   b. *First desire to void* [2]: The first feeling that the woman may wish to pass urine.

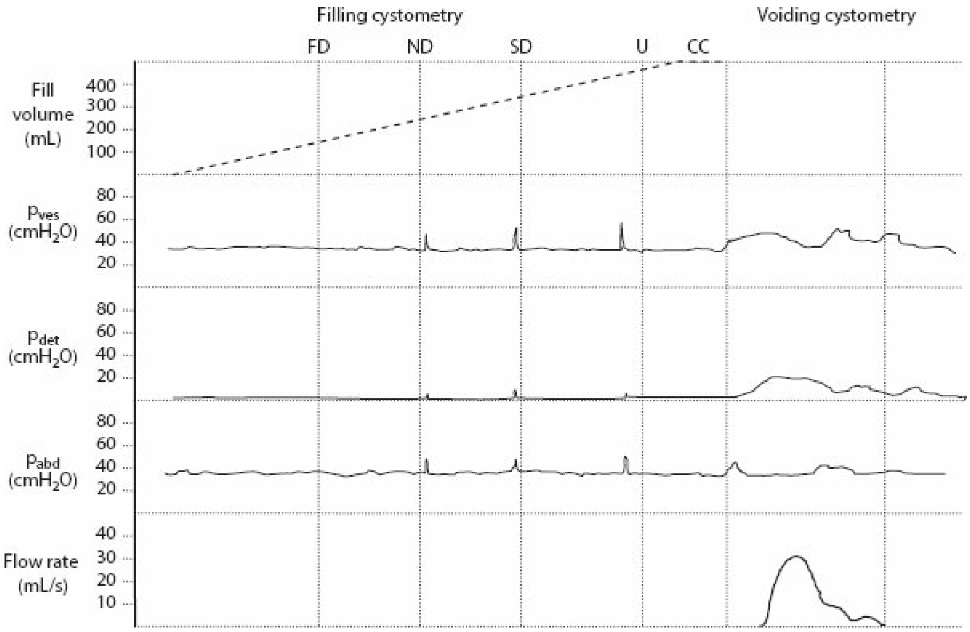

Figure C.5 Filling cystometry—normal detrusor function. Forty-eight-year-old female with urinary frequency. No phasic activity during filling. Voided with normal urine flow rate at normal detrusor voiding pressure. Normal study. *Abbreviations*: FD, first desire to void; ND, normal desire to void; SD, strong desire to void; U, urgency; CC, cystometric capacity (permission to void given).

   c. *Normal desire to void*: The feeling that leads the woman to pass urine at the next convenient moment, but voiding can be delayed if necessary.
   d. *Strong desire to void*: The persistent desire to pass urine without the fear of leakage.
   e. *Urgency*: Sudden, compelling desire to pass urine that is difficult to defer [3]*
   f. *Bladder oversensitivity—also referred to as either “increased bladder sensation” [3] or “sensory urgency” ([2] now obsolete)*: Increased perceived bladder sensation during bladder

filling with an early first desire to void; an early strong desire to void, which occurs at low bladder volume; a low maximum cystometric bladder capacity (*3D[4b]*); no abnormal increases in P_{det}.

g. *Reduced bladder sensation*: Bladder sensation is perceived to be diminished during filling cystometry.

h. *Absent bladder sensation*: The woman reports no bladder sensation during filling cystometry (Figure C.5).

i. *Pain*: The complaint of pain during filling cystometry is abnormal. Its site, character, and duration should be noted.

4. *Bladder capacity during filling cystometry*

a. *Cystometric capacity*: Bladder volume at the end of filling cystometry, when "permission to void" is usually given by the urodynamicist. This end point and the level of the woman's bladder sensation at that time, for example, "normal desire to void," should be noted.

b. *Maximum cystometric capacity*: In patients with normal sensation, this is the bladder volume when she can no longer delay micturition.

5. *Detrusor function during filling cystometry*

a. *Normal (previously "stable") detrusor function*: There is little or no change in detrusor pressure with filling. There are no involuntary phasic contractions despite provocation with activities such as postural changes, coughing, hearing the sound of running water, handwashing, etc.

b. *Detrusor overactivity*: The occurrence of involuntary detrusor contractions during filling cystometry. These contractions, which may be spontaneous or provoked, produce a wave form of variable duration and amplitude on the cystometrogram. The contractions may be phasic or terminal. Symptoms, for example, urgency and/or urgency incontinence, may or may not occur. If a relevant neurological cause is present, then *neurogenic detrusor overactivity* is noted; otherwise, *idiopathic detrusor overactivity* should be the term used (Figure C.6).

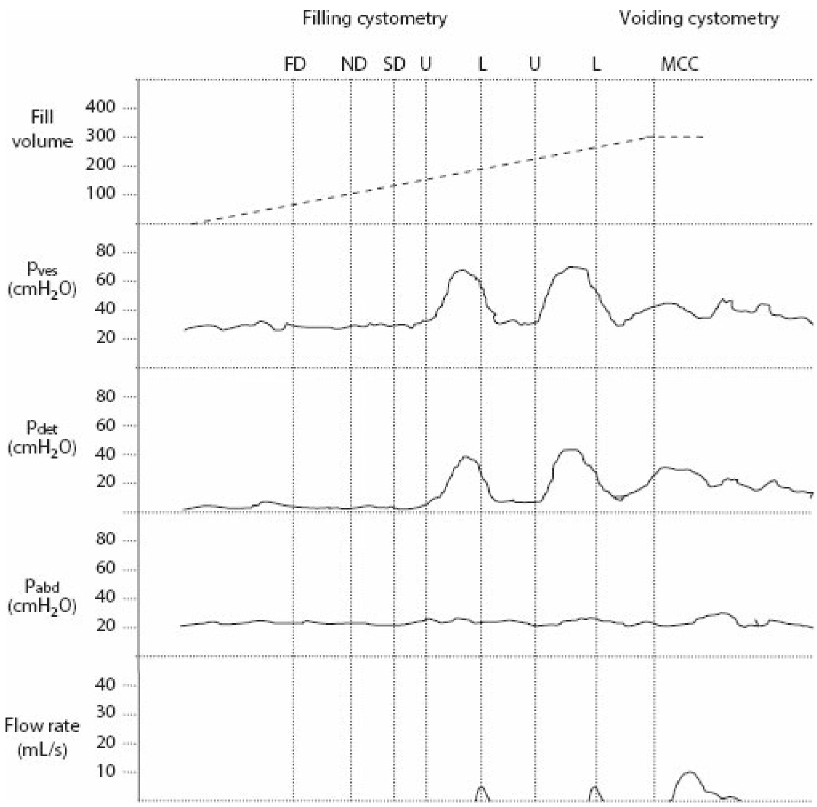

Figure C.6 Filling cystometry—detrusor overactivity. Fifty-two-year-old female with urgency and frequency. Phasic detrusor activity during filling. Leakage is associated with urgency and detrusor contractions.

Abbreviations: FD, first desire to void; ND, normal desire to void; SD, strong desire to void; U, urgency; L, leakage; MCC, maximum cystometric capacity.

   c. *Neurogenic detrusor overactivity*: This is where there is detrusor overactivity and there is evidence of a relevant neurological disorder.

6. *Bladder compliance [2,3]*: This describes the relationship between a change in bladder volume and change in P_{det} [3]. Compliance is calculated by dividing the volume change ($\otimes V$) by the change in P_{det} ($\otimes P_{det}$) during that change in bladder volume. ($C = \otimes V/\otimes P_{det}$). Compliance is expressed as mL/cmH_2O. Bladder compliance can be affected by the following:
   a. *Bladder filling*: Faster filling is more provocative. An artifact may be produced, which settles when filling is interrupted.
   b. *Contractile/relaxant properties of the detrusor*: For example, postradiation changes of the detrusor wall.
   c. *Starting point for compliance calculations [3]*: Usually, the P_{det} at the start of bladder filling and the corresponding bladder volume (usually zero).
   d. *End point for compliance calculations [3]*: The P_{det} (and corresponding bladder volume) at cystometric capacity or immediately before the start of any detrusor contraction that causes significant leakage (and therefore causes the bladder volume to decrease, affecting compliance calculations). Both points are measured excluding any detrusor contraction.

3E: Urethral Function during Filling Cystometry (Filling Urethrocystometry)

1. *Urethral pressure measurement [2,3,30]*: Urethral pressure and urethral closure pressure are idealized concepts that represent the ability of the urethra to prevent leakage. Urethral pressure is currently measured by a number of different techniques that don't tend to have consistent results, either between methods or for a single method [31]. For example, the effect of catheter rotation will be relevant when urethral pressure is measured by a catheter-mounted transducer. Urethral pressure might, nonetheless, be measured as follows:
   - At rest, with the bladder at a given volume
   - During coughing or straining
   - During the process of voiding

   a. *Urethral pressure (intraluminal)*: This is the fluid pressure needed to just open a closed urethra.
   b. *Urethral pressure profile (UPP)*: This is a graph indicating the intraluminal pressure along the length of the urethra.
      - Resting UPP: The bladder and subject are at rest.
      - Stress UPP: Defined applied stress (e.g., cough, strain, Valsalva).

      All systems are zeroed at atmospheric pressure. For external transducers, the reference point is the superior edge of the symphysis pubis. For catheter-mounted transducers, the reference point is the transducer itself. P_{ves} should be measured to exclude a simultaneous detrusor contraction. Methodology should be noted [2] including patient position, catheter type, transducer orientation, fluid and rate of infusion (if fluid-filling system), bladder volume, and rate of catheter withdrawal.
   c. *Maximum urethral pressure*: Maximum pressure in the UPP
   d. *Urethral closure pressure profile (UCPP)*: The relevant pressure is the urethral closure pressure (urethral pressure minus the P_{ves}).
   e *Maximum urethral closure pressure (MUCP)*: Maximum pressure in the UCPP, that is, the maximum difference between the urethral pressure and the P_{ves}.
   f. *Functional profile length*: The length of the urethra along which the urethral pressure exceeds P_{ves} in a woman.
   g. *Functional profile length (on stress)*: The length over which the urethral pressure exceeds the P_{ves} on stress.
   h. *Pressure "transmission" ratio*: This is the increment in urethral pressure on stress as a percentage of the simultaneously recorded increment in P_{ves}. For stress profiles obtained

during coughing, pressure transmission ratios can be obtained at any point along the urethra. If single values are given, the position in the urethra should be stated. If several transmission ratios are defined at different points along the urethra, a pressure transmission "profile" is obtained. During "cough profiles," the amplitude of the cough should be stated if possible.

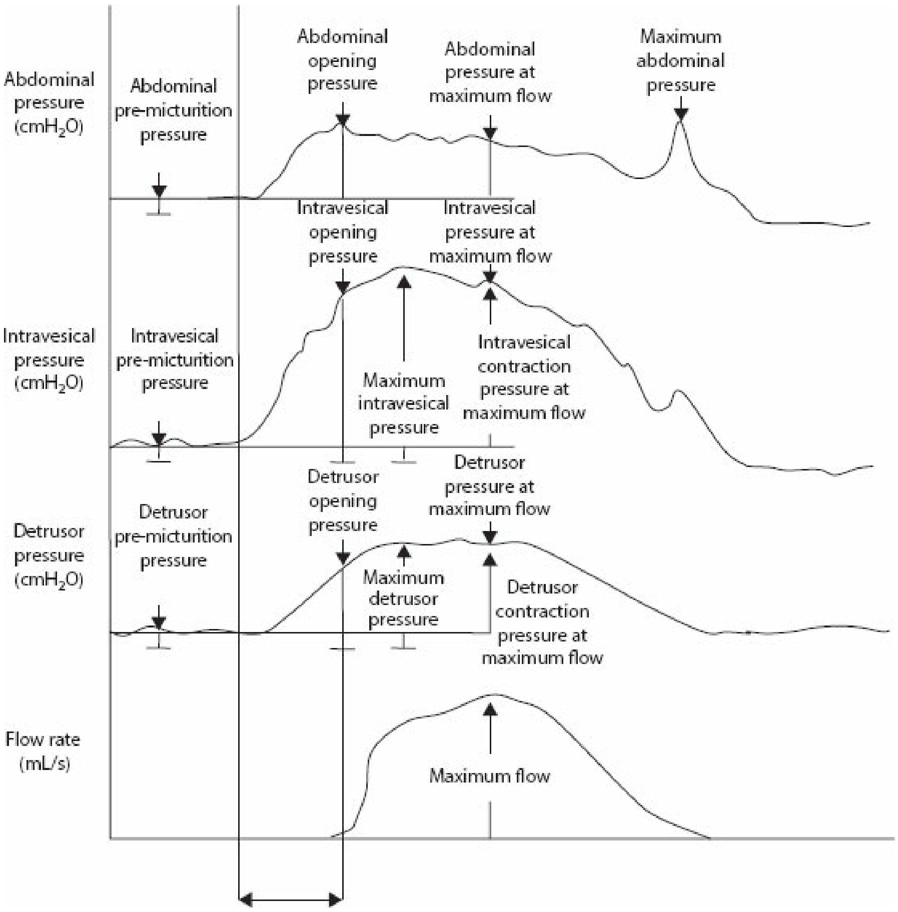
2. *Urethral closure mechanism [3]*
    a. *Normal urethral closure mechanism*: A positive urethral closure pressure is maintained during bladder filling even in the presence of increased P_{abd}, although it may be overcome by detrusor overactivity.
    b. *Incompetent urethral closure mechanism*: Leakage of urine occurs during activities that might raise intra-abdominal pressure in the absence of a detrusor contraction.
    c. *Urethral relaxation incompetence ("urethral instability")*: Leakage due to urethral relaxation in the absence of raised P_{abd} or a detrusor contraction.
    d. *Urodynamic stress incontinence*: This is the involuntary leakage of urine during filling cystometry, associated with increased intraabdominal pressure, in the absence of a detrusor contraction.
3. *Leak point pressures [2,32,33]*: There are two types of leak point pressure measurement. The pressure values at leakage should be measured at the moment of leakage.
    a. *Detrusor leak point pressure (DLPP)*: This a static test. The pressure is the lowest value of the P_{det} at which leakage is observed in the absence of increased P_{abd} or a detrusor contraction. High DLPP (e.g., over 40 cmH_2O [32]) may put patients at risk for upper urinary tract deterioration or secondary damage to the bladder in the cases of known underlying neurological disorders such as paraplegia or multiple sclerosis. There are no data on any correlation between DLPP and upper tract damage in nonneurogenic patients.
    b. *Abdominal leak point pressure (ALPP)*: This is a dynamic test. It is the lowest value of the intentionally increased P_{ves} that provokes urinary leakage in the absence of a detrusor contraction [33]. The increase in pressure can be induced by a cough (CLPP) or Valsalva (VLPP). Multiple estimates at a fixed bladder volume (200–300 mL) are desirable. Catheter size will influence LPP values and should be standardized. LPP values might also be affected by many other factors such as the technique to confirm urine loss, location of catheter, type of pressure sensor, bladder volume, rate of bladder filling, and patient position. A low ALPP is suggestive of poor urethral function.[*]

3F: Voiding Cystometry (Pressure–Flow Studies)

1. *Voiding cystometry*: This is the pressure/volume relationship of the bladder during micturition [1]. It begins when the "permission to void" is given by the urodynamicist and ends when the woman considers her voiding has finished [3]. Measurements to be recorded should be the intravesical, intraabdominal, and detrusor pressures and the urine flow rate.
2. *Measurements during voiding cystometry [2,3,30]*
    a. *Premicturition pressure*: The pressure recorded immediately before the initial isovolumetric contraction.
    b. *Opening time*: The time elapsed from initial rise in pressure to the onset of flow. This is the initial isovolumetric contraction period of micturition. It reflects the time taken for the fluid to pass from the point of pressure measurement to the uroflow transducer. Flow measurement delay should be taken into account when measuring the opening time.
    c. *Opening pressure*: The pressure recorded at the onset of measured flow (consider time delay).
    d. *Maximum pressure*: Maximum value of the measured pressure.
    e. *Pressure at maximum flow*: Pressure recorded at maximum measured flow rate.
    f. *Closing pressure*: Pressure recorded at the end of measured flow.
    g. *Contraction pressure at maximum flow*: This is the difference between pressure at maximum flow and the premicturition pressure.
    h. *Flow delay*: This is the delay in time between a change in pressure and the corresponding change in measured flow rate.

Figure C.7 shows a schematic diagram of voiding cystometry.

3. *Detrusor function during voiding [2,3]*
   a. *Normal detrusor function*: Normal voiding in women is achieved by an initial (voluntary) reduction in intraurethral pressure (urethral relaxation) [34]. This is generally followed by a continuous detrusor contraction that leads to complete bladder emptying within a normal time span. Many women will void successfully (normal flow rate and no PVR) by urethral relaxation alone, without much of a rise in P_{det} [35]. The amplitude of the detrusor contraction will tend to increase to cope with any degree of bladder outflow obstruction [36].



Abdominal pressure (cmH$_2$O)
Abdominal pre-micturition pressure
Abdominal opening pressure
Abdominal pressure at maximum flow
Maximum abdominal pressure
Intravesical opening pressure
Intravesical pressure at maximum flow
Intravesical pressure (cmH$_2$O)
Intravesical pre-micturition pressure
Maximum intravesical pressure
Intravesical contraction pressure at maximum flow
Detrusor opening pressure
Detrusor pressure at maximum flow
Detrusor pressure (cmH$_2$O)
Detrusor pre-micturition pressure
Maximum detrusor pressure
Detrusor contraction pressure at maximum flow
Flow rate (mL/s)
Maximum flow

Figure C.7 A schematic diagram of voiding cystometry.

   b. *Detrusor underactivity*: Detrusor contraction of reduced strength and/or duration, resulting in prolonged bladder emptying and/or a failure to achieve complete bladder emptying within a normal time span.
   c. *Acontractile detrusor*: The detrusor cannot be observed to contract during urodynamic studies, resulting in prolonged bladder emptying and/or a failure to achieve complete bladder emptying within a normal time span. The term "areflexia" has been used where there is a neurological cause but should be replaced by *neurogenic acontractile detrusor*.

3G: Urethral Function during Voiding Cystometry (Voiding Urethrocystometry) [2,3,30]

This technique may assist in determining the nature of urethral obstruction to voiding. Pressure is recorded in the urethra during voiding. This may be at one specific point, for example, high-pressure zone, or it may be measured as a profile. A voiding urethral pressure profile (VUPP) uses a similar technique to that described earlier for the UPP measured during bladder filling. Simultaneous P_{ves} measurement is required. Localization of the site of the intraurethral pressure measurement is desirable.

1. *Normal urethral function*: The urethra opens and is continuously relaxed to allow micturition at a normal pressure, urine flow, and PVR.*
2. *Bladder outflow obstruction*: This is the generic term for obstruction during voiding. It is a reduced urine flow rate and/or presence of a raised PVR and an increased P_{det}.† It is usually diagnosed by studying the synchronous values of urine flow rate and P_{det} and any PVR measurements. A urethral stricture or obstruction due to higher degrees of uterovaginal prolapse or obstructed voiding after stress incontinence procedures is among the possible causes.
3. *Dysfunctional voiding*: This is characterized by an intermittent and/or fluctuating flow rate due to involuntary intermittent contractions of the periurethral striated or levator muscles during voiding in neurologically normal women. This type of voiding may also be the result of an acontractile detrusor (abdominal voiding) with EMG or videourodynamics required to distinguish between the two entities.
4. *Detrusor sphincter dyssynergia*: This is incoordination between detrusor and sphincter during voiding due to a neurological abnormality (i.e., detrusor contraction synchronous with contraction of the urethral and/or periurethral striated muscles). This is a feature of neurological voiding disorders. Neurological features should be sought. Videocystourethrography (VCU)–(radiological imaging [VCU]) is generally valuable to conclude this diagnosis.

3H: Ultrasound Imaging [38]

1. *Ultrasound in urogynecology*: Ultrasound has become an increasingly frequent adjunct investigation in urogynecology and female urology both in the office and in the urodynamic laboratory.
2. *Modalities in current routine clinical use*
   a. *Perineal*: Curved array probe applied to the perineum. This term incorporates transperineal and translabial ultrasound.
   b. *Introital*: Sector probe applied to the vaginal introitus.
   c. *Transvaginal (TV)*: Intravaginal curvilinear, linear array, or sector scanning.
   d. *Transabdominal (TA)*: Curvilinear scanning applied to the abdomen.
3. *Current routine possible uses of ultrasound in urogynecology and female urology*
   a. *Bladder neck descent/mobility/opening*
      - Position of bladder neck at rest and on Valsalva.‡

NB: Ideally, the Valsalva should be standardized, but it is appreciated that at present, a reliable noninvasive method is lacking. Consensus has not been reached on criteria for excessive bladder neck mobility nor the relationship of this finding to a diagnosis of urodynamic stress incontinence [37].

- Position of bladder neck during pelvic floor contraction.
- Retrovesical angle: That is, angle between proximal urethra and trigonal surface of the bladder. o Urethral rotation: That is, rotation of the proximal urethra on Valsalva.§
- Angle gamma: That is, angle defined by lines from the inferoposterior symphyseal margin to the bladder neck at rest and on Valsalva.¶

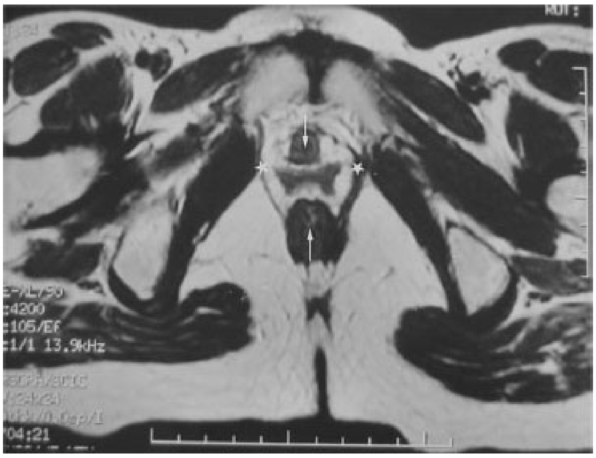


Figure C.8 Axial T2-weighted image of the pelvic floor of a healthy nulliparous Caucasian woman showing measurement of the anteroposterior diameter of the genital hiatus between the arrows from midurethra to midanus at the level of the lower border of the pubic symphysis. Transverse diameter (width) of the levator hiatus was measured between the stars at the point of maximum extension of the levator muscles at the level of the urinary bladder and proximal urethra. (From Rizk DE et al., *Am J Obstet Gynecol*, 191, 83, 2004.)

- Urethral funneling: That is, opening of the proximal third of the urethra during coughing or on Valsalva.[*]
- Urine loss: Full urethral opening during coughing, Valsalva,[†]

Figure C.8 shows a number of possible measurements using MRI.

a. *PVRs*: See Section *3B*.
b. *Intercurrent pelvic pathology*: For example, uterine and adnexal pathology.
c. *Uterine version*: Anteverted or retroverted; flexion at the level of the isthmus [39].[‡]
d. *Bladder abnormalities*: For example, tumor and foreign body.
e. *Urethral abnormality*: For example, diverticulum.
f. *Postoperative findings*: For example, bladder neck position and mobility, position of meshes, tapes, or implants.
g. *Pelvic floor/levator defects*: Bladder neck elevation during pelvic floor contraction.
h. *Descent of pelvic organs*: Visualization of descent of the bladder, uterine cervix, and rectum during Valsalva and coughing.

4. *3D and 4D ultrasound*: The potential of 3D ultrasound in urogynecology and female urology is currently being researched with validated applications likely to be included in future updates of this report and/or separate ultrasound reports. Applications with the most current research include (1) major morphological abnormalities such as levator defects [40] and (2) excessive distensibility of the puborectalis muscle and levator hiatus ("ballooning"—[41]). The additional diagnostic potential of 4D (i.e., the addition of movement) ultrasound awaits clarification by further research.
5. *Other assessments*: Synchronous ultrasound screening of the bladder and/or urethra and measurement of the bladder and P_{abd} during filling and voiding cystometry.
6. *Anal ultrasound (endosonography) [42]*: This is the gold standard investigation in the assessment of anal sphincter integrity. There is a high incidence of defecatory symptoms in women with anal sphincter defects.

3I: Radiological Imaging

1. *Modalities in current routine clinical use*
   a. *VCU [43]*: Synchronous radiological screening of the bladder and measurement of the bladder and P_{abd} during filling and voiding cystometry. When indicated for complex cases, VCU allows direct observation of the effects of bladder events, the position and conformation

of the bladder neck in relation to the pubic symphysis, bladder neck closure during rest and stress, diverticula of the bladder and urethra, vesicovaginal and urethrovaginal fistulae, vesicoureteric reflux, and voiding events.

2. *Other modalities*: None of these are office or urodynamic laboratory based.
   a. *Intravenous urography [43]*: This provides an anatomical outline of the urinary tract including a nephrogram prior to passage of the contrast to the calyces, renal pelvis, ureter, and bladder.
   b. *Micturating cystogram [44]*: The principal use is the detection of vesicoureteric reflux, some fistulae, and diverticula.
   c. *Defecography [42]*: This demonstrates normal anatomy of the anorectum as well as disorders of rectal evacuation. Barium paste is inserted rectally prior to defecation over a translucent commode. Measurement of the anorectal angle is allowed with evidence of the presence, size, or emptying of any rectocele. Enteroceles, rectal intussusception, and mucosal prolapse might be diagnosed as well as a spastic pelvic floor (anismus).
   d. *Colporectocystourethrography (colpocystodefecography) [43]*: This involves the instillation of radiopaque media into the bladder, vagina, and rectum simultaneously for pelvic floor evaluation with images obtained during rest and straining.

3J: Magnetic Resonance Imaging [45,46]

1. *MRI in urogynecology and female urology*
   MRI *provides* the opportunity to examine the soft tissue structures of the pelvic support apparatus in toto. It is noninvasive, has excellent soft tissue contrast resolution without exposure to ionizing radiation, and allows the study of function of pelvic floor structures under different dynamic conditions such as increased P_{abd} during Valsalva [45,46]. Several anatomical landmarks used for pelvic measurements are also easily identified in MRI and most measurements are thus highly reproducible. Currently, the clinical value of these examinations is still under investigation with its impact on therapeutic decisions not yet fully evaluated.
2. *Current possible measurements using MRI in urogynecology and female urology [45,46]*
   a. *Bladder neck and cervical descent/mobility*
      – Position of bladder neck and cervix at rest and on Valsalva.
      – Pubococcygeal line: A line extending from the inferior border of the pubic symphysis to the last joint of the coccyx. Bladder neck or cervical descent >2 cm below this line with straining indicates weakness of the pelvic floor. If alternative landmarks are used in scientific papers, they should be clearly described.
   b. *Intercurrent pelvic pathology*: For example, fibroids and ovarian pathology.
   c. *Uterine version*: Anteverted or retroverted and flexion at the isthmus [47].
   d. *Bladder abnormalities*: For example, tumor and foreign body.
   e. *Urethral abnormality*: For example, diverticulum.
   f. *Postoperative findings*: For example, bladder neck mobility.
   g. *Pelvic floor measurements/levator defects*: Assessment of the configuration of pelvic floor muscles, in particular, the levator ani.
   h. *Descent of pelvic organs*.

NB: Diagnostic ability may be enhanced by the use of 3D MRI. New techniques with high-speed sequence of pictures allow a functional MRI.

DIAGNOSES (MOST COMMON)*

This report again [2,3] highlights the need to base diagnoses for female pelvic floor dysfunction on the correlation between a woman’s symptoms, signs, and any relevant diagnostic investigations.

A: Urodynamic Stress Incontinence

Definition: As noted in Section *3E(2d)*, this diagnosis by *symptom, sign, and urodynamic investigations* involves the finding of involuntary leakage during filling cystometry, associated with increased intra-abdominal pressure, in the absence of a detrusor contraction.[†]

B: Detrusor Overactivity

1. *Definition*: As noted in Section *3D(5b)*, this diagnosis by *symptoms and urodynamic investigations* is made in women with lower urinary tract symptoms (more commonly OAB—type symptoms—section 1B[4]) when involuntary detrusor muscle contractions occur during filling cystometry.[‡]

C. Bladder Oversensitivity

Definition: Bladder oversensitivity, a diagnosis made by *symptoms and urodynamic investigations*, is more likely to occur in women with symptoms of frequency and nocturia and a voiding diary showing a clearly reduced average voided volume. Also referred to as "increased bladder sensation" [3], bladder oversensitivity replaces the now obsolete term of "sensory urgency" [50,51]. As noted in Section *3D(3f)*, it can be defined as an increased perceived bladder sensation during bladder filling *1C(1)* with specific cystometric findings of (1) an early first desire to void *3D(3b)*; (2) an early strong desire to void, which occurs at low bladder volume *3D(3d)*; (3) a low maximum cystometric bladder capacity *3D(4b)*; and (4) no abnormal increases in P_{det} [50,51]. Specific bladder volumes at which these findings occur will vary in different populations. There should be no known or suspected UTI.[§]

D: Voiding Dysfunction

1. *Definition*: Voiding dysfunction, a diagnosis by *symptoms and urodynamic investigations*, is defined as abnormally slow and/or incomplete micturition [53]. Abnormal slow urine flow rates and abnormally high postvoid residuals, the basis of this diagnosis, are outlined in Sections *3A(10)* and *3B(3)*. This diagnosis should be based on a repeated measurement to confirm abnormality.[*]
2. *Further evaluation—pressure–flow studies (voiding cystometry)*: Pressure–flow studies are indicated to evaluate the cause of any voiding dysfunction. Some possible causes have been already defined: *3F(3b) detrusor underactivity*, *3F(3c) acontractile detrusor*, and *3G(2) bladder outflow obstruction*.
3. *Alternative presentations*
   a. *Acute retention of urine [3]*: This is defined as a generally (but not always) painful, palpable, or percussible bladder, when the patient is unable to pass any urine when the bladder is full.
   b. *Chronic retention of urine*: This is defined as a nonpainful bladder, where there is a chronic high PVR.[†]

E: POP

Definition: This diagnosis *2B(1)* by *symptoms and clinical examination, assisted by any relevant imaging*, involves the identification of descent of one or more of the anterior vaginal wall (central, paravaginal, or combination cystocele), posterior vaginal wall (rectocele), the uterus (cervix), or the apex of the vagina (vaginal vault or cuff scar) after hysterectomy.[‡]

F: Recurrent UTIs

Definition: This diagnosis by *clinical history* assisted by *the results of diagnostic tests* involves the determination of the occurrence of at least three symptomatic and medically diagnosed UTIs over the previous 12 months[§]

[*] This report is reproduced, in a slightly abridged form, by kind permission of IUGA, Wiley, ICS, and Springer Science+Business Media, from Haylen, B.T., An international urogynecological association (IUGA)/international continence society (ICS) joint report on the terminology for female pelvic floor dysfunction, *Neurourology and Urodynamics*, 2010;29:4–20.

[*] “Continence” is defined as voluntary control of bladder and bowel function.

[†] “Urgency” replaces “urge” as the “accepted” terminology for the abnormal rather than the normal phenomenon.

[‡] This is a common symptom, the mechanism of which has not been adequately researched. It is uncertain whether it should be linked to 1A(2) (stress urinary incontinence) or 1A(3) (urgency urinary incontinence).

[§] Traditionally, seven episodes of micturition during waking hours have been deemed as the upper limit of normal, though it may be higher in some populations [7].

[¶] It is common to void during the night when sleep is disturbed for other reasons—for example, insomnia and lactation—this does not constitute nocturia [8]. Each void is preceded and followed by sleep.

[**] The use of the word “sudden,” defined as “without warning or abrupt,” used in earlier definitions [2,8] has been subject to much debate. Its inclusion has been continued. Grading of “urgency” is being developed.

[*] Dyspareunia, the symptom most applicable to female pelvic floor dysfunction, will depend on many factors including a woman’s introital relaxation and/or pain tolerance and her partner’s hesitancy or insistence.

[†] Other symptoms of female sexual dysfunction including (1) decreased sexual desire, (2) decreased sexual arousal, (3) decreased orgasm, and (4) abstention are less specific for female pelvic floor dysfunction and will not be defined here. The Pelvic Organ Prolapse/Urinary Incontinence Sexual Questionnaire (PISQ) is a measure of sexual function in women with urinary incontinence or POP [9].

[‡] Symptoms of defecatory dysfunction are commonly associated with POP, particularly posterior vaginal prolapse.

[*] Rome II criteria for 1G(9) constipation: Complaint that bowel movements are infrequent (Using this definition, two or

more and three or more UTIs can occur with a prevalence of 19% and 11% respectively in women presenting with symptoms of pelvic floor dysfunction [57]. This then becomes a significant, generally intercurrent, diagnosis likely to require treatment additional to that planned for the other diagnoses found.

† The definitions of pelvic pain and especially chronic pelvic pain are being debated in several societies with a view to simplification and restructuring of the classification. The chronic (present for at least 3 months) pain syndromes have not been included till consensus is reached.

‡ The definitions of pelvic pain and especially chronic pelvic pain are being debated in several societies with a view to simplification and restructuring of the classification. The chronic (present for at least 3 months) pain syndromes have not been included till consensus is reached.

§ Commonly suggested criteria for (1) bacteriuria are >100,000 CFU/mL on voided specimen or >1000 CFU/mL on catheterized specimen and (2) pyuria are >10 WBC/mm^3. usually accompanied by symptoms such as increased bladder sensation, urgency, frequency, dysuria, urgency urinary incontinence, and/or pain in the lower urinary tract.

¶ Recurrent UTIs have not been consistently defined. There is the difficulty of balancing the practical clinical definition and the scientific one. Records of diagnostic tests are often inaccessible over the medium to longer term. With a bias toward the former category, a definition might be the presence of at least three medically diagnosed UTI over the previous 12 months. "Recur" strictly means to "occur again" or "be repeated." This would imply a minimum of (1) two or more or the more commonly accepted (2) three or more UTI in the previous 12 months. The previous UTIs should have resolved prior to a further UTI being diagnosed.

** Stress incontinence on prolapse reduction is a sign frequently alluded to but not properly defined to date. The means of reducing the prolapse will vary. The use of a Sims speculum is common. A pessary or ring might, at times, obstruct the urethra, giving a false negative for this sign.

* The ICS POP quantification system that describes the topographic position of six vaginal sites is the subject of a review by the IUGA Standardization and Terminology Committee with a view to simplification. These sites and the methodology behind the measurement format [15] have therefore not been included here. Consensus was not reached on inserting a valuation of the different prolapse stages into the report, though it will be subject to ongoing discussion, for example, considering stage 0 or 1 as different degrees of normal support and considering stage 2 or more, where the leading edge is at or beyond the hymen, as definite prolapse [17,18].

† Most gynecologists are generally comfortable with the terms cystocele, rectocele, vaginal vault prolapse, and enterocele. Coupled with the brevity of these terms and their clinical usage for up to 200 years [19], the inclusion of these terms is appropriate. Some regard it as important to surgical strategy to differentiate between a central cystocele (central defect with loss of rugae due to stretching of the subvesical connective tissue and the vaginal wall) and a paravaginal defect (rugae preserved due to detachment from the arcus tendineus fascia pelvis).

‡ Most gynecologists are generally comfortable with the terms cystocele, rectocele, vaginal vault prolapse, and enterocele. Coupled with the brevity of these terms and their clinical usage for up to 200 years [19], the inclusion of these terms is appropriate. Some regard it as important to surgical strategy to differentiate between a central cystocele (central defect with loss of rugae due to stretching of the subvesical connective tissue and the vaginal wall) and a paravaginal defect (rugae preserved due to detachment from the arcus tendineus fascia pelvis).

Some regard it as important to surgical strategy to differentiate between a central cystocele (central defect with loss of rugae due to stretching of the subvesical connective tissue and the vaginal wall) and a paravaginal defect (rugae preserved due to detachment from the arcus tendineus fascia pelvis). Enterocele formation can also occur in the presence of an intact uterus.

* More than 20% (young adults) to 33% (over 65 years) has been suggested as excessive [3].

* The use of the word "sudden," defined as "without warning or abrupt," used in earlier definitions [2,8] has been subject to much debate. Its inclusion has been continued. Grading of "urgency" is being developed..

* The correlation between MUCP and ALPP may depend on the catheter type used.

* The use of the word "sudden," defined as "without warning or abrupt, used in earlier definitions [2,8] has been subject to much debate. Its inclu sion has been continued. Grading of "urgency" is being developed.

† In scientific studies, consideration should be given to standardization of the Valsalva strength, for example, by using an intrarectal pressure transducer.

‡ In scientific studies, consideration should be given to standardization of the Valsalva strength, for example, by using an intrarectal pressure transducer.

§ In scientific studies, consideration should be given to standardization of the Valsalva strength, for example, by using an intrarectal pressure transducer.

¶ In scientific studies, consideration should be given to standardization of the Valsalva strength, for example, by using an intrarectal pressure transducer.

* In scientific studies, consideration should be given to standardization of the Valsalva strength, for example, by using an intrarectal pressure transducer.

† In scientific studies, consideration should be given to standardization of the Valsalva strength, for example, by using an intrarectal pressure transducer. bladder contraction, or micturition.

‡ The use of transvaginal ultrasound with an empty bladder optimizes this assessment [39].

* The most common diagnoses are those where there is evidence for a prevalence of 10% or more in women presenting with symptoms of pelvic floor dysfunction.

† This is the most common urogynecological diagnosis, occurring in up to 72% patients presenting for the first time [48]. This diagnosis may be made in the absence of the symptom of stress (urinary) incontinence in women who have the sign of occult or latent stress incontinence.

‡ The prevalence of detrusor overactivity can vary widely between 13% [48] and 40% [49] of patients undergoing urodynamic studies at different centers.

§ The prevalence of the oversensitive bladder in urogynecology and female urology patients (from studies on the now obsolete term "sensory urgency") is around 10%–13% [51,52].

* Depending on definition, voiding dysfunction has a prevalence of 14% [54] to 39% [48], the latter figure making it either the third or fourth most common urodynamic diagnosis (after urodynamic stress incontinence, POP, and possibly detrusor overactivity).

† Approximately 2% of PVR measurements are over 200 mL [29]. This is a suggested cutoff.

‡ Around 61% [48] of women presenting for initial urogynecological assessment will have some degree of prolapse, not always symptomatic. Objective findings of prolapse in the absence of relevant prolapse symptoms may be termed "anatomic prolapse." Approximately half of all women over the age of 50 years have been reported to complain of symptomatic prolapse [55]. There is a 10% lifetime incidence for women of undergoing surgery to correct pelvic organ prolapse [56]. The presence of any such sign should correlate with relevant POP symptoms.

§ Using this definition, two or more and three or more UTIs can occur with a prevalence of 19% and 11% respectively in women presenting with symptoms of pelvic floor dysfunction [57]. This then becomes a significant, generally intercurrent, diagnosis likely to require treatment additional to that planned for the other diagnoses found..

Appendix D

Commentary on the 2009 IUGA/ICS Joint Report on the Terminology for Female Pelvic Floor Dysfunction

Rufus Cartwright

INTRODUCTION

Since 1976, the International Continence Society (ICS) has published a series of standardization reports relating to lower urinary tract function [1–12], pelvic floor dysfunction [13–15], and urodynamic technique [16–18]. These reports have had a huge impact on usage of terminology in the field, achieving an unprecedented degree of harmonization between researchers around the globe. Not all the recommendations, however, have been universally accepted [19], particularly for the 2002 lower urinary tract function terminology report [9], which made many controversial changes.

The 2009 International Urogynecological Association (IUGA)/ICS joint report [11] expands and updates this work, aiming to be comprehensive account of terminology for the signs, symptoms, and investigations of the whole range of female pelvic floor dysfunction. As in previous terminology reports, the description of each disorder is spread through multiple sections, separately describing the symptoms, examination findings, investigations, and holistic diagnoses. In order to maintain user-friendliness, the document is however extensively footnoted and cross-referenced both between sections and to previous standardization reports.

This commentary on the 2009 standardization report aims to highlight the major changes from previous reports and suggest areas of new controversy that may need to be addressed in future revisions.

Symptoms

Table D.1 compares the terminology and definitions for incontinence symptoms from the 2002 report with the now current 2009 recommendations. In each definition, the new report has replaced the term "involuntary urine leakage," with "involuntary urine loss," recognizing that leakage might be adequately contained by pads or other products, but still be a significant bothersome symptom. The 2002 report recommended that the term "urinary" be included when describing stress, urge, and continuous incontinence, to distinguish urine leakage from fecal or flatal incontinence. This has certainly been adopted to some extent, but in many contexts is unnecessary. The new report has therefore made the "urinary" qualifier optional.

The terms urge and urgency have always caused some confusion and certainly should not be interchangeable. A strong urge to void is a normal bladder sensation, whereas urge incontinence is a pathological symptom. Over recent years, the term "urgency urinary incontinence" had been recommended to resolve this ambiguity (241) and has now been approved by the new report. Encouragingly, it has already gained some usage in the literature [20]. Three "new" subtypes of incontinence have been introduced: "postural," "insensible," and "coital incontinence." In each case, the underlying pathophysiology is less clear than for stress and urge incontinence, and hopefully formal recognition of these problems will stimulate further research.

Table D.2 again compares the terminology and definitions for bladder storage symptoms from the 2002 to 2009 reports. The definitions of urgency and overactive bladder (OAB) syndrome have attracted more attention than almost any other items in the 2002 report. Critics attacked the definition of OAB, suggesting that the simplistic framing created clinical and intellectual confusion [21–24], and new experimental evidence suggested that the onset of urgency was not necessarily "sudden" [25,26]. In the absence of consensus, the 2009 report has elected to leave both definitions largely unchanged.

Increased, reduced, and absent bladder sensation now have their own section in the report and exactly match their cystometric counterpart signs. The prognostic significance of symptomatic altered bladder sensation is however unclear. Even in healthy volunteers, there is a wide variation in the volumes at which bladder sensations occur [27]. The reliability of reporting of sensations at differing bladder volumes is variable with many groups reporting poor results [28,29], and others finding near perfect reliability [27,30]. There are even conflicting results regarding sensations associated with sham cystometry [31,32]. These new definitions should help researchers reach new understanding regarding the relationships between symptoms and signs.

Bernard Haylen, who spearheaded the joint report, has been a pioneer in the objective assessment of voiding symptoms in women. Not surprisingly, this section has been extensively updated (Table D.3). The list of voiding symptoms has been expanded from 8 to 11, with the loss of "terminal dribble," a more characteristically male symptom, and the introduction of "need to immediately revoid" and "position-dependent micturition." Retention has been added as a symptom in its own right, although it can also be an examination finding and a diagnosis. "Dysuria" was discouraged by the 2002 report as part of a trend away from Latinate words. "Urethral pain" was suggested as a suitable alternative, but has not made any significant impact on the literature (Figure D.1). The present report now contains both terms, with dysuria being a special case of urethral pain associated with voiding.

Table D.1 Comparison of Incontinence Symptom Terminology and Definitions 2002–2009

Symptom terminology		**Symptom definition**	
2002	**2009**	**2002**	**2009**
Urinary incontinence	Urinary incontinence	Complaint of any involuntary leakage of urine	Complaint of involuntary loss of urine
Stress urinary incontinence	Stress (urinary) incontinence	Complaint of involuntary leakage on effort or exertion or on sneezing or coughing	Complaint of involuntary loss of urine on effort or physical exertion (e.g., sporting activities) or on sneezing or coughing
Urge urinary incontinence	Urgency (urinary) incontinence	Complaint of involuntary leakage of urine accompanied or immediately preceded by urgency	Complaint of involuntary loss of urine associated with urgency
n/a	Postural (urinary) incontinence	n/a	Complaint of involuntary loss of urine associated with change of body position, for example, rising from a seated or lying position
Nocturnal enuresis	Nocturnal enuresis	Complaint of loss of urine occurring during sleep	Complaint of involuntary urinary loss of urine that occurs during sleep
Continuous urinary incontinence	Continuous (urinary) incontinence	Complaint of continuous leakage	Complaint of continuous involuntary loss of urine
n/a	Insensible (urinary) incontinence	n/a	Complaint of urinary incontinence where the woman has been unaware of how it occurred
n/a	Coital incontinence	n/a	Complaint of involuntary loss of urine with coitus

Abbreviation:n/a, not applicable

Table D.2 Comparison of Storage Symptom Terminology and Definitions 2002–2009

Symptom terminology		**Symptom definition**	
2002	**2009**	**2002**	**2009**
Increased daytime frequency	Increased daytime urinary frequency	Complaint by the patient who considers that he/she voids too often by day	Complaint that micturition occurs more frequently during waking hrs than previously deemed normal by the woman
Nocturia	Nocturia	Complaint that the individual has to wake at night one or more times to void	Complaint of interruption of sleep one or more times because of the need to micturate
Urgency	Urgency	Complaint of sudden	Complaint of sudden compelling desire to pass urine, which is

		compelling desire to pass urine, which is difficult to defer	difficult to defer (unchanged)
Overactive bladder syndrome	Overactive bladder syndrome	Urgency with or without urge incontinence, usually with frequency and nocturia	Urinary urgency, usually accompanied by frequency and nocturia, with or without urgency urinary incontinence, in the absence of urinary tract infection or other obvious pathologies

The 2009 report includes short sections on sexual dysfunction, defining superficial and deep dyspareunia, and an expanded description of prolapse symptoms. Despite the successful dissemination of the Pelvic Organ Prolapse Quantification (POPQ) system for objective assessment of prolapse, there has remained huge heterogeneity in subjective assessment. Five core symptoms are now listed, namely, vaginal bulging, pelvic pressure, bleeding/discharge/infection, splinting/digitation, and low backache. The symptoms of vaginal bulging [33] and pressure [34] are usually thought to be most important. It would, however, be useful for future unified standardization documents to include cross-references to other key symptom areas affected by prolapse, including sexual dysfunction, incontinence, voiding symptoms, and anorectal dysfunction, as in the previous pelvic floor standardization report [15].

The section on anorectal dysfunction is entirely new in keeping with the expanded remit. Most anorectal symptoms are now couched in terms that exactly match their corresponding urinary symptom. For example, fecal (rectal) urgency is a “sudden compelling desire to defecate that is difficult to defer,” and a feeling of incomplete (bowel) evacuation is the “complaint that the rectum does not feel empty after defecation.” This approach could be extended to diminished rectal sensation, and rectal prolapse, to bring them in line with reduced bladder sensation and POP, respectively.

The new section on lower urinary tract infection (UTI) suggests increased bladder sensation, urgency, frequency, dysuria, urgency urinary incontinence, and pain as the likely symptoms of infection. Since none of these are sensitive or specific for UTI and each of these occurs elsewhere in the report, it might have been clearer to include UTI only in the section on diagnoses.

Table D.3 Comparison of Voiding Symptom Terminology 2002–2009

Symptom terminology		**Symptom definition**	
2002	**2009**	**2002**	**2009**
Hesitancy	Hesitancy	Difficulty in initiating micturition resulting in a delay in the onset of voiding after the individual is ready to pass urine	Complaint of a delay in initiating micturition
Slow stream	Slow stream	Perception of reduced urine flow usually compared to previous performance or in comparison to others	Complaint of a urinary stream perceived as slower compared to previous performance or in comparison with others
Intermittent stream (intermittency)	Intermittency	Urine flow that stops and starts, on one or more occasions, during micturition	Complaint of urine flow that stops and starts on one or more occasions during voiding
Straining	Straining to void	Muscular effort used to either initiate, maintain, or improve the urinary stream	Complaint of the need to make an intensive effort (by abdominal straining, Valsalva, or suprapubic pressure) to either initiate, maintain, or improve the urinary stream
Splitting or spraying	Spraying (splitting) of urinary stream	n/a	Complaint that the urine passage is a spray or split rather than a single discrete stream
Feeling of incomplete emptying	Feeling of incomplete (bladder) emptying	Self-explanatory term for feeling experienced by the individual after passing urine	Complaint that the bladder does not feel empty after micturition
n/a	Need to immediately revoid	n/a	Complaint that further micturition is necessary soon after passing urine

Postmicturition dribble	Postmicturition leakage	Involuntary loss of urine immediately after he or she has finished passing urine	Complaint of a further involuntary passage of urine following the completion of micturition
n/a	Position-dependent micturition	n/a	Complaint of having to take specific positions to be able to micturate spontaneously or to improve bladder emptying
n/a	Dysuria	n/a	Complaint of burning or other discomfort during micturition
n/a	(Urinary) retention	n/a	Complaint of the inability to pass urine despite persistent effort

Abbreviation:n/a, not applicable

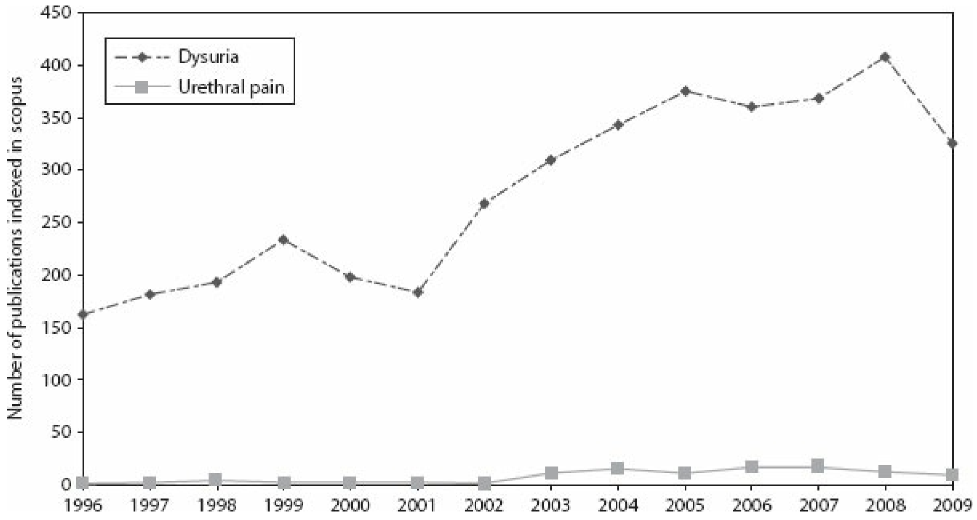

Figure D.1 Publications indexed in Scopus 1996–2009, using the terms “dysuria” or “urethral pain.”

Signs

The new report specifies that stress (urinary) incontinence and urge (urinary) incontinence can each be a sign as well as a symptom. Although assessment of stress (urinary) incontinence, with a cough test, has an extensive supporting literature, some sources have cast doubt on the validity of patient reports of a “sudden compelling desire to void” [25,35], as a useful indicator of urgency. For the first time, occult or latent stress incontinence is formally defined and properly termed “stress incontinence on prolapse reduction.” Treatment of coexisting prolapse and incontinence is considered a priority area in pelvic floor research [36]. Although “stress incontinence on prolapse reduction” may be found in half of women considering prolapse surgery [37], current evidence is inconclusive [38,39] about optimal treatment.

The POPQ system has had excellent uptake in research settings, facilitating comparisons between studies, but the complexity of the system has limited its use in clinical practice [40]. A simplified version of the POPQ [41] is currently subject to ongoing validation work. At present, the joint report gives only a brief overview of staging and compartments, but in the future might serve as one route for the dissemination of this important aspect of standardization.

Uniquely among assessments of lower urinary tract symptom severity and frequency, volume charts are found to be both highly reliable [42] and cost-effective [43]. The 2009 report, along with other major guidance [44], stresses their importance in the initial assessment of women with incontinence. The description of frequency volume charts and bladder diaries has been simplified by removing the category of “micturition time charts.” The definitions given specify cutoffs for polyuria and nocturnal polyuria, but not for frequency and nocturia themselves. Recent longitudinal and cross-sectional population-based studies, using questionnaires or diaries, have provided accurate estimates of the distribution of day- and nighttime voids in men and women [45–47]. It is to be hoped that these estimates can be incorporated into future revisions of the standardization document.

Urodynamics and Imaging

Urodynamics has always formed a core part of the ICS standardization reports. As the 2009 report covers only women, there are presently three current ICS documents on the standardization of urodynamics [9,11,16]. There are new recommendations for the assessment of average flow rate during free uroflowmetry and for calculation of bladder compliance. The section on detrusor function during filling has been extensively updated, and changes are described in Table D.4. Some clarification may be required regarding the status of terms that do not appear in the current report, including "phasic detrusor overactivity," "terminal detrusor overactivity," and "detrusor overactivity incontinence." Detrusor function during voiding is largely unchanged although the description of normal function in women describes a new sequence "initial (voluntary) relaxation in intraurethral pressure (urethral relaxation) … generally followed by continuous detrusor contraction that leads to complete bladder emptying within a normal time span."

The inclusion of a section on diagnoses has led to some inconsistencies. Urodynamic stress incontinence (USI) is defined in the urodynamics section solely as "the involuntary leakage of urine during filling cystometry, associated with increased intra-abdominal pressure, in the absence of detrusor contraction," but appears later as a combination of the stress urinary incontinence symptom and sign, with this cystometric finding. "Dysfunctional voiding" is defined as "an intermittent and/or fluctuating flow rate due to involuntary intermittent contractions of the peri-urethral striated or levator muscles during voiding," while the very similar "voiding dysfunction" is "abnormally slow and/or incomplete micturition." This seems liable to lead to some confusion, particularly if these terms need to be translated.

Table D.4 Filling Detrusor Function Terminology and Definitions 2002–2009

Filling detrusor function terminology		**Filling detrusor function definitions**	
2002	**2009**	**2002**	**2009**
Normal detrusor function	Normal (previously "stable") detrusor function	Allows bladder filling with little or no change in pressure. No involuntary phasic contractions occur despite provocation.	There is little or no change in detrusor pressure with filling. There are no involuntary phasic contractions despite provocation with activities such as postural changes, coughing, hearing the sound of running water, and hand washing.
Detrusor overactivity	Detrusor overactivity	A urodynamic observation characterized by involuntary detrusor contractions during the filling phase, which may be spontaneous or provoked.	The occurrence of involuntary detrusor contractions during filling cystometry. These contractions, which may be spontaneous or provoked, produce a waveform on the cystometrogram or variable duration and amplitude.
Phasic detrusor overactivity	n/a	Defined by a characteristic waveform and may or may not lead to urinary incontinence.	n/a
Terminal detrusor overactivity	n/a	A single involuntary detrusor contraction occurring at cystometric capacity, which cannot be suppressed, and results in incontinence, usually resulting in bladder emptying.	n/a
Detrusor overactivity incontinence	n/a	Incontinence due to an involuntary detrusor contraction.	n/a

Abbreviation:n/a, not applicable

At a little over one page, and with only two figures, the new section on pelvic imaging can provide only the briefest overview of the roles of ultrasound, radiography, and MRI in the evaluation of pelvic floor dysfunction. At present, it provides key references for further reading, and as the validity of each methodology is developed, this section can clearly be expanded.

DIAGNOSES

The final section on diagnoses addresses six common conditions that make up a majority of clinical practice in urogynecology or female urology. The report stresses that the diagnoses should be based on symptoms, signs, and investigation findings. Although this may sound uncontroversial, in practice in each case, the appropriate diagnostic criteria are very much a matter of ongoing research and debate.

The report recommends USI as a diagnosis requiring cystometry. The best available current evidence does not however suggest additional prognostic benefit from the observation of "involuntary leakage during filling cystometry, associated with increased intra-abdominal pressure, in the absence of a detrusor contraction," as opposed to a simple cough test [48–50]. Other evidence-based guidance has specifically recommended against cystometry for uncomplicated stress incontinence [51]. The decision to reaffirm the role of cystometry effectively means the diagnosis can only be made in secondary care settings, which might limit patient access to appropriate community-based care.

The 2002 report revised detrusor overactivity from a diagnosis to a urodynamic observation on the basis that no available evidence supported the additional benefit of cystometry over noninvasive symptom assessment [52]. New research in the intervening years has supported that decision. It is a retrograde step to have divided patients with urgency and frequency symptoms into "detrusor overactivity" and the new "bladder oversensitivity" on the basis of "involuntary detrusor muscle contractions during filling cystometry." Recent studies have suggested that detrusor overactivity is a poor prognosticator of treatment outcome for a wide variety of incontinence interventions, including stress incontinence surgery [48,53], anticholinergic treatment [54,55], with or without behavioral modification [56], and sacral neuromodulation [57,58]. Further threats to the validity of detrusor overactivity as a measure of urgency have come from studies demonstrating unacceptably poor interrater reliability [59,60] and no significant association between individual contractions and reporting of increased sensation [61,62]. The consensus process for drafting the 2009 report would therefore seem to have reiterated the conventional wisdom regarding cystometry, in the face of the best evidence. The concept of OAB has, however, gained enormous popularity in the years since the 2002 report [63], including with EU and U.S. regulatory bodies. It seems unlikely that these new suggested diagnoses "detrusor overactivity" and "bladder oversensitivity" will supplant OAB. In some quarters, "voiding dysfunction" has become a catchall term for lower urinary tract symptoms. This report specifies however that the term refers only to "abnormally slow and/or incomplete micturition." The 2002 standardization report did not give a standardized urodynamic definition for voiding dysfunction, reflecting a lack of consensus. The new report suggests a 30 mL residual as the upper limit of normal and a 200 mL residual as representing chronic retention [64]. Although usage of the Liverpool nomogram for average flow rate is recommended, the report recognizes that this is an area requiring further validation studies, with poorly defined relationships between symptoms and pathology [65,66]. The report specifies that the diagnosis requires both subjective symptoms and objective findings. It is not entirely clear which term is intended to represent objective voiding dysfunction but without symptoms.

CONCLUSIONS

The 2009 report truly represents a landmark in the development of terminology for female pelvic floor dysfunction. For the first time, it provides unifying coverage of urogynecology and female urology. It should be an invaluable reference both for researchers planning and reporting studies and for clinicians who need to map the research evidence base onto the myriad of individual complaints and symptoms reported by patients. This commentary, however, identifies some sections that would benefit from greater depth and other areas where recommendations substantially diverge from recent evidence. Future reports should consider incorporating systematic reviews of current evidence, such as those provided by the International Consultation on Incontinence [44], and use of a formal Delphi method to achieve better balance of coverage.

Appendix E

Standardization of Terminology of Female Pelvic Organ Prolapse and Pelvic Floor Dysfunction*

Richard C. Bump, Anders Mattiasson, Kari Bø, Linda P. Brubaker, John O.L. DeLancey, Peter Klarskov, Bob L. Shull, and Anthony R.B. Smith

INTRODUCTION

The International Continence Society (ICS) has been at the forefront in the standardization of terminology of lower urinary tract function since the establishment of the Committee on Standardization of Terminology in 1973. The committee's efforts over the past two decades have resulted in the worldwide acceptance of terminology standards that allow clinicians and researchers interested in the lower urinary tract to communicate efficiently and precisely. While female pelvic organ prolapse and pelvic floor dysfunction are intimately related to lower urinary tract function, such accurate communication using standard terminology has not been possible for these conditions.

There is no universally accepted system for describing the anatomic position of the pelvic organs. Many reports use terms for the description of pelvic organ prolapse, which are undefined; none of the many aspiring grading systems has been adequately validated with respect either to reproducibility or to the clinical significance of different grades. The absence of standard, validated definitions prevents comparisons of published series from different institutions and longitudinal evaluation of an individual patient. A primary goal of this report is to introduce a system that will allow the accurate, quantitative description of pelvic support findings in individual patients.

This document is a first effort toward the establishment of standard, reliable, and validated descriptions of female pelvic anatomy and function. The subcommittee acknowledges a need for well-designed reliability studies to evaluate and validate various descriptions and definitions. We have tried to develop guidelines that will promote new insights rather than existing biases. Acknowledgment of these standards in written publications and scientific presentations should be indicated in the methods section with the following statement: "Methods, definitions, and descriptions conform to the standards recommended by the ICS, except where specifically noted."

DESCRIPTION OF PELVIC ORGAN PROLAPSE

The clinical description of pelvic floor anatomy is determined during the physical examination of the external genitalia and vaginal canal. Although the specifics of the examination technique are not dictated by this document, authors should describe their specific technique precisely. Segments of the lower reproductive tract will replace such terms as "cystocele, rectocele, enterocele, or urethrovesical junction" because these terms may imply an unrealistic certainty as to the structures on the other side of the reproductive tract bulge, particularly in women who have had previous prolapse surgery.

Conditions of the Examination

Many variables of examination technique may influence findings in patients with pelvic organ prolapse. It is critical that the examiner sees and describes the maximum protrusion noted by the individual subject during her daily activities. Therefore, the criteria for the end point of the examination and the full development of the prolapse must be specified in any report.

Suggested criteria for demonstration of maximum prolapse should include one or all of the following:

- Any protrusion of the vaginal wall has become tight during straining by the patient.
- Traction on the prolapse causes no further descent.

- The subject confirms that the size of the prolapse and extent of the protrusion seen by the examiner is as extensive as the most severe protrusion that she has experienced. The means of this confirmation should be specified. For example, the subject may use a small handheld mirror to visualize the protrusion.
- A standing, straining examination confirms that the full extent of the prolapse was observed in other positions used.

Other variables of technique that should be specified during the quantitative description and the ordinal staging of pelvic organ prolapse include the following:

- The position of the subject (e.g., supine lithotomy, lateral Sims' position, specified degrees of upright, erect sitting, standing)
- The type of examination table or chair used
- The type of standard vaginal specula, retractors, or tractors used
- Diagrams of any customized retraction, traction, or measuring devices used
- The type (e.g., Valsalva maneuver, cough) and, if measured, intensity (e.g., vesical or rectal pressure rise) of straining used to develop the prolapse maximally
- Fullness of the bladder and, if the bladder was empty, whether this was by spontaneous voiding or by catheterization
- Content of the rectum
- The method by which any quantitative measurements were made (e.g., estimation by visualization or palpation, direct measurement with a calibrated device)

There is a critical need to define the importance of all variables of technique as they relate to the ease of assessment and reproducibility of measurements. Researchers should determine the intra- and interobserver reliability of measurements made with their assessment techniques before utilizing them as baseline and outcome variables. Manuscript descriptions of assessment techniques should include sufficient detail to ensure that other researchers can replicate them precisely.

Quantitative Description of Pelvic Organ Position

This description system is a tandem profile in that it contains a series of component measurements grouped together in combination, but listed separately in tandem, without being fused into a distinctive new expression or "grade." It allows for the precise description of an individual woman's pelvic support without assigning a "severity value." Second, it allows accurate site-specific observations of the stability or progression of prolapse over time by the same or different observers. Finally, it allows similar judgments as to the outcome of surgical repair of prolapse. For example, noting that a surgical procedure moved the vaginal apex from 0.5 cm beyond the hymeneal ring to 0.5 cm above the hymeneal ring denotes more meager improvement than stating that the prolapse was reduced from grade 3 to grade 1 as would be the case using some current grading systems.

Definition of Anatomic Landmarks

Prolapse should be evaluated by a standard system relative to clearly defined anatomic points of reference. There are two types of points of reference: fixed reference points and defined points for measurement.

Fixed Point of Reference

Prolapse should be evaluated relative to a fixed anatomic landmark that can be consistently and precisely identified. The hymen will be the fixed point of reference used throughout this system of quantitative prolapse description.

Visually, the hymen provides a precisely identifiable landmark for reference. Although it is recognized that the plane of the hymen is somewhat variable depending upon the degree of levator ani dysfunction, it remains the best landmark available. "Hymen" is preferable to the ill-defined and imprecise term "introitus." The anatomic position of the six defined points for measurement (see section "Defined Points for Measurement") should be centimeters above or proximal to the hymen (negative number) or centimeters below or distal to the hymen (positive number) with the plane of the hymen being defined as zero (0). For example, a cervix that protruded 3 cm distal to the hymen would be +3 cm.

Palpably, the ischial spines provide precisely identifiable landmarks. In the sitting or standing position, or in situations with limited viability due to obesity or limited ability for hip abduction, the position of the cervix or the leading point of the prolapse relative to the ischial spines may be measured by palpation. Measurements so obtained should be normalized to the level of the hymen by noting the distance between the ischial spines and the plane of the hymen. For example, a cervix that is 3 cm distal to the ischial spines would be at −2 cm if the spines were 5 cm above the plane of the hymen.

Defined Points for Measurement

Anterior Vaginal Wall. Because the only structure directly visible to the examiner is the surface of the vagina, anterior prolapse should be discussed in terms of a segment of the vaginal wall rather than the organs that lie behind it. Thus, the term “anterior vaginal wall prolapse” is preferable to “cystocele” or “anterior enterocele” unless the organs involved are identified by ancillary tests.

- *Point Aa*: A point located in the midline of the anterior vaginal wall 3 cm proximal to the external urethral meatus. This corresponds to the approximate location of the “urethrovesical crease,” a visible landmark of variable prominence that is obliterated in many patients. By definition, the range of position of point Aa relative to the hymen is −3 to +3 cm.
- *Point Ba*: A point that represents the most distal (i.e., most dependent) position of the upper portion of the anterior vaginal wall from the vaginal cuff or anterior vaginal fornix to point Aa. By definition, point Ba is at −3 cm in the absence of prolapse and would have a positive value equal to the position of the cuff in women with total posthysterectomy vaginal eversion.

Vaginal Apex. These points represent the most proximal locations of the normally positioned lower reproductive tract.

- *Point C*: A point that represents either the most distal (i.e., most dependent) edge of the cervix or the leading edge of the vaginal cuff scar in a woman who has undergone total hysterectomy.
- *Point D*: A point that represents the location of the posterior fornix (or pouch of Douglas) in a woman who still has a cervix. It represents the level of uterosacral ligament attachment to the proximal posterior cervix. It is included as a point of measurement to differentiate suspensory failure of the uterosacral–cardinal ligament complex from cervical elongation. When the location of point C is significantly more positive than the location of point D, this is indicative of cervical elongation, which may be symmetrical or eccentric (e.g., involving only the anterior lip of the cervix due to a prior laceration). Point D is omitted as a point for measurement in the absence of the cervix.

Posterior Vaginal Wall. Analogous to anterior prolapse, posterior prolapse should be discussed in terms of segments of the vaginal wall rather than the organs that lie behind it. Thus, the term “posterior vaginal wall prolapse” is preferable to “rectocele” or “enterocele” unless the organs involved are identified by ancillary tests. If small bowel appears to be present in the rectovaginal space, the examiner should comment on this fact and should clearly describe the basis for this clinical impression (e.g., by observation of peristaltic activity in the distended posterior vagina, by palpation of loops of small bowel between an examining finger in the rectum and one in the vagina). In such cases, a “pulsion” addendum to the point Bp position should be noted (e.g., Bp = +5 [pulsion]) (see section “Supplementary Physical Examination Techniques,” points A and B).

- *Point Bp*: A point that represents the most distal (i.e., most dependent) position of the upper portion of the posterior vaginal wall from the vaginal cuff or posterior vaginal fornix to point Ap. By definition, point Bp is at –3 cm in the absence of prolapse and would have a positive value equal to the position of the cuff in a woman with total posthysterectomy vaginal eversion.
- *Point Ap*: A point located in the midline of the posterior vaginal wall 3 cm proximal to the hymen. By definition, the range of position of point Ap relative

Other Landmarks and Measurements

The *genital hiatus* is measured from the middle of the external urethral meatus to the posterior midline hymen. If the location of the hymen is distorted by a loose band of skin without underlying muscle or connective tissue, the firm palpable tissue of the perineal body should be substituted as the posterior margin for this measurement.

The *perineal body* is measured from the posterior margin of the genital hiatus (as just described) to the midanal opening. Measurement of the genital hiatus and perineal body is expressed in centimeters.

The total *vaginal length* is the greatest depth of the vagina in centimeters when point C or D is reduced to its full normal position. (*Note*: Eccentric elongation of a prolapsed anterior or posterior vaginal wall should not be included in the measurement of total vaginal length [see Figure E.1a and accompanying discussion].) The points and measurements discussed in this section are presented in Figure E.2.

Making and Recording Measurements

The position of points Aa, Ba, Ap, Bp, C, and (if applicable) D with reference to the hymen should be measured and recorded. Positions are expressed as centimeters above or proximal to the hymen (negative number) or centimeters below or distal to the hymen (positive number) with the plane of the hymen being defined as zero (0). While an examiner may be able to make measurements to the nearest half (0.5) cm, it is doubtful that further precision is possible.

-3_{Aa}	-3_{Ba}	-6_{C}
4.5_{gh}	1_{pb}	8_{tvl}
$+2^{Ap}$	$+5^{Bp}$	–

Figure E.1 (a) Predominant anterior prolapse and (b) predominant posterior prolapse. *Abbreviations*: gh, genital hiatus; pb, perineal body; tvl, total vaginal length.

All reports should clearly specify how measurements were derived. For example, were direct measurements made using a probe, ruler, glove, speculum, or other device marked in centimeters, were indirect measurements made with the examiner’s fingers and then measured off a centimeter tape, were measurements estimated by the examiner without using a graduated device, or were combinations of techniques used? If customized measuring devices were used, diagrams of such should be included in any manuscript or presentation.

Measurements may be recorded as a simple line of numbers (e.g., −3, −3, −7, −9, −3, −3, 9, 2, 2 for points Aa, Ba, C, D, Bp, Ap, total vaginal length, genital hiatus, and perineal body, respectively). Note that the last three numbers have no sign (i.e., − or +) attached to them because they denote lengths and not positions relative to the hymen. Alternatively, a three-by-three “tic-tac-toe” grid can be used to organize concisely the measurements as noted in Figure E.3. If point D is not applicable due to a prior hysterectomy, this should be noted as such with “NA” or “—” either in the line of numbers or in the grid.

Figure E.4 is a line diagram contrasting measurements indicating normal support to those of posthysterectomy vaginal eversion.

In the example of normal support (Figure E.4a), points Aa and Ba and points Ap and Bp are all −3 since there is no anterior or posterior wall descent. The lowest point of the cervix is 8 cm above the hymen (−8) and the posterior fornix is 2 cm above this (−10). The vaginal length is 10 cm and the genital hiatus and perineal body measure 2 and 3 cm, respectively.

In the example of complete eversion (Figure E.4b), the most distal point of the anterior wall (point Ba), the vaginal cuff scar (point C), and the most distal point of the posterior wall (point Bp) are all at the same position (+8) and points Aa and Ap are maximally distal (both at +3). The fact that the total vaginal length equals the maximum protrusion reflects the fact that the eversion is total.

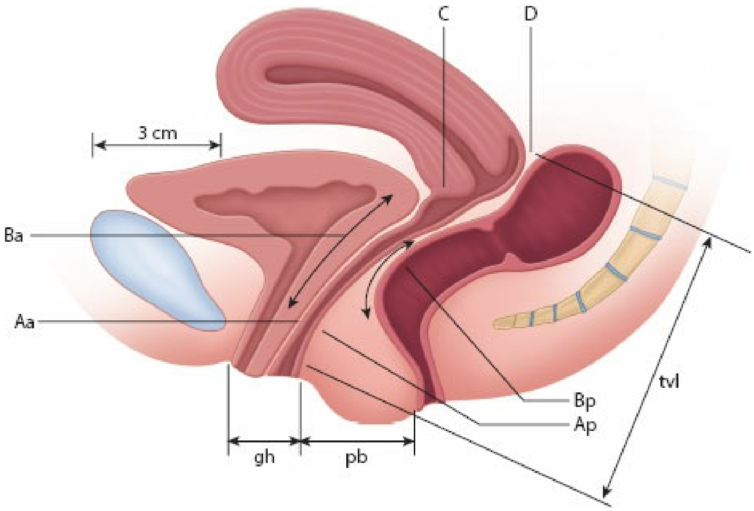

Figure E.2 Six points, genital hiatus (gh), perineal body (pb), and total vaginal length (tvl) used for prolapse quantitation.

Figure E.4 (a) Complete eversion and (b) normal support. *Abbreviations*: gh, genital hiatus; pb, perineal body; tvl, total vaginal length.

Figure E.1 is a line diagram representing predominant anterior and posterior vaginal wall prolapse with partial vault descent.

In the example of a predominant anterior support defect (Figure E.1a), the leading point of the prolapse is the upper anterior vaginal wall, point Ba (+6). Note that there is significant elongation of the bulging anterior wall. Point Aa is maximally distal (+3) and the vaginal cuff scar is 2 cm above the hymen (C = −2). The cuff scar has undergone 4 cm of descent since it would be at −6 (the total vaginal length) if it were perfectly supported. In this example, the total vaginal length is not the maximum depth of the vagina with the elongated anterior vaginal wall maximally reduced, but rather the depth of the vagina at the cuff with point C reduced to its normal full extent as specified in section "Other Landmarks and Measurements."

In the example of the predominant posterior support defect (Figure E.1b), the leading point of the prolapse is the upper posterior vaginal wall, point Bp (+5). Point Ap is 2 cm distal to the hymen (+2) and the vaginal cuff scar is 6 cm above the hymen (−6). The cuff has undergone only 2 cm of descent since it would be at −8 (the total vaginal length) if it were perfectly supported.

Ordinal Staging of Pelvic Organ Prolapse

The tandem profile for quantifying prolapse just described provides a precise description of anatomy for individual patients. However, because of the many possible combinations, such profiles cannot be directly ranked; the many variations are too numerous to permit useful analysis and comparisons when populations are studied. Consequently, they are analogous to other tandem profiles such as the tumor–node–metastasis (TNM) index for various cancers. For the TNM description of individual patients' cancers to be useful in population studies evaluating prognosis or response to therapy, they are clustered into an ordinal set of stages. Ordinal stages represent adjacent categories that can be ranked in an ascending sequence of magnitude, but the categories are assigned arbitrarily and the intervals between them cannot actually be measured.

While the committee is aware of the arbitrary nature of an ordinal staging system and the possible biases that it introduces, we conclude that such a system is necessary if populations are to be described and compared, if symptoms putatively related to prolapse are to be evaluated, and if the results of various treatment options are to be assessed and compared.

Stages are assigned according to the most severe portion of the prolapse when the full extent of the protrusion has been demonstrated according to the criteria in section "Conditions of the Examination." In order for a stage to be assigned to an individual subject, it is essential that her quantitative description be completed first. The 2 cm buffer related to the total vaginal length in stages 0–IV is an effort to compensate for vaginal distensibility and the inherent imprecision of the measurement of total vaginal length. The 2 cm buffer around the hymen in stage II is an effort to avoid confusing a stage to a single plane and to acknowledge practical limits of precision in this assessment.

Stage 0

No prolapse is demonstrated. Points Aa, Ap, Ba, and Bp are all at −3 cm and either point C or D is between −X cm and – (X – 2) cm, where X is the total vaginal length in centimeters (i.e., the quantitation value of point C or D is ≤ – (X – 2) cm). Figure E.4a represents stage 0 pelvic organ prolapse.

Stage I

The criteria for stage 0 are not met but the most distal portion of the prolapse is more than 1 cm above the level of the hymen (i.e., its quantitation value is <−1 cm). stage I can be subgrouped according to which portion of the lower reproductive tract is the most distal part of the prolapse using the following letter qualifiers: a, anterior vaginal wall; p, posterior vaginal wall; C, vaginal cuff; Cx, cervix; and Aa, Ap, Ba, Bp, and D for the points of measurement already defined (e.g., I-Cx if the cervix is the most distal, I-Bp if the upper posterior wall is most distal, or I- if the junction of the distal and proximal anterior wall is the most distal part of the prolapse).

Stage II

The most distal portion of the prolapse is 1 cm or less proximal to or distal to the plane of the hymen (i.e., its quantitation value is ≥−1 cm but ≤+1 cm). Stage II can be subgrouped according to the scheme described under stage I (e.g., II-a, II-C, or II-Bp).

Table E.1 International Continence Society Pelvic Organ Prolapse Ordinal Staging System

Stage 0	Points Aa, Ap, Ba, and Bp are all at −3 cm and either point C or D is at ≤–(X – 2) cm.
Stage I	The criteria for stage 0 are not met and the leading edge of prolapse is <–1 cm.
Stage II	Leading edge of prolapse is >–1 cm but ≤+1 cm.
Stage III	Leading edge of prolapse is >+1 cm but <+(X – 2) cm.
Stage IV	Leading edge of prolapse is ≥+(X – 2) cm

Notes:X = total vaginal length in centimeters in stages 0, III, and IV. Stages I through IV can be subgrouped according to which portion of the lower reproductive tract is the leading edge of the prolapse using the following qualifiers: a, anterior vaginal wall; p, posterior vaginal wall; C, vaginal cuff; Cx, cervix; and Aa, Ba, Ap, Bp, and D for the defined points of measurement (e.g., IV-Cx, II-a, or III-Bp).

Stage III

The most distal portion of the prolapse is more than 1 cm below the plane of the hymen but protrudes no further than 2 cm less than the total vaginal length in centimeters (i.e., its quantitation value is >+1 cm but <+(X − 2) cm where X is the total vaginal length). stage III can be subgrouped according to the scheme described under stage I. For example, Figure E.1a represents stage III-Ba and Figure E.1b represents stage III-Bp prolapse.

Stage IV

Essentially, complete eversion of the total length of the lower genital tract is demonstrated. The distal portion of the prolapse protrudes to at least (X − 2) cm where X is the total vaginal length in centimeters (i.e., its quantitation value is ≤+(X − 2) cm). In most instances, the leading edge of stage IV prolapse will be the cervix or vaginal cuff scar. Rare exceptions to this can be noted according to the subgrouping scheme described under stage I. Figure E.4b represents stage IV-C prolapse. Table E.1 summarizes the staging system.

ANCILLARY TECHNIQUES FOR DESCRIBING PELVIC ORGAN PROLAPSE

This series of procedures may help to further characterize pelvic organ prolapse in an individual patient. They are considered ancillary either because they are not yet standardized or validated or because they are not universally available to all patients.

Authors utilizing these procedures should include the following information in their manuscripts:

- Describe the objective information they intended to generate and how it enhanced their ability to evaluate or treat prolapse
- Describe precisely how the test was performed, any instruments that were used, and the specific testing conditions (see section “Conditions of the Examination”) so that other authors can reproduce the study
- Document the reliability of the measurement obtained with the technique

Supplementary Physical Examination Techniques

Many of these techniques are essential to the adequate preoperative evaluation of a patient with pelvic organ prolapse. While they do not directly affect either the tandem profile or the ordinal stage, they are important for the selection and performance of an effective surgical repair. These techniques include, but are not necessarily limited to, the following:

1. Performance of a digital rectal–vaginal examination while the patient is straining and the prolapse is maximally developed to differentiate between a high rectocele and an enterocele
2. Digital assessment of the contents of the rectal–vaginal septum during the examination (noted in (1)) to differentiate between a “traction” enterocele (the posterior cul-de-sac is pulled down with the prolapsing cervix or vaginal cuff but is not distended by intestines) and a “pulsion”

enterocele (the intestinal contents of the enterocele distend the rectal–vaginal septum and produce a protruding mass)
3. Q-tip testing for the measurement of urethral axial mobility
4. Measurements of perineal descent
5. Measurements of the transverse diameter of the genital hiatus or of the protruding prolapse
6. Measurements of vaginal volume
7. Description and measurement of rectal prolapse
8. Examination techniques for differentiating between various types of defect (e.g., central vs. paravaginal defects of the anterior vaginal wall)

Endoscopy

Cystoscopic visualization of bowel peristalsis under the bladder base or trigone may identify an anterior enterocele in some patients. The endoscopic visualization of the bladder base and rectum and observation of the voluntary constriction and dilation of the urethra, vagina, and rectum has, to date, played a minor role in the evaluation of pelvic floor anatomy and function. When such techniques are described, authors should include the type, size, and lens angle of the endoscope used; the doses of any analgesic, sedative, or anesthetic agents used; and a statement of the level of consciousness of the subject in addition to a description of the other conditions of the examination.

Photography

Still photographic documentation of prolapse beyond stage II may be utilized both to document serial changes in individual patients and to illustrate findings for manuscripts and presentations. Photographs should contain an internal frame of reference such as a centimeter ruler or tape.

Imaging Procedures

Different imaging techniques have been used to visualize pelvic floor anatomy, support defects, and relationships among adjacent organs.

These techniques may be more accurate than physical examination in determining which organs are involved in pelvic organ prolapse. However, they share the limitations of the other techniques in this section, that is, a lack of standardization, validation, and/or availability. For this reason, no specific technique can be recommended, but guidelines for reporting various techniques will be considered.

General Guidelines for Imaging Procedures

Landmarks should be defined to allow comparisons with other imaging studies and the physical examination. The lower edge of the symphysis pubis should be given high priority as a landmark. Other examples of bony landmarks include the superior edge of the pubic symphysis, the ischial spine, the obturator foramen, and the promontory of the sacrum.

All reports on imaging techniques should specify the following:

- Position of the patient including the position of her legs (images in manuscripts should be oriented to reflect the patient's position when the study was performed and should not be oriented to suggest an erect position unless the patient was erect)
- Specific verbal instructions given to the patient
- Bladder volume and content and bowel content, including any prestudy preparations
- The performance and display of simultaneous monitoring such as pressure measurements that might be used to document that exposures were made at the most appropriate moment

Ultrasonography

Continuous visualization of dynamic events is possible. All reports using ultrasound should include the following information:

- Transducer type and manufacturer (e.g., sector, linear, MHz)
- Transducer size
- Transducer orientation

- Route of scanning (e.g., abdominal, perineal, vaginal, rectal, urethral)

Contrast Radiography

Contrast radiography may be static or dynamic and may include voiding colpocystourethrography, defecography, peritoneography, and pelvic fluoroscopy, among others. All reports of contrast radiography should include the following information:

- Projection (e.g., lateral, frontal, horizontal, oblique).
- Type and amount of contrast media used and sequence of opacification of the bladder, vagina, rectum and colon, small bowel, and peritoneal cavity.
- Any urethral or vaginal appliance used (e.g., tampon, catheter, bead chain).
- Type of exposure (e.g., single exposure, video).
- Magnification—an internal reference scale should be included.

Computed Tomography and Magnetic Resonance Imaging

These techniques do not allow for continuous imaging under dynamic conditions. Currently available equipment usually dictates supine scanning. Details of the technique should be specified including

- The specific equipment used, including the manufacturer
- The plane of imaging (e.g., axial, sagittal, coronal, oblique)
- The field of view
- The thickness of sections and the number of slices
- The scan time
- The use and type of contrast
- The type of image analysis

Surgical Assessment

Intraoperative evaluation of pelvic support defects is intuitively attractive but as yet of unproven value. The effects of anesthesia, diminished muscle tone, and loss of consciousness are of unknown magnitude and direction. Limitations due to the position of the patient must also be evaluated.

PELVIC FLOOR MUSCLE TESTING

Pelvic floor muscles are voluntarily controlled, but selective contraction and relaxation necessitate muscle awareness. Optimal squeezing technique involves contraction of the pelvic floor muscles without contraction of the abdominal wall muscles and without a Valsalva maneuver. Squeezing synergists are the intraurethral and anal sphincteric muscles. In normal voiding, defecation, and optimal abdominal-strain voiding, the pelvic floor is relaxed, whereas the abdominal wall and the diaphragm may contract. With coughs and sneezes and often when other stresses are applied, the pelvic floor and abdominal wall are contracted simultaneously.

Evaluation and measurement of pelvic floor muscle function includes (1) an assessment of the patient’s ability to contract and relax the pelvic muscles selectively (i.e., squeezing without abdominal straining and vice versa) and (2) measurement of the force (strength) of contraction.

There are pitfalls in the measurement of pelvic floor muscle function because the muscles are invisible to the investigator and because patients often simultaneously and erroneously activate other muscles. Contraction of the abdominal, gluteal, and hip adductor muscles, Valsalva maneuver, straining, breath holding, and forced inspirations are typically seen. These factors affect the reliability of available testing modalities and have to be taken into consideration in the interpretation of these tests.

The individual types of test cited in this report are based on both the scientific literature and current clinical practice. It is the intent of the committee neither to endorse specific tests or techniques nor to restrict evaluations to the examples given. The standards recommended are intended to facilitate comparison of results obtained by different investigators and to allow investigators to replicate studies precisely.

For all types of measuring technique, the following should be specified:

- Patient position, including the position of the legs

- Specific instructions given to the patient
- The status of the bladder and bowel fullness
- Techniques of quantification or qualification (estimated, calculated, directly measured)
- The reliability of the technique

Inspection

A visual assessment of muscle integrity, including a description of scarring and symmetry, should be performed. Pelvic floor contraction causes inward movement of the perineum and straining causes the opposite movement. Perineal movements can be observed directly or assessed indirectly by movement of an externally visible device placed into the vagina or urethra. The abdominal wall and other specified regions might be watched simultaneously. The type, size, and placement of any device used should be specified as should the state of undress of the patient.

Palpation

Palpation may include digital examination of the pelvic floor muscles through the vagina or rectum as well as assessment of the perineum, abdominal wall, and/or other specified regions. The number of fingers and their position should be specified. Scales for the description of the strength of voluntary and reflex (e.g., with coughing) contractions and of the degree of voluntary relaxation should be clearly described and intra- and interobserver reliability documented. Standardized palpation techniques could also be developed for the semiquantitative estimation of the bulk or thickness of pelvic floor musculature around the circumference of the genital hiatus. These techniques could allow for the localization of any atrophic or asymmetric segments.

Electromyography

Electromyography from the pelvic floor muscles can be recorded alone or in combination with other measurements. Needle electrodes permit visualization of individual motor unit action potentials, while surface or wire electrodes detect action potentials from groups of adjacent motor units underlying or surrounding the electrodes. Interpretation of signals from these latter electrodes must take into consideration that signals from erroneously contracted adjacent muscles may interfere with signals from the muscles of interest. Reports of electromyographic recordings should specify the following:

- Type of electrode
- Placement of electrodes
- Placement of reference electrode
- Specifications of signal processing equipment
- Type and specifications of display equipment
- Muscle in which needle electrode is placed
- Description of decision algorithms used by the analytic software

Pressure Recording

Measurements of urethral, vaginal, and anal pressures may be used to assess pelvic floor muscle control and strength. However, interpretations based on these pressure measurements must be made with a knowledge of their potential for artifact and their unproven or limited reproducibility. Anal sphincter contractions, rectal peristalsis, detrusor contractions, and abdominal straining can affect pressure measurements. Pressures recorded from the proximal vagina accurately mimic fluctuations in abdominal pressure. Therefore, it may be important to compare vaginal pressures to simultaneously measured vesical or rectal pressures. Reports using pressure measurements should specify the following:

- The type and size of the measuring device at the recording site (e.g., balloon, open catheter)
- The exact placement of the measuring device
- The type of pressure transducer
- The type of display system
- The display of simultaneous control pressures

As noted in the section “Inspection,” observation of the perineum is an easy and reliable way to assess for abnormal straining during an attempt at a pelvic muscle contraction. Significant straining or a Valsalva maneuver causes downward/caudal movement of the perineum; a correctly performed pelvic muscle contraction causes inward/cephalad movement of the perineum. Observation for perineal movement should be considered as an additional validation procedure whenever pressure measurements are recorded.

DESCRIPTION OF FUNCTIONAL SYMPTOMS

Functional deficits caused by pelvic organ prolapse and pelvic floor dysfunction are not well characterized or absolutely established. There is an ongoing need to develop, standardize, and validate various clinimetric scales such as condition-specific quality-of-life questionnaires for each of the four functional symptom groups (described in the following texts) thought to be related to pelvic organ prolapse.

Researchers in this area should try to use standardized and validated symptom scales whenever possible. They must always ask precisely the same questions regarding functional symptoms before and after therapeutic intervention. The description of functional symptoms should be directed toward four primary areas: (1) lower urinary tract, (2) bowel, (3) sexual, and (4) other local symptoms.

Urinary Symptoms

This report does not supplant any currently approved ICS terminology related to lower urinary tract function [1]. However, some important prolapse-related symptoms are not included in the current standards (e.g., the need to manually reduce the prolapse or assume an unusual position to initiate or complete micturition). Urinary symptoms that should be considered for dichotomous, ordinal, or visual analog scaling include, but are not limited to, the following:

- Stress incontinence
- Frequency (diurnal and nocturnal)
- Urgency
- Urge incontinence
- Hesitancy
- Weak or prolonged urinary stream
- Feeling of incomplete emptying
- Manual reduction of the prolapse to start or complete voiding
- Positional changes to start or complete voiding

Bowel Symptoms

Bowel symptoms that should be considered for dichotomous, ordinal, or visual analog scaling include, but are not limited to, the following:

- Difficulty with defecation
- Incontinence of flatus
- Incontinence of liquid stool
- Incontinence of solid stool
- Fecal staining of underwear
- Urgency of defecation
- Discomfort with defecation
- Digital manipulation of the vagina or perineum to complete defecation
- Feeling of incomplete evacuation

Sexual Symptoms

Research is needed to attempt to differentiate the complex and multifactorial aspects of “satisfactory sexual function” as it relates to pelvic organ prolapse and pelvic floor dysfunction. It may be difficult to distinguish between the ability to have vaginal intercourse and normal sexual function. The development of satisfactory tools will require multidisciplinary collaboration. Sexual function symptoms that should be considered for dichotomous, ordinal, or visual analog scaling include, but are not limited to, the following:

- Is the patient sexually active?
- If she is not sexually active, why?
- Does sexual activity include vaginal coitus?
- What is the frequency of vaginal intercourse?
- Does the patient experience pain with coitus?
- Is the patient satisfied with her sexual activity?
- Has there been any change in orgasmic response?

Other Local Symptoms

We currently lack knowledge regarding the precise nature of symptoms that may be caused by the presence of a protrusion or bulge. Possible anatomically based symptoms that should be considered for dichotomous, ordinal, or visual analog scaling include, but are not limited to, the following:

- Vaginal pressure or heaviness
- Vaginal or perineal pain
- Sensation or awareness of tissue protrusion from the vagina
- Low back pain
- Abdominal pressure or pain
- Observation or palpation of a mass

Good Urodynamic Practices: Uroflowmetry, Filling Cystometry, and Pressure–Flow Studies*

Werner Schaefer, Paul Abrams, Limin Liao, Anders Mattiasson, Francesco Pesce, Anders Spangberg, Arthur M. Sterling, Norman R. Zinner, and Philip van Kerrebroeck

INTRODUCTION

A good urodynamic practice comprises three main elements:

1. A clear indication for, and appropriate selection of, relevant test measurements and procedures
2. Precise measurement with data quality control and complete documentation
3. Accurate analysis and critical reporting of results

The aim of clinical urodynamics is to reproduce symptoms while making precise measurements in order to identify the underlying causes for the symptoms and to quantify the related pathophysiological processes. By doing so, it should be possible to establish objectively the presence of a dysfunction and understand its clinical implications. Thus, we may either confirm a diagnosis or give a new, specifically urodynamic, diagnosis. The quantitative measurement may be supplemented by imaging (videourodynamics).

Urodynamic measurements cannot yet be completely automated, except for the most simple urodynamic procedure—uroflowmetry. This is not an inherent problem of the measurement itself but is due to the current limitations of urodynamic equipment and the lack of a consensus on the precise method of measurement, signal processing, quantification, documentation, and interpretation. With the publication of this International Continence Society (ICS) standardization document on good urodynamic practice, it is expected that the necessary technological developments in automation will follow.

Urodynamics allows direct assessment of lower urinary tract (LUT) function by the measurement of relevant physiologic parameters. The first step is to formulate the "urodynamic question or questions" from a careful history, physical examination, and standard urologic investigations. The patient's recordings of micturitions and symptoms on a frequency volume chart, and repeated free uroflowmetry with determination of postvoid residual volume, provide important, noninvasive, objective information that helps to define the specific urodynamic question(s) prior to invasive urodynamics such as filling cystometry and pressure–flow studies.

Recommendations for good urodynamic practice are bullet pointed.

RECORDING MICTURITIONS AND SYMPTOMS

A micturition time chart records the time of each micturition. The usefulness of such a record is significantly enhanced when the voided volumes are recorded in a frequency volume chart. The bladder diary adds to this the relevant symptoms and events such as urgency, pain, incontinence, episodes, and pad usage. Recording for a minimum of 2 days is recommended. From the recordings, the average voided volume, voiding frequency, and, if the patient's time in bed is recorded, day/night urine production and nocturia can be determined. This information provides objective verification of the patient's symptoms, together with key values for plausibility control of subsequent urodynamic studies, for example, in order to prevent overfilling of the patient's bladder.

UROFLOWMETRY

Uroflowmetry is noninvasive and relatively inexpensive. Therefore, it is an indispensable, first-line screening test for most patients with suspected LUT dysfunction. Objective and quantitative information, which helps in the understanding of both storage and voiding symptoms, is provided by this simple urodynamic measurement.

Adequate privacy should be provided and patients should be asked to void when they feel a “normal” desire to void. Patients should be asked if their voiding was representative of their usual voiding and their view should be documented. Automated data analysis must be verified by inspection of the flow curve, artifacts must be excluded, and verification must be documented. The results from uroflowmetry should be compared with the data from the patient’s own recording on a frequency/volume chart. Sonographic estimation of postvoid residual volume completes the noninvasive assessment of voiding function.

Normal Uroflow

Normal voiding occurs when the bladder outlet relaxes (is passive) and the detrusor contracts (is active). An easily distensible bladder outlet with a normal detrusor contraction results in a smooth arc-shaped flow rate curve with high amplitude. Any other shapes—such as curves that are flat, asymmetric, or have multiple peaks (fluctuating and/or intermittent)—indicate abnormal voiding, but are not specific for its cause.

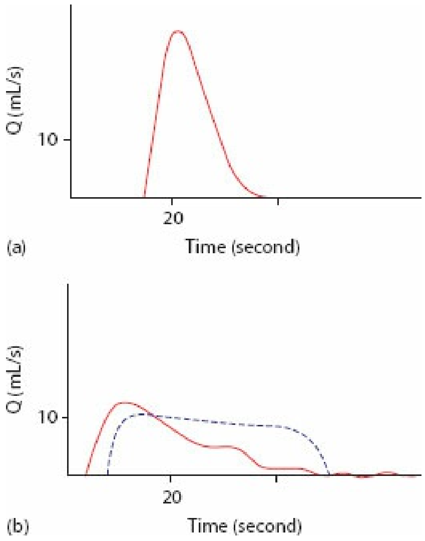

Figure F.1 (a) Typical normal flow; (b) constrictive flow curve (dotted line), compressive flow curve (solid line).

It is assumed that it is normal for the mechanical properties of a relaxed outlet to be constant, and that the properties can be defined by the dependency of the cross-sectional area of the urethral lumen on the intraurethral pressure at the flow rate controlling zone (FRCZ). Typically, below the minimum urethral opening pressure, the urethral lumen is closed. The lumen then opens widely with little additional pressure increase. With normal detrusor contractility and low intraurethral pressure, the normal flow curve is arc shaped with a high maximum flow rate (Figure F.1a).

A normal flow curve is a smooth curve without any rapid changes in amplitude because the shape of the flow curve is determined by the kinetics of the detrusor contraction that—arising from smooth muscle—does not show rapid variations. A decreased detrusor power and/or a constant increased urethral pressure will both result in a lower flow rate and a smooth flat flow curve. A constrictive obstruction (e.g., urethral stricture) with reduced lumen size results in a plateaulike flow curve (Figure F.1b, dotted line).

A compressive obstruction with increased urethral opening pressure (e.g., benign prostatic obstruction) shows a flattened asymmetric flow curve with a slowly declining end part (Figure F.1b, solid line).

The same pattern may also originate from a weak detrusor in aging males and females. Fluctuations in detrusor contractility or abdominal straining, as well as variable outlet conditions (e.g., intermittent sphincter activity), will lead to complex flow rate patterns.

Rapid changes in flow rate may have physiological or physical causes that are due either to changes in outlet resistance (e.g., sphincter/pelvic floor contraction or relaxation, mechanical compression of the urethral lumen, or interference at the meatus) or to changes in driving energy (e.g., abdominal straining). These intracorporeal causes lead to true flow rate changes. Rapid changes in flow rate may also be artifacts, when the flow rate signal is extracorporeally modified through interference between the stream and the collecting funnel (the flowmeter), movement of the stream across the surface of the funnel, or patient movements (see flow curves in Figures F.2 through F.7).

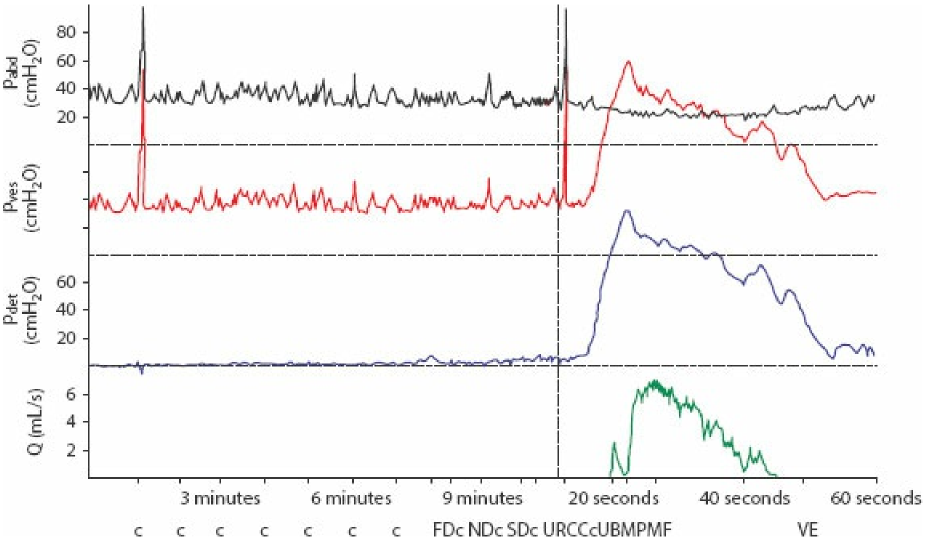

Figure F.2 Full recording of filling and voiding. Starting with initial values for p_{ves}, p_{abd} of 32 cmH_2O in the typical range for a standing patient with zero p_{det}; testing signal quality with a vigorous cough at the beginning, and regularly repeated (here less strong) coughs. Additionally, the pressure recordings show the typical pattern of a talking patient, while the p_{det} trace is unaffected; a weak contraction at first desire (FD); another vigorous cough before voiding; beginning of flow shows dyssynergic sphincter activity as proven by a decrease in flow with an increase in p_{det}.

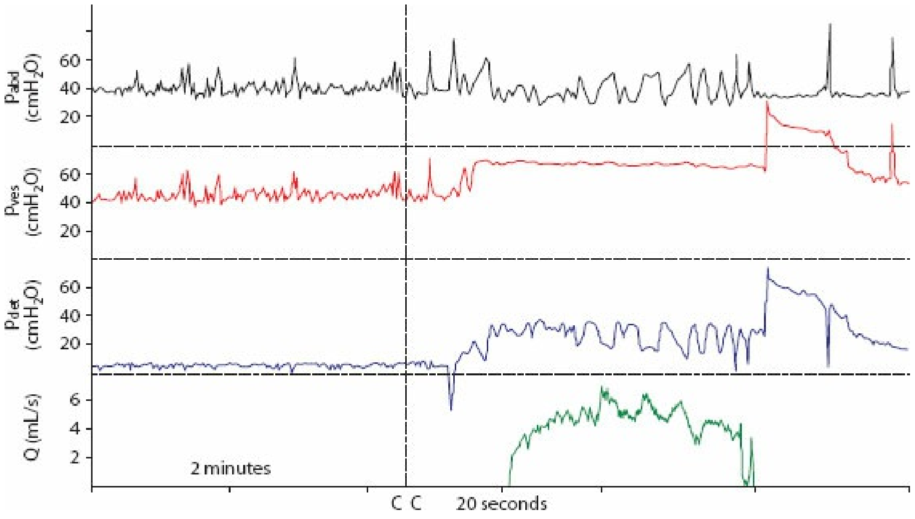

Figure F.3 Good recording quality until cystometric capacity is reached; at second cough before voiding the intravesical signal is lost (no response in p_{ves}, negative spike in p_{det}). Dead p_{ves}—signal during voiding, which is “live” again only at the second cough after voiding. Thus, pressure–flow study is lost. Careful observation of signals would have made it possible to interrupt the study immediately the signal failed and to correct this problem before voiding started.

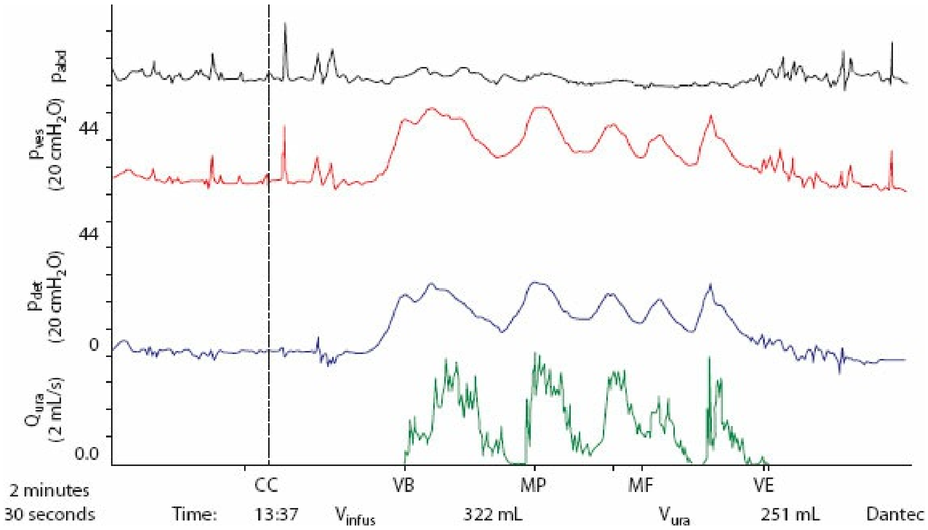

Figure F.4 Variable flow rate due to varying detrusor contraction strength (VO ID: 7/250/70). *Abbreviations*: CC, cystometric capacity; VB, void begins; MP, maximum pressure; MF, maximum flow; VE, void ends.

Accuracy of Uroflowmeters

Uroflowmetry measures the flow rate of the external urinary stream as volume per unit time in milliliters per second. The ICS Technical Report [1] made recommendations with respect to uroflowmetry, but did not compare different flowmeters by specific testing. There are, however, differences in the accuracy and precision of the flow rate signals that depend on the type of flowmeter, on internal signal processing, and on the proper use and calibration of the flowmeter. The desired and actual accuracy of uroflowmetry should be assessed in relation to the potential information that could be obtained from the urinary stream compared to the information actually abstracted for clinical and research purposes. Some relevant aspects of the physiological and physical information contained in the urinary stream are outlined here.

The desired clinical accuracy may differ from the technical accuracy of a flowmeter. The ICS Technical Report recommended the following standards: a range of 0–50 mL/s for Q_{max} and 0–1000 mL for voided volume, maximum time constant of 0.75 second, and an accuracy of ±5% relative to full scale, although a calibration curve representing the percentage error over the entire range of measurement should be made available. However, technical specifications from the manufacturers are rare and often not in accordance with ICS recommendations; this situation should be rectified.

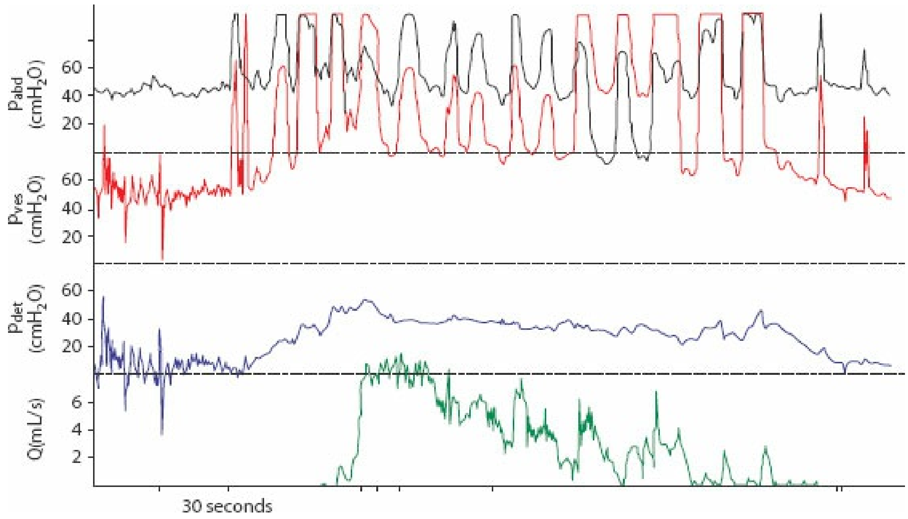

Figure F.5 The first part of the traces shows typical biphasic movement artifacts. The two coughs before voiding prove good recording quality. The typical picture of an unobstructed voiding: a weak detrusor

contraction with pdet of 40 cmH_2O and a Q_{max} of 9 mL/s is supported by vigorous straining, which causes some variability in flow (VO ID: 9/380/100).

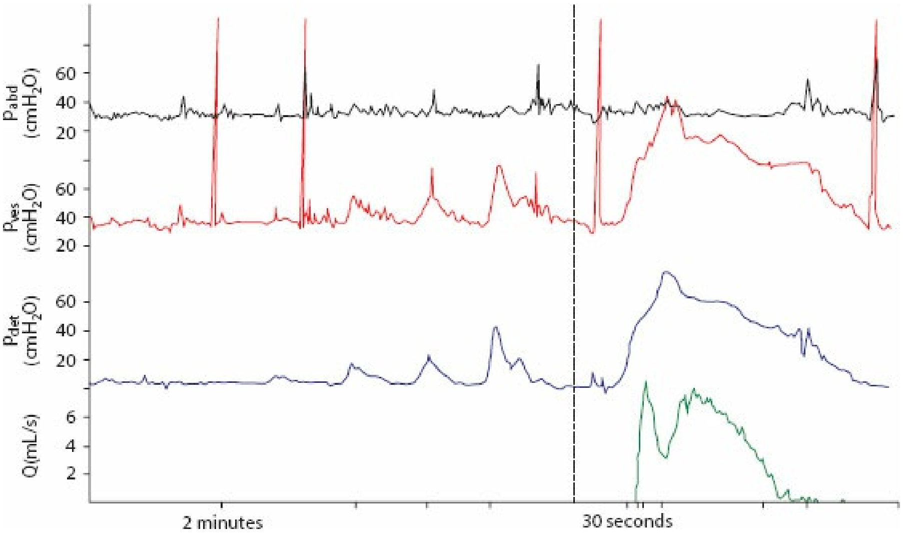

Figure F.6 A good recording showing the typical pattern of increasing detrusor overactivity and a dyssynergic event during voiding.

Furthermore, as most flowmeters are mass flowmeters (e.g., a weight transducer or rotating disk), variations in the specific gravity of the fluid will have a direct influence on the measured flow rate. For example, urine of high concentration may increase apparent flow rate by 3%. With x-ray medium, the flow rate may be overestimated by as much as 10%. These effects should be corrected by calibration software.

Thus, since the overall accuracy of flow rate signals will not be better than ±5%, it would not be meaningful to report a maximum flow rate of a resolution better than a full milliliter per second. Under carefully controlled research conditions, a better resolution may be possible by flowmeter calibration and instrument selection. However, such improvements in resolution may not be required for routine clinical applications. The dynamic properties of most flowmeters will be good enough for free uroflowmetry. When pressure–flow data are analyzed, however, the limitation in signal dynamics should be taken into account because pressure will be different from flow. Flow signals have a much slower response and are less accurate than pressure signals.

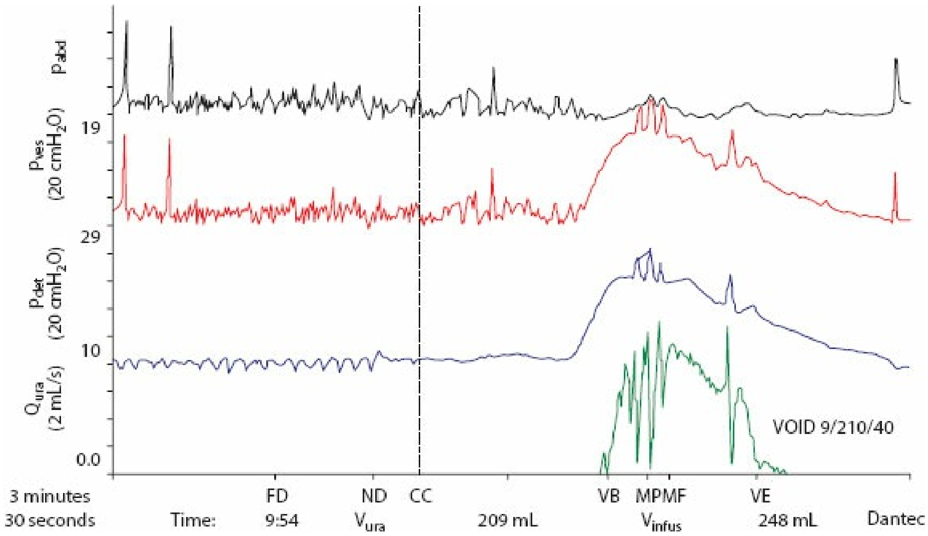

Figure F.7 High-quality recordings allow detailed interpretation. The typical pattern of rectal activity becomes clearly visible in p_{det}. The flow artifacts can be identified as dyssynergic events and manually

corrected from $Q_{max.raw}$ = 11.2 mL/s to Q_{max} = 9 mL/s. *Abbreviations*: CC, cystometric capacity; FD, first desire; ND, normal desire; MP, maximum pressure; MF, maximum flow; VB, void begins; VE, void ends.

Problems in Urine Flow Rate Measurement

The problems in measurement, as well as the information that can be abstracted from the flow rate signal, are rather different for free uroflowmetry compared to combined pressure–flow recordings.

In free uroflowmetry, the shape of the flow curve may suggest specific types of abnormality; however, reliable, specific, and detailed information about the cause of abnormal voiding cannot be derived from a flow curve alone. Only when uroflowmetry is combined with intravesical and abdominal pressure (p_{abd}) recordings does it become possible, from the pressure–flow relationship, to analyze separately the contributions of detrusor contractility and bladder outlet function to the overall voiding pattern (Figures F.2 through F.7).

Urine flow rate measurement is affected by a number of important factors.

Detrusor Contractility

As the voiding function reflects the interaction between the relaxed outlet and the contracting detrusor, variation of both will affect the flow. For steady outflow conditions, all variations in flow rate are related to changes in detrusor activity alone. The detrusor contraction strength varies neurogenically and myogenically, and can cause significant variability in urine flow rate measurements (Figure F.4).

Bladder Outflow Resistance

If detrusor contractility is constant, then changes in outflow resistance will lead to changes in flow rate, for example, in patients with detrusor–sphincter dyssynergia (Figures F.2, F.6, and F.7).

Bladder Volume

As the bladder volume increases and the detrusor muscle fibers become more stretched, there is an increase in the potential bladder power and work associated with a contraction. This is most pronounced in the range from empty up to 150–250 mL bladder filling volume. It appears that, at volumes higher than 400–500 mL, the detrusor may become overstretched and contractility may decrease again. Therefore, Q_{max} is physiologically dependent on the bladder volume. This dependency will vary between individuals and with the type and degree of pathology; for example, in constrictive obstruction, Q_{max} is almost independent of volume, and in compressive obstruction, the dependency becomes weaker with increasingly obstructed outlet conditions and lower flow rate.

Technical Considerations

The flow rate signal is influenced by the technique of measurement and by signal processing. The external urinary stream should reach the flowmeter unaltered and with minimal delay. However, any funnel or collecting device, as well as the flowmeter, will inevitably introduce modifications to the flow rate recording. Physically, the external urinary stream breaks into drops not far from the meatus. This fine structure of the stream has a high frequency, which can be assessed by drop spectrometry, and contains interesting information. For standard uroflowmetry, however, such high frequencies should be eliminated by signal processing.

For free uroflowmetry, all intracorporeal modulations of the flow rate are physiologic artifacts and should be minimized (e.g., by asking the patient to relax and not to strain). Nevertheless, certain dynamic patterns of intracorporeal modulations can provide information about functional obstruction (e.g., typical patterns of detrusor–sphincter dyssynergia or abnormal straining). This information may be lost by excessive filtering or during analog to digital (A/D) conversion with a filter speed of <10 Hz. The precise interpretation of dynamic variations in the flow rate signal is only possible when the flow rate is viewed together with the simultaneously recorded pressure signals. Thus, only in combined pressure–flow recordings can the details of the flow signal be fully understood.

For the determination of the “true” maximum flow rate value, particularly during free flow, such high-frequency signal variations are more likely to be misleading, and consequently they should be suppressed electronically.

Recommendations for Uroflowmetry

In order to facilitate the recording of urine flow rate and pattern recognition of flow curves, it is recommended that graphical scaling should be standardized as follows: 1 millimeter should equal 1 second on the x-axis and 1 mL/s and 10 mL voided volume on the y-axis.

With respect to the technical accuracy of uroflowmeters, it is meaningful for routine clinical measurements to read flow rate values only to the nearest full milliliters per second and volumes to the nearest 10 mL.

In order to make electronically read Q_{max} values more reliable, comparable, and clinically useful, we recommend internal electronic smoothing of the flow rate curve. It is recommended that a sliding average over 2 seconds should be used to remove positive and negative spike artifacts.

If curves are smoothed by hand, the same concept should be applied. That is, when reading Q_{max} graphically, the line should be smoothed by eye into a continuous curve so that in each period of 2 seconds, there are no rapid changes. Such a smoothed, clinically meaningful maximum free flow Q_{max} will be different (lower) from the peak value in the flow rate recording of electronic instruments currently available (Figures F.4, F.5, F.7, and F.8).

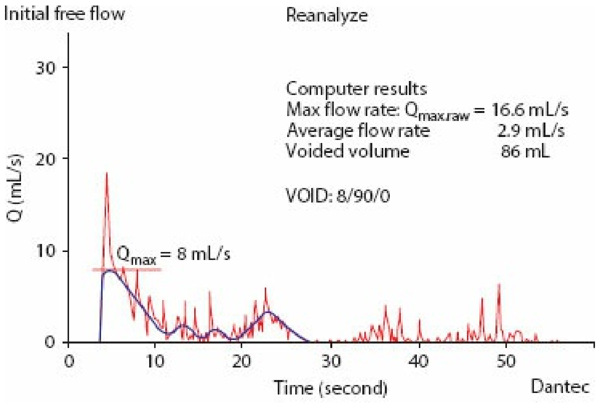
It is recommended that only flow rate values that have been “smoothed,” either electronically or manually, should be reported.

If a maximum flow value is determined electronically by simple signal peak detection without the recommended electronic smoothing, it should be labeled differently—$Q_{max.raw}$. Such raw data have meaning only if a detailed specification of the type of flowmeter used is given.

The interpretation of any dynamic variation (signal patterns) in free flow will rely on personal experience, can be only descriptive, and in general will remain speculative.

For the documentation of the results of uroflowmetry, the following recommendations are made:

- Maximum (smoothed) urine flow rate should be rounded to the nearest whole number (a recording of 10.25 mL/s would be recorded as 10 mL/s).
- Voided volume and postvoid residual volume should be rounded to the nearest 10 mL (a recording of a voided volume of 342 mL would be recorded as 340 mL).



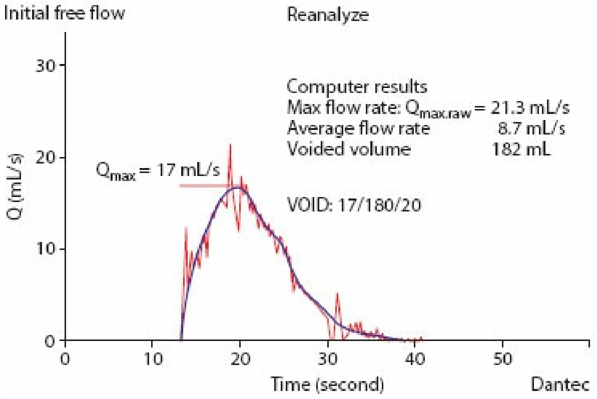


Figure F.8 Exclusion of artifactual spikes in the flow curve, $Q_{max.raw}$, and determination of a clinically relevant maximum flow rate, Q_{max}, by manual smoothing. The results from uroflowmetry should be reported in the standard format: $Q_{max}/V_{void}/V_{res}$.

- The maximum flow rate should always be documented together with voided volume and postvoid residual volume using a standard format (VOID: maximum flow rate/volume voided/postvoid residual volume).

For example, the automatically detected flows, $Q_{max.raw}$, are 16.6 and 21.3 mL/s with voided volumes of 86 and 182 mL, respectively. The smoothed Q_{max} values are 8 and 17 mL/s and should be reported with voided volumes of 90 and 180, respectively, and the estimated residuals as VOID1 = 8/90/0 and VOID2 = 17/180/20 (Figures F.4, F.5, and F.8).

The adoption of these standards will aid the interpretation of uroflowmetry results. If data are not available, then a minus sign should be used;, for example, if only the voided volume is known, VOID = −/340/−, or if the voided volume was missing, VOID = 10/−/90.

- If a flow/volume nomogram is used, this should be stated and referenced.

Uroflowmetry data from other than free flow (e.g., measured in combination with intravesical pressure) should be reported with an additional descriptive index, p, that is, Q_{maxp}, for pressure–flow recording.

INVASIVE URODYNAMICS: FILLING CYSTOMETRY, PRESSURE–FLOW STUDY OF VOIDING

Introduction

Invasive urodynamic procedures should not be performed without clear indications and the formulation of specific urodynamic question(s). This process will usually be aided by the a priori completion of a frequency volume chart and free uroflowmetry. There are certain key recommendations that will lead to the performance of a successful urodynamic study: First, a good urodynamic investigation should be performed interactively with the patient. It should be established by discussion with the patient that the patient's symptoms have been reproduced during the test. Second, there should be continuous and careful observation of the signals as they are collected, and the continuous assessment of the qualitative and quantitative plausibility of all signals. Third, artifacts should be avoided, and any artifacts that occur should be corrected immediately. It is always difficult and is often impossible to correct artifacts during a retrospective analysis. Furthermore, it is more time-consuming than if the signals are continuously observed and tested at regular intervals and artifacts recognized during the urodynamic study and corrected.

At present, ambulatory urodynamic monitoring has to rely on retrospective quality control and artifact corrections. However, in principle, the same quality criteria apply for ambulatory urodynamic monitoring as for standard urodynamics [2]. This makes a consensus on quality even more important, because only when such criteria are precisely defined can they be implemented in an "automated intelligent" ambulatory system.

Quality control relies on pattern recognition and a knowledge of normal values as well as prior identification of useful information obtained from noninvasive urodynamics and all other sources relevant for the urodynamic question. Thus, before invasive urodynamics, a frequency volume chart should be completed. Useful information obtained from noninvasive testing includes typical voided volumes and postvoid residual volumes as well as the expected values for Q_{max}. This information should be used for the control of subsequent invasive studies. Only by good preparation can it be ensured that (1) the proper answers to the urodynamic questions will be obtained before the study is terminated and (2) essential modifications, additions, or repetitions of measurements will have been performed in order to derive the necessary information.

The effective practice of urodynamics requires (1) a theoretical understanding of the underlying physics of the measurement, (2) practical experience with urodynamic equipment and procedures, (3) an understanding of how to ensure quality control of urodynamic signals, and (4) the ability to analyze critically the results of the measurements. Because urodynamics deals largely with mechanical measurements such as pressure and volume and their related changes in time, and because many analytical models use mechanical concepts such as resistance to flow or contraction power, it is essential that the nature of these measurements and concepts, in particular for pressure and flow rate, are understood. Therefore, in addition to a comprehensive understanding of anatomy and physiology, some basic knowledge of biomechanics and physics is required.

The quality control of urodynamic measurements must be approached on a holistic basis. Different types and levels of data quality and plausibility control should be used (1) on a physical and technical level, (2) on a biomechanical level, and (3) on a pathophysiological clinical level. A common problem in urodynamics is that clinicians often proceed immediately to a clinical interpretation, that is, to level 3, without a critical analysis of the potential pathophysiologic information content, without considering the plausibility of the signals (level 1), without considering the biomechanical context of the measurements (level 2), and without taking into account the physical properties of the parameters, technical limitations, and accuracy of the signals. Therefore, it is recommended that invasive urodynamics should not be performed without precise indications and well-defined "urodynamic questions" that are to be answered by the results of the urodynamic study.

Measurement of Urine Flow Rate during Pressure–Flow Studies

The usefulness of the concept of a FRCZ for data analysis requires that the recorded pressure and flow rate signal be synchronized with respect to the FRCZ [3]. Normally, no measurable time delay will exist between the intravesical pressure signal and the actual flow at the FRCZ. However, a significant delay is to be expected for the typical urodynamic flow rate recorded extracorporeally. This delay will vary with anatomy, pathology, flow rate, and the setup for measurement. Our understanding of the actual dynamics of flow rate changes is limited, and the relatively slow response of most flowmeters may not be sufficient to match the dynamics of the much faster pressure signal. The actual time difference may be from 0.5 to 2 seconds; the time delay between urethral closure and the end of any flow recording may be much longer, particularly in prostatic obstruction and terminal dribbling than between the opening of the urethra and the start of a flow rate signal. Therefore, we recommend the use of more descriptive terminology for synchronizing pressure and flow values, such as $p_{det.Qbeg}$ for the pressure at which flow begins instead of $p_{det.open}$, and $p_{det.Qend}$ when flow ends instead of $p_{det.close}$. The time delay correction needs to be considered when analyzing pressure–flow studies [3].

On average, the maximum flow rate recorded during pressure–flow studies ($Q_{max.p}$) is lower than during free flow (Q_{max}). This, however, is not due simply to a mechanical increase of outflow resistance by the intraurethral catheter, because such a difference is also found in suprapubic pressure–flow studies. A difference has also been reported between $Q_{max.p}$ during conventional and ambulatory urodynamics. This indicates more complex causes, possibly psychogenic, but also physiologic, for example, that a difference in detrusor contraction strength may be involved, and that the fast filling rate used in clinical studies may lead to reduced contractility. This could also explain the difference in results between conventional and ambulatory studies.

Measurement of Intravesical and Abdominal Pressure

It is recommended that there is strict adherence to the ICS standardization of zero pressure and reference height. Only then can pressure recordings be compared between patients and centers.

Zero pressure and reference height are concepts that are often confused in urodynamics, for example, by use of the misleading term "zero reference height." As both are independent features of pressure, they must be considered separately, and both must follow recommended ICS methodology:

- Zero pressure is the surrounding atmospheric pressure. Zero pressure is the value recorded when a transducer is open to the environment when disconnected from any tubes or catheters, or when the open end of a connected, fluid-filled tube is at the same vertical level as the transducer. Only then can a "set zero" or "balance" be performed.
- The reference height is defined as the upper edge of the symphysis pubis. The reference height is the level at which the transducers must be placed so that all urodynamic pressures have the same hydrostatic component. It is often argued that it does not make a difference for the most relevant parameter, p_{det}, if the same error is introduced to p_{ves} and p_{abd}, as they tend to cancel each other out. This is not an acceptable argument. The hydrostatic pressure is real and important, and

inevitably plays a role in any intracorporeal pressure recording. Many important aspects of quality and plausibility control, such as typical resting value ranges at different patient positions, are based on the proper recording of pressures, and will not apply if pressures are not recorded according to ICS standards. Also, it is only meaningful to subtract one pressure from the other—for example, ($p_{ves} - p_{abd} = p_{det}$)—when both are recorded to the same reference level.

Pressure Transducers

Urodynamic techniques are developed using external pressure transducers connected to the patient with fluid-filled lines, allowing easier compliance with the standards of correct zero and reference height. Catheter-mounted pressure transducers, so-called microtip transducer catheters, have become popular due to their apparent higher accuracy, better dynamic resolution, and their apparent independence from hydrostatic pressure. A catheter-mounted pressure transducer is an advantage for dynamic recordings of urethral pressures during coughing (stress profiles) as well as for ambulatory urodynamics in mobile patients. Here, only the application of catheter-mounted pressure transducers for intravesical and p_{abd} recordings will be discussed as urethral pressures are dealt with in a separate report [4].

All aspects of urodynamic pressure recording outlined in the preceding section are valid and independent of transducer type. It is impossible to define the precise position of an intravesical and a rectal catheter-mounted pressure transducer as to place them at any common level, and impossible to position them at the standard level of the upper border of the symphysis pubis. It has become popular to circumvent this problem by setting the catheter-mounted pressure transducer to zero pressure when inside the body at the start of pressure recording. This, however, means that both the standard zero pressure as well the reference level are ignored, so that such recorded pressure cannot be compared between patients or centers. The fact is that the initial intravesical and abdominal resting pressures are real, are different between patients, and depend significantly on the patient's position. Thus, there are significant potential errors: By ignoring the correct atmospheric zero pressure, an error of up to 50 cmH_2O can occur, and as the reference height of catheter-mounted pressure transducers is usually undetermined, another potential error of 10 cmH_2O is possible for a full bladder. In addition, when a study starts with zero p_{abd}, then the commonly observed p_{abd} decrease at pelvic floor relaxation during voiding will result in negative p_{abd} values, and thus in p_{det} being higher than p_{ves}.

The same problem of apparent independence from the existing hydrostatic pressure also applies to air-filled catheters and/or connection tubings. Due to the absence of a water column between the balloon-covered opening on the catheter and the external transducer, the reference height in an air-filled system will refer to the position of the sensing balloon on the catheter and not to the external transducer.

It is recommended that external transducers connected to fluid-filled tubings and catheters be used for intravesical and p_{abd} recording. If microtip or air-filled catheters are used, any deviation from standard zero and reference level should be minimized and taken into account at the time of data analysis.

Urodynamic Catheters

Comparison between patients and urodynamic studies performed in different centers would be facilitated by the use of standard catheters. It is recommended that for the measurement of intravesical pressure and for bladder filling, the standard catheter for routine urodynamics is a transurethral double-lumen catheter.

Only in small children and patients with severe constrictive obstruction (stricture) does suprapubic pressure recording have clear advantages. Intraurethral catheters should be as thin as possible, limited only by the practicality of insertion and by internal lumen sizes, which should be sufficiently large to avoid excessive damping of pressure transmission and to achieve the desired filling rate with standard pumps. A 6 Fr double-lumen catheter is the smallest practical size at present.

The major advantage of a double-lumen catheter is that the fill/void sequence can be repeated without the need for recatheterization. Note that the use of a 6 Fr double-lumen catheter can limit the infusion rate during cystometry to 20–30 mL/min, as a typical roller pump may not manage to transport a higher perfusion rate through such a small lumen. This can result in an incorrect filling volume being indicated by the machine when the filling volume is calculated from the pump setting. For example, with a filling rate set at 60 mL/min and an actual filling rate of 30 mL/min, the machine will show double the filling volume. Thus, after voiding, a high calculated residual will occur. With some equipment, higher filling rates are possible; it is essential that any system should be critically tested to (1) measure the maximum filling rate that can be achieved by a particular catheter attached to an individual pump and (2) correct or calibrate the indicated infused volume.

The use of two separate tubes for filling and recording is less convenient. Removing the larger filling tube for voiding may appear to be an advantage because only a single small tube is left in the urethra. However, there are no data to suggest that, for example, in a compressive obstruction such as benign prostatic obstruction, a 6 Fr catheter has a detrimental influence on the pressure or flow data. There are, however, data suggesting that results from a single study may be misleading. A double-lumen catheter facilitates a second fill/void study to establish reproducibility. Reintroduction of the separate filling tube for a repeated study is more invasive and complicated.

- The use of rectal balloon catheter is recommended for the measurement of p_{abd}.

Although there are various methods for the successful recording of p_{abd}, a flaccid, air-free balloon in the rectal ampulla gives a suitable signal for p_{abd} to determine a meaningful p_{det} when p_{ves} is measured synchronously ($p_{det} = p_{ves} - p_{abd}$). In females, vaginal recording may be more acceptable and provides comparable results. The recording of p_{abd} allows the measurement of any abdominal (i.e., perivesical) pressure component during changes in intravesical pressure. The role of the balloon is to maintain a small fluid volume at the catheter opening and to avoid fecal blockage, which can prevent or impair pressure transmission to the transducer. Additionally, as the rectal ampulla and the vagina are not homogeneously fluid-filled spaces, the balloon prevents pressure artifacts arising from contact between the catheter opening and the wall tissue. The balloon serves this function best when it is filled to only 10%–20% of its unstretched capacity. Overfilling and elastic distension of the balloon is the most common mistake in p_{abd} recording. The resultant high balloon (not abdominal) pressure will produce a misleading pressure reading. Such an artificially elevated balloon distention pressure can be avoided by making a small hole in the balloon, although this is unnecessary if the balloon is filled properly as described earlier. It is also possible to record reliable p_{abd} with a very slowly perfused (<2 mL/min) open-ended catheter. However, excessive fluid volume in the rectal ampulla may cause problems.

Equipment: Minimum Requirements for Filling Cystometry and Pressure–Flow Studies of Voiding

The ICS has not yet specified definite technical standards in respect of minimum requirements for filling cystometry and pressure–flow studies beyond the ICS Technical Equipment Report [1] and the appendix to the ICS document on pressure flow [3], where a data exchange software standard is recommended. Some further aspects will be discussed in more detail here.

Equipment Recommendations

The minimum recommended requirements for a urodynamic system are as follows:

- Three measurement channels—two for pressure and one for flow.
- A display (on printer and/or monitor) and secure storage of three pressures (p_{abd}, p_{ves}, p_{det}) and flow (Q) as tracings against time.
- Infused volume and voided volume may be shown graphically or numerically.
- Online display of pressures and flow, with adequate scale and resolution; scales must be clearly given on all axes; no information should be lost electronically when tracings go off-scale on display.
- Possibilities to record standard information about sensation and additional comments (event recordings).

Meaningful plausibility assessment and quality control are possible only when the measured and derived signals are displayed continuously as curves over time, without delay (in real time), as the examination proceeds. Each displayed curve and number should be labeled according to ICS standards, with clear scaling of amplitudes and the time axis. The following sequential position of tracings is suggested: p_{abd} at the top, then p_{ves}, p_{det}, and Q (Figures F.2 through F.7). It is least important when p_{abd} goes off-scale and is cut off (Figure F.5). Additional parameters such as electromyography (EMG), bladder filling, and voided volumes can be displayed either as curves or digitally as numbers.

The following minimum technical specifications are recommended:

- Minimum accuracy should be ±1 cmH_2O for pressure and ±5% full scale for flow and volume.
- Ranges of 0–250 cmH_2O, 0–25 (50) mL/s, and 1000 mL for pressure, flow, and volume, respectively.
- The software must ensure that no information for pressures up to 250 cmH_2O and for flow rates up to 50 mL/s is lost internally, even when not displayed, and that off-scale values are clearly identified.
- An A/D frequency of 10 Hz per channel as the lower limit for pressure and flow.
- A higher frequency (minimum 20 kHz) is necessary for recording EMG.
- Calibration of all measurements should be possible.

The scalings should be kept unchanged as much as possible, because urodynamic data quality control is based on pattern recognition, and the recognition of patterns depend on scaling. Therefore, it is recommended that during recording and for analysis, minimum scaling for pressure should be of 50 cmH_2O/cm, for flow 10 mL/s/cm, and for the time axis 1 min/cm or 5 s/mm during filling and 2 s/mm during voiding.

To enable a retrospective judgment of the curves, urodynamic measurements should be documented as curves over time with comments and explanations. It is usually insufficient to document urodynamic measurements by a few numerical values alone. The same amplitude of scaling should be used for all documentation, although the time axis may be compressed. Only if there is no relevant information to be lost by reducing resolution (e.g., during filling), the time scale can be compressed.

For a printout, maximum full-scale deflections of 200 cmH_2O, 50 mL/s, and 1000 mL are sufficient for pressure, flow, and volume, respectively. In most cases, half the maximum full scale will be sufficient to show all relevant parts of curves. Line resolution should be better than 0.10 mm.

During interventions (e.g., interruption of bladder filling or manipulation of catheters), the continuation of both measurement and recording must always be possible.

Online recording of comments should be possible, to complete the documentation.

Calibration of Equipment

The need to calibrate pressure transducers, flowmeters, and pumps cannot be stated simply as “yes” if there is a need or “no” if there is not. The specification of the manufacturer should be studied. Two aspects must be considered: the intended accuracy of the system and the investigator’s experience with the system. If a new system is installed or new transducers are being used, it is recommended that regular calibration be carried out. If experience with daily calibration shows that the potential error is small (e.g., <2 cmH_2O), then it will be sufficient to calibrate once a month. However, calibration should not be ignored and good urodynamic equipment makes it technically possible to perform a calibration. Calibration should not be confused with simple “zero balancing,” which is only one part of calibration. In addition to setting the zero, it must be possible to check and adjust the amplitudes of all measurement channels, that is, to calibrate all signals.

Calibration of a flowmeter can be achieved by pouring a precisely measured volume at a constant flow into the flowmeter, typically 400 mL in 20–30 seconds (at 15–20 mL/s), and checking the recorded volume. Special constant flow rate bottles are available for flow calibration. Similarly, one can test a pump by measuring the time to deliver a known volume (e.g., 100 mL) into a measuring cylinder. It is recommended that pump calibration be performed with the filling catheter connected. Such a pump calibration can only be as good as the cylinder used, which needs to have good resolution and be accurate. Some measuring beakers usually available in clinics are not accurate.

Pressure Signal Quality Control: Qualitative and Quantitative Plausibility

It is very important to observe and to test signals carefully and to correct any problems before starting the urodynamic study. If the signals are perfect at the beginning of the study, they usually remain so without the need for major intervention. If the signals are not perfect, remedial action must be taken. If a quality problem does not disappear at once, when filling commences, it will usually deteriorate further during the study.

Conscientious observation of the patient and of the signals, in particular p_{det}, during all parts of the study, together with continuous signal testing, are the keys to high-quality urodynamics. The first aim is to avoid artifacts and the second to correct the source of all artifacts immediately they occur.

The following three criteria form the minimum recommendations for ensuring quality control of pressure recordings:

1. Resting values for abdominal, intravesical, and detrusor pressure are in a typical range (see in the following text).
2. The abdominal and intravesical pressure signals are “live,” with minor variations caused by breathing or talking being similar for both signals; these variations should not appear in p_{det}.
3. Coughs are used (every 1 minute or, for example, 50 mL filled volume) to ensure that the abdominal and intravesical pressure signals respond equally. Coughs immediately before voiding and immediately after voiding should be included.

When standards are followed, that is, with the transducer zeros set to atmospheric pressure and the transducers placed at the level of the upper edge of the symphysis, the typical ranges for initial resting pressure values for p_{ves} and p_{abd} are as follows (Schäfer, unpublished communications):

- Supine 5–20 cmH_2O
- Sitting 15–40 cmH_2O
- Standing 30–50 cmH_2O

Usually both recorded pressures are almost identical, so that the initial p_{det} is zero, or close to zero, that is, 0–6 cmH_2O in 80% of cases and in rare cases up to 10 cmH_2O [5].

All initial pressure values should be verified and the patient’s position should be documented on the urodynamics trace.

All negative pressure values, except when caused by rectal activity, should be corrected immediately. It should always be kept in mind that p_{abd} is recorded not in order to ascertain the actual rectal pressure but to eliminate the impact of (abdominal) pressure changes on p_{ves}. The principal aim is to determine the p_{det}, which is the pressure in the bladder without the influence of p_{abd}. Therefore, p_{det} cannot be negative.

By talking to the patient during the study, the proper dynamic response in the pressure signals can be observed and is “automatically” documented (Figures F.2, F.3, and F.7).

Problem Solving

If either detrusor or rectal contractions occur, the recorded pressures in p_{ves} and p_{abd} will be different. Such changes can be identified and interpreted with sufficient accuracy and reliability only when the patient is observed and the relation between signal changes and patient sensation/activity are checked for plausibility and documented. Any pressure change caused by smooth muscle contractions will show a “smooth” pattern (Figures F.4, F.6, and F.7), that is, there should be no rapid (“stepwise”) changes (Figure F.3). If pressures increase or decrease stepwise, or with a constant slope over a long period of time, a nonphysiologic cause, such as catheter movement, should be considered.

If a sudden drop or increase occurs in either the p_{ves} or the p_{abd} signal, the usual cause is the movement, blockage (Figure F.3), or disconnection of a catheter. When the patient changes position, sudden changes in resting values occur and are seen equally in both pressure signals. If p_{ves} (without change in p_{abd}) increases slowly—as is typical for a low-compliance bladder—it is important to test for any other possible cause for a slow pressure increase. One cause could be a problem with the intravesical catheter measurement; for example, the hole for the pressure conducting lumen is slowly moving into the bladder neck region. This should be assessed by asking the patient to cough, if there is no other apparent artifact. Furthermore, it is recommended that bladder filling is stopped if the filling rate is above a physiological limit of 10 mL/min. If the value of p_{ves} drops after filling is stopped, it is likely that “low compliance” was, at least in part, related to fast filling.

There are several common problems that must be solved before the study is started or when observed during a study:

- *Problem*: Initial resting p_{det} is negative, for example, −5 cmH_2O.
    - *Possible explanation*: The p_{abd} is too high.
    - *Solution*: If p_{ves} is in the typical range, and both pressures are “live,” open the valve in the abdominal line and drain one or two drops from the rectal balloon filling volume. This will usually cause p_{abd} to fall to a proper value. If not, gently reposition the rectal balloon and/or make a small hole in the balloon.
    - Because p_{ves} is too low.
    - *Solution*: This may be due to air bubbles trapped in the catheter, the catheter not being in the bladder, or the catheter being blocked/kinked. Gently flush through the p_{ves} line (maximum 10 mL). It is very important to flush slowly while observing the pressure signal because pressures above 300 cmH_2O may damage the transducer. If this does not solve the problem, add some more volume to the bladder via the filling lumen. If resistance to filling is high and it does not drain easily when opened, it will be necessary to check the catheter position, and to reposition the catheter, if necessary.
- *Problem*: Initial p_{det} is too high, for example, 15 cmH_2O.
    - *Possible explanations*: (1) The key problem here is indicated by the measurement of 15 cmH_2O. The situation is different from the clear statement that “p_{det} cannot be negative” as we do not have a definite upper limit for the normal maximum “resting” value for p_{det}. Thus, we can only follow the present guidelines that, in most tests in an empty bladder, p_{det} is between 0 and 5 cmH_2O, and in some 90%, it is between 0 and 10 cmH_2O. For any higher value, stringent plausibility checking must be applied. If the patient has no detrusor overactivity, a p_{det} of 15 cmH_2O is unlikely to be valid and there may be a signal problem. First check if p_{abd} and p_{ves} are in the expected ranges. For example, if, in a standing patient, initial p_{ves} is 30 cmH_2O and p_{abd} is 15 cmH_2O, then by experience the value of p_{abd} is too low (because p_{abd} is too low). If in a supine patient p_{abd} is 10 cmH_2O and p_{ves} is 25 cmH_2O, then the value of p_{ves} is too high (because p_{ves} is too high). Check the zero balance and proper signal response to coughing for both signals. (2) The p_{abd} is too low.
    - *Solution*: Very slowly flush the rectal balloon with 1 or 2 mL. o Because p_{ves} is too high.
    - *Solution*: This problem can be related to a misplaced catheter, a kink in the catheter, or contact with the bladder wall in an empty bladder, which occludes the eyehole(s) of the catheter. Proceed according to the solution of p_{ves} being too high, in the first aforementioned example.
    - If no signal problems can be identified, the clinical study may be started, but the p_{det} signal deserves particular attention. If compliance is normal and the bladder normal at filling, then it is very important to record and check, for some period after the micturition, the postvoiding resting value of p_{det}. Only if an elevated p_{det} is perfectly reproducible for repeated filling and voiding studies can it be accepted. However, it is most likely that a high resting p_{det} will not be reproducible and will be corrected by the measures described earlier.
    - In summary, if any resting value or cough response does not fit the usual values or patterns, it should be corrected before bladder filling is started. If this is not possible, the signals must be observed even more carefully and every effort made to reveal the potential source of error or artifact during the study.

Retrospective Artifact Correction

In principle, a good p_{det} signal requires only that p_{ves} and p_{abd} show the same fine structure and quality of signals before filling, during filling, and after a voiding (Figures F.2, F.3, F.6, and F.7). Both p_{ves} and p_{abd} must have the same zero and reference level. The most common mistake is to set (balance) the initial pressure values of p_{ves} and p_{abd} to zero with the catheters connected to the patient instead of setting zero to atmospheric pressure. This results in incorrect p_{ves} and p_{abd}. If this is done, urodynamic studies cannot be compared between centers and between patients. Although it may seem convenient and easy to start with a value of p_{det} as zero, this practice will lead to problems later in the test. As soon as pelvic floor relaxation occurs, which is particularly common during voiding, the value of p_{abd}, if starting at zero, becomes negative. With a negative pabd, p_{det} will be higher than p_{ves}, a conceptually meaningless result. Furthermore, it will then be impossible to correct a negative p_{abd}. Cough tests at regular intervals, particularly before and after voiding, document the dynamic response of the pressure channels and are fundamentally important.

A typical physiological artifact that can be easily recognized is a rectal contraction. Rectal contractions are usually of low amplitude and may or may not be felt by the patient (Figure F.7). The value of p_{abd} shows a phasic rise with no change in the p_{det} signal—a potentially confusing fall in p_{det} results from the electronic subtraction, but this is, of course, an artifact. Usually, rectal contractions are relevant only because they may be misinterpreted as detrusor overactivity (Figure F.7); they have no relevance to voiding.

Biphasic spikes as a response to cough tests are another example of artifacts that are easy to correct. However, any other artifacts—such as a signal that is nonresponding (dead), has stepwise changes in pressure, or has negative pressures—often cannot be corrected or can be corrected only with extensive speculation about the underlying causes of the problem. Studies with such artifacts should be repeated (see the next section).

Retrospective corrections require the same strategies for plausibility control as during recording, but are then much more difficult and less successful to perform.

A few common artifacts (e.g., rectal activity, biphasic spikes at cough tests, or insufficient p_{abd} response during straining) can be accepted during the study as they can be corrected retrospectively. Usually, this is easier to do manually than through a computerized system.

Urodynamic Computer Software

Computer applications should allow the easy use of even the most complicated analytical algorithms. However, most of the software offered by the urodynamic equipment industry is neither original nor validated. The software may, in fact, not do what the original developer(s) of the algorithm intended. Therefore, it is recommended that when analytical urodynamic software is used to perform data analysis according to any published concept, the source of the software should be specified. It should also be clearly stated if the software has been validated, that is, proven to provide results consistent with the algorithms to which the analyses are attributed.

STRATEGY FOR REPETITION OF URODYNAMIC TESTS

- It is recommended that a urodynamic test should be repeated if the initial test suggests an abnormality, leaves the cause of troublesome LUT symptoms unresolved, or if there are technical problems preventing proper analysis.

It may not be necessary, however, to repeat a study that, beyond any doubt, confirms the expected pathology, for example, detrusor overactivity that correlates with the patient’s symptoms. However, if the study is inconclusive, then the consequences of not finding a clear answer to the urodynamic question(s) should be considered. If an invasive therapy is planned, the urodynamics should be repeated. Therefore, it is necessary to analyze the signals during the study and document the study immediately upon its conclusion. Only then is it possible to be sure that the urodynamic study is of a quality that answers the urodynamic question and provides an understanding about the patient’s clinical problem. Therefore, it is recommended that the urodynamic findings and the interpretation of the results should be documented immediately after the study is finished, that is, before the patient has left the urodynamic laboratory, thus allowing for a second test if required.

The analysis of a good study is easy and straightforward. Indeed, an easy analysis is actually the key criterion for good urodynamics. A good study is one that is easy to read and one from which any experienced urodynamicist will abstract the same results and come to the same conclusions. For computerized analyses, high data quality is even more important than for manual graphical data analysis. The future development of urodynamic equipment and software should force investigators to conduct proper online data quality control. Analysis of ambulatory studies will remain problematic, as it is less easy to conduct online assessment of quality, and analysis is time-consuming. Hence, it will be necessary to ask the patient to return, on another occasion, should the investigation require repeating, for whatever reason.

CONCLUSIONS

This is the first report of the ICS Standardization Committee of Good Urodynamic Practice. The authors are well aware that this is just a first step and many more will have to follow. Only the essential aspects are considered, but if these basic standards are followed, the quality of urodynamic studies will be significantly improved.

ACKNOWLEDGMENTS

The standardization committee is grateful for the extensive editing performed by Vicky Rees, ICS administrator. The committee is also grateful for the detailed comments received from Linda Cardozo, Paul Dudgeon, Guus Kramer, Joseph Macaluso, Gerry Timm, and Alan Wein.

Appendix G

Developing Evidence-Based Standards for Diagnosis and Management of Lower Urinary Tract or Pelvic Floor Dysfunction*

Peter F.W.M. Rosier, Dirk de Ridder, Jane Meijlink, Ralph Webb, Kristene Whitmore, and Marcus J. Drake

INTRODUCTION

One of the most recognized activities of the International Continence Society (ICS) has been the publication of standardizations of terminology for diagnosis and testing in functional urology. This work started in 1976, with subsequent updates.

The 1988 [1] and the 2002 [2] reports, with ±1000 and ±2500 citations, respectively, are among the most widely quoted publications in urology.

There have been two particularly important categories of publication. The first is the standardization of terminology, such as the "Standardization of Terminology of Lower Urinary Tract Function" [2]. Standardized definitions of key medical terms with international consensus are increasingly needed as analysis and registration in health care become ever more automated and communication increasingly global. The establishment of the International Health Terminology Standards Development Organization (http://www.ihtsdo.org/index.php?id¼502) signifies the increasing weight attached to the agreed definitions of terminology to describe conditions at a fundamental level in medicine. The second category deals with the provision of guidelines for quality control and improvement of standards, which serve as a benchmark for professional activity, exemplified by the "Good Urodynamic Practice" document [3].

ICS standards and standardization have led the way and have been widely accepted. The process by which they have been produced has been based on intensive expert discussion and consensus with input from the ICS membership, but without inclusion of the published evidence in a systematically weighed and transparent manner. The most recent report, a joint report with the International Urogynecological Association [4,5], was developed in a similar manner. Ease of modern electronic communication has allowed more experts to monitor the content of draft editions of newer documents. This has meant that expert opinions were included in a "numerically" more balanced manner. However, no "methods" paragraph was given to explain explicitly how decisions on topics to include were made nor how evidence and expert opinion were prioritized, included, or excluded beyond acknowledgement of the commenting experts in a final paragraph.

Ideally, only "genuine evidence" is included in standards and guidelines. Where genuine evidence is lacking or conflicting, it is preferable that expert opinion is separately added to recommendations in a transparent and explicit manner. In the mid-1980s, a group led by David Sackett, a key figure in evidence-based medicine (EBM) [6], developed a systematic approach to evaluate published evidence, after he analyzed the problem of "observer error" in the interpretation of medical literature [7]. "EBM is the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients. The practice of EBM means integrating individual clinical expertise with the best available external clinical evidence from systematic research" [8]. Standards to produce evidence-based clinical practice guidelines have been developed [9], with guidance manuals [10].

EBM as a strategy to improve health care is not disputed, but the implications in a rapidly expanding field of knowledge are substantial [11]. In the modern era of information technology, transparency, accountability, and complex multidisciplinary responsibilities cannot be ignored; expert opinion is only acceptable where evidence is lacking and must be clearly marked and explained as being expert opinion.

The ICS Standardization Committee recognized the importance of adhering to EBM principles. In

2010, a reorganization took place from which the renamed Standardization Steering Committee (SSC) emerged. A key difference between the new SSC and the old Standardization Committee is that the SSC does not itself deliver standardization documents; instead, it oversees ad hoc working groups (WGs) (see in the succeeding text) that deliver the documents, aiming to ensure transparency, balance, and adherence to the methods and principles of EBM. The SSC chairman is elected from the ICS membership according to the ICS articles and bylaws. The chairman and the SSC members serve for a term of 3 years, once renewable.

The ICS SSC aims to ensure ongoing development of high-quality terminology and/or practice standards, for guidance of professionals dealing with the basic scientific investigation, diagnosis, and management of lower urinary tract, pelvic floor, genital, and anal function and dysfunction. Developing these standards requires transparency and integrity; the SSC's process and expectations for modern-day development of some of the most important ICS documents are described in the succeeding text and illustrated in Figure G.1.

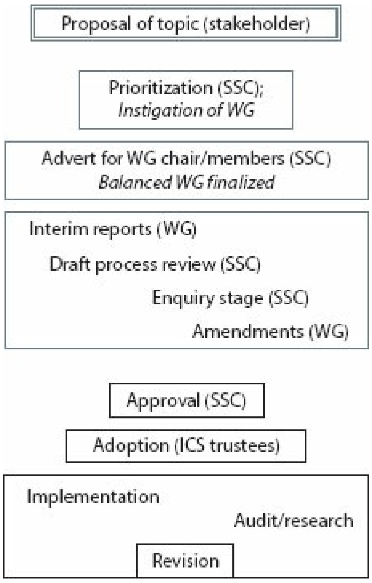

Figure G.1 Summary diagram of the key stages in the development of an International Continence Society standard (SS C, Standardization Steering Committee; WG, working group).

PROCESS OF DEVELOPING AN ICS STANDARD

Topics selected by the SSC for development or revision of standardization reports will be based on areas of priority need, whether identified by the SSC itself or in response to stakeholder suggestions. The delivery of a standardization document on a selected topic will be the remit of a specifically created ad hoc WG, which will focus on that specific subject (see Table G.1). The SSC's role is to agree the scope of the WG's activity, instigating and steering activity, checking compliance with suitable working practices, monitoring progress, ensuring adequate stakeholder input, and evaluating the end result.

Once the need for a new or revised standard has been identified, the SSC will invite applications from ICS members wishing to chair the relevant WG. The person selected will have submitted the proposal with the best strategy for developing the document in the opinion of the majority of SSC members. The SSC will evaluate proposals according to key criteria (Table G.2).

WG Composition

The selected chairperson will establish a WG of interested and knowledgeable individuals from a multinational and interdisciplinary background, representing all key stakeholder groups. Technical expertise relevant to the WG's remit will be taken into consideration in the selection of members. The WG will also be permitted or asked by the SSC to invite input from outside consultants where this is needed. This will typically be applicable in specialist contexts that are not widely represented within the ICS, such as engineering, computer sciences, or data handling. It may also be relevant in other fields, such as consumer perspectives or economic issues.

The SSC will ensure a transparent process for selection of WG members and will evaluate and adapt the composition to ensure a balance between different viewpoints (professional, patient, and other stakeholders’ perspectives). Once agreed, the proposal and the names of the WG’s members will be published on the ICS website. If a member of the SSC is also a member of a WG, he/she will not be included in SSC decisions related to that particular WG. All (potential) conflicts of interest will be published on the ICS website.

Table G.1 Structure and Function of Standardization Document Working Group

- The composition needs to be multidisciplinary and multinational, representing the most important stakeholders (including, e.g., patient representatives, health economists, and others as appropriate).
- Non-ICs members can be part of the WG as experts or representatives of specific stakeholders.
- The WG should generally not include more than 15 people.
- Selection of WG members should follow a transparent process, which is recorded and publically available.
- Additional contributions to a WG’s deliberations can be received from outside individuals.
- The WG should not receive any sponsorship from industry and the members should disclose all relationships.
- All members of the WG will be responsible for the entire content of the document as a group.
- The WG has a chairman who
    - Will propose the key question or topics of discussion to the SSC, together with a strategic plan
    - Will keep a digital working log of the WG activities
    - Will make sure that the composition of the WG is well balanced and that the process of standardization is transparent
    - Will use web-based and e-mail exchange of information and monitor the execution of assignments within the assigned timeline
    - Will adhere to EBM principles, where appropriate
    - Will report to the SSC
    - Will be responsible for production of a first draft of the report within a stipulated time frame (generally 18 months)
    - Will be responsible for submission for publication and dissemination
- After publication of the standard, the WG will be dissolved.
- A typical lifespan for an ad hoc WG will maximally be 36 months. If the WG fails to be productive, the SSC dissolves the WG.
- The ICS or ICS SSC will not provide financial budget for face-to-face meetings of any ad hoc WG.

Table G.2 SSC Criteria for Assessing WG Proposals

- Title of the project
- Name of applicant
- Description of the topic: The arguments for creating the WG are (explain why one or more of the following arguments are relevant)
    - Area of clinical uncertainty or “debate” exists
    - Evidence of better treatment is available
    - Evidence for renewal of the existing standard is available
    - Evidence of practice variation is available
    - Other clinical or scientific relevance
    - There is significant controversy in practice or literature
    - There is conflicting or incomplete evidence
    - There are cultural differences in practices or viewpoints
    - There is socioeconomic relevance
- List of proposed names (with CVs)
    - Confirmation that individuals have agreed to contribute
    - Evidence of multinational and interdisciplinary balance
    - Opportunity for ICS members to apply to join the WG and transparent, documented process for selection
    - Process to register contributions from individuals or groups not in the WG
- Description of the methodology and how it will be used:
    - Web-based approach
    - E-mail
    - Conference calls or webcasts
    - Face-to-face meeting (mainly during ICS international meetings)
    - Proposed timeline
- Description of topic, proposed WG composition, likelihood of
    - Implementation, likelihood of publication, innovation of approach, realistic timeline, use of electronic tools

Stages of a Standard

Stages through which a standardization document will progress are summarized in Table G.3. These will be listed in the project management-working log of the WG and the chairperson of the WG should report progress to the SSC. The SSC will provide a mentor for the WG, who will evaluate the progress at least every 6 months and be available if any problems arise. The mentor will keep a log of these contacts.

Table G.3 Development of an ICS Standard

	Timescale (months)	**WG**	**SSC**
Proposal stage	−6 to 0	Applications for chairmanship or membership	Call for applications. Review subject, chair, group, criteria, timeline, and starting date
Preparatory stage	0 to 18	WG constituted. Development of draft	Evaluate progress. Appoint mentor. Evaluation (at least every 6 months)
Committee stage	18 to 21	Draft submitted to SSC	Review of the process and document against criteria. Approval by consensus
Enquiry stage	21 to 24	Draft on ICS website	Internal and external review. Comments by ICS members and stakeholders
Approval stage	24 to 27	Submit final document to SSC	Process review, Submission to ICS Board of Trustees.
Publication	27 to 36	Final text to ICS office for web publication. Journal submissions	official ICS document. WG dissolved
Implementation stage	>36		Support implementation. Education (with ICS Education Committee). Register of comments. Identify research needs. Support health technology and economic assessment
Revision stage		Submit proposal to SSC	Start new process

Preparation of a Draft Report

The WG will prepare successive working drafts, circulating the drafts, and amending according to comments, until the group is satisfied that it has developed the best solution for the subject being addressed. Standards should adhere to EBM principles, where appropriate and possible. At an early stage, therefore, the WG has to devise a strategy for a comprehensive review of published literature and use an inclusive and transparent approach to derivation of expert opinion. It might sometimes be necessary to use the Delphi method [12]. Each WG will ensure a strategy for capturing and assimilating the views of all groups of stakeholders and criteria for inclusion or exclusion of these views in the finished document.

Throughout, the WG’s chairperson is responsible for

- Keeping a digital log of the WG’s activities
- Documenting the methods that were used to produce the draft document
- Promoting web-based and e-mail exchange of information and monitoring the execution of assignments within the agreed timeline
- Reporting to the SSC
- Producing a first draft of the report within 18 months

Committee Stage (Assessing the Process of Standardization)

As soon as a draft is available, the chairperson of the SSC will forward it to all the members of the SCC for internal process review. The process by which the draft standard was created will be evaluated according to preset criteria. The document requires SSC approval prior to progressing to the next stage of development. The SSC may require revisions or amendments that will need to be undertaken by the WG in a defined time frame. A document that fails to meet the objectives or was not developed in accordance with the appropriate approach will be rejected, and the WG will be dissolved.

Enquiry Stage (Wider Assessment of the Content of the Document)

The actual assessment of the content of the document will be undertaken by internal and external experts (invited by the SSC) and the ICS membership. The draft standard will be circulated to all members by website publication for commenting over a period of 3 months.

Approval Stage

The WG should resubmit the final version based on the comments received. Explicit criteria for the inclusion or exclusion of comments should be developed and each comment should be accompanied by a narrative explaining the reason why it was either included in or excluded from the final version. All comments and accompanying narrative will be published on the relevant document web forum. The revised version should be resubmitted to the SSC for process review and assessment of the amendments. If approved, the document and the log of the development process will be sent to the ICS Board of Trustees for confirmation and adoption.

Publication

Once the board has confirmed and adopted the document and the process, the final text will be published on the ICS website and will then be referred to as the new ICS standard, superseding previous standards. Thus, the new report must outline where it differs from previous reports. The WG will be encouraged to submit the document as an ICS Standard to Neurourology and Urodynamics, and the SSC will advise in this process. Copublication with other journals can be considered if relevant, within copyright regulations. Publication of the respective ICS standard will conclude the WG's activities.

Implementation Stage

The ICS SSC will promote the implementation of the standards by publication, dissemination, and education and the proposing of new standards to its affiliate and collaborating societies and organizations. Additionally, the SSC will monitor the undertaking of clinical audit based on the ICS standards' recommendations as a key aspect of successful introduction of the documents into mainstream practice [13] and the undertaking of the research and development necessary for ongoing development of the evidence base.

Standards will be written in UK English. Translation into other languages will be supported; for terminology standards, this will require that appropriate linguistic validation procedures are followed (for an example of the application of linguistic validation in the context of translation of symptom assessment tools, see Acquadro et al., 2006).

Revision of Standards

The ICS SSC will also keep track of comments that are received for consideration during a future revision of the standard text, as well as identifying future research needs. A revision or update can be proposed by the SSC or any ICS member or group of ICS members when there is a perceived need, and the timescale for anticipated revision of a standard will be specified at the time of adoption—subject to future developments in the field. The SSC can discuss not to revise outdated documents and declare them obsolete.

CONCLUSIONS

In developing evidence-based standardization documents, the ICS SSC aims to ensure inclusiveness, responsiveness, transparency, accessibility, flexibility, and evolution. The ICS SSC presents a structured process for ad hoc WGs to develop ICS standards and a strategy to guide that process. Consequently, each WG will be responsible for several stages of development, each clearly documented, until a high-quality document has been approved as an ICS standard.

The presented structure and strategy place emphasis on the principles of EBM and transparency in the development of ICS standards. They also provide the flexibility necessary for the varied nature of the initiatives established by the ICS, where multiple stakeholders are generally present, and also circumstances in which the evidence base may be limited. ICS standards will continue to be adopted and promoted as the basis for good professional practice, suitable for the demands of the modern era of

EBM.

Appendix H

Standardization of Dynamic Magnetic Resonance Imaging Measurements of Pelvic Organ Prolapse: Can the PICS Line Help?*

Diaa E.E. Rizk and Ralf Tunn

Dynamic magnetic resonance imaging (MRI) of the pelvis has been rapidly introduced into urogynecological research and practice in recent years mainly to address the shortcomings of clinical assessment systems in women with pelvic organ prolapse (POP). The primary objective was to better select candidates for surgical intervention and choose the appropriate procedure in order to reduce recurrences by allowing accurate identification and objective measurement of prolapse and simultaneous topographic assessment of the pelvis at rest and straining [1–5]. MRI is particularly indicated in women with multicompartment POP and in those who had undergone previous repair, as imaging can reveal more extensive prolapse than physical examination alone with detection rates similar to other conventional fluoroscopic and ultrasound methods [1,3,4]. Staging of POP using MRI has also been suggested by measuring the perpendicular distance between several reference points and lines in each compartment at rest and after straining [1–5]. The two most commonly used lines are one connecting the inferior aspect of the pubic symphysis to the last coccygeal joint, the pubococcygeal line (PCL), and one extending caudally along the long axis of the symphysis pubis, the midpubic line (MPL). Several MRI staging systems have been published for both of these lines [1,3,4].

Despite the widely accepted role of MRI in supplementing clinical evaluation and management of women with POP, this imaging modality has certain limitations. Most importantly, so far, there has been no standardized technique for performing MRI examination of the pelvis. Imaging protocols vary according to patient positioning, filling media, pelvic organ opacification, patient maneuvers (i.e., rest, Kegel, Valsalva, evacuation), and MRI sequences and planes [1–5]. Most of the available imaging systems are unable to demonstrate the full extent of POP because patients are examined in a supine position promoting current efforts to image patients in the sitting and upright position using open-magnet MRI units [1,3–5]. In fact, sagittal plane images of women with POP that are commonly displayed in the literature as if taken in the upright position had been made in the supine position [6]. A further major problem with MRI studies of the pelvis is the incomplete reproducibility and lack of standardization of the patient effort exerted during straining [3–5].

The anatomical landmarks used for pelvic measurements are easily identified in MRI, and this is expected to increase the validity of measurement [5]. The intra- and interobserver reliability of most MRI measurements is, however, rarely described in POP studies [2]. Furthermore, the reference line used for MRI interpretation of POP is not consistent in all studies as this is often based on radiologist experience and referring physician preference [1,5]. In a recent systematic review, seven different reference lines in relation to a wide variety of reference points have been used in different studies with imprecise definition or interchangeable use of some lines, e.g., “MPL/hymenal line” and “PCL/sacrococcygeal inferior pubic point line” [2]. Although the MPL corresponds anatomically to the level of the hymen on cadaveric dissection, the landmark used for clinical staging of POP, the reliability of MRI using the MPL versus clinical findings in women with POP was lower than that of the PCL in most reports [1,2].

It is obvious that we lack a proper validation system for interpreting MRI measurements of POP, and we urgently need to reach a consensus on a more standardized and scientifically robust MRI protocol for examination of the pelvis. Betschart et al. review this topic further in a seminal clinical opinion [6]. The authors discuss the strengths and weaknesses of the current pelvic reference systems for dynamic MRI studies of POP. They clearly demonstrate, after analyzing their database of pelvic MRI scans from 149 women with and without POP, that existing reference lines can produce different measurements because of the following three factors:

1. The distances measured to the reference line vary with anteroposterior location in oblique line systems.
2. The soft tissue–based reference lines can underestimate organ movement relative to the pelvic bones.
3. The systems defined relative to the scanner are affected by intra- and interindividual differences in the pelvic inclination angle at rest and strain.

Based on these findings, Betschart et al. propose a standardized MRI measurement system for POP called the pelvic inclination correction system (PICS), which allows standardized measurement of organ displacement in the direction of prolapse by controlling for variation in pelvic inclination, at rest or straining, bony structures, and the body axis [6]. The hypothesis is biologically plausible since variations in pelvic inclination alter the direction of intra-abdominal vector forces and the degree of transmission of abdominal pressure onto the pelvic floor, thereby influencing the development of pelvic floor weakness and subsequent prolapse [7].

The PICS line, a new reference line, is a significant novelty in the standardization of pelvic floor measurements using MRI. Classifications and reference systems are widely used in medicine and define groups by similar properties, e.g., the POP-Q system for the clinical staging of POP or the TNM system for the staging of cancer. The PICS line allows the determination of descent of any pelvic organ in a standardized way, independent of the location of the pelvis in the scanner, whether it is tilted, flexed, or extended, the size or shape of the pelvis, and the orientation between different examinations or individuals. The advantages of this new system are as follows:

1. It is capable of measuring the line of the body axis.
2. It results in reliable distance calculation independent of the anteroposterior midsagittal location of the organ because it is not oblique.
3. It is related to a bony landmark (pubic bone).
4. It follows the movements of the pelvis.

The most significant value, however, is that the PICS line measures the prolapse (or any organ of interest) in the line of gravity, that is, the natural vector/direction for urogynecological disorders.

The development of the PICS is a product of a fruitful and interdisciplinary collaboration of the Michigan Pelvic Floor Research Group, led by Dr. John DeLancey, which implemented the basic geometrical theorems to solve this measurement problem. Since the group published their first article about the standardized MRI investigation technique in 2001 [8], this contribution 12 years later shows how long the research process takes and how important the ongoing process of standardization of MRI measurements of POP is [6].

Introduction of the new PICS reference line and, hopefully in the future, a new reference plane to measure distances out of the midsagittal plane is an important step in the field of urogynecology toward obtaining standardized and comparable measurements for both clinical practice and research. Until more prospective data are available on the reproducibility of the PICS line in larger and more diverse populations of women with POP, imaging of the pelvic organs using error correction models would assist in establishing a uniform diagnostic and classification system for describing structural defects. It remains to be seen whether the PICS line could also be applied to ultrasound measurements of POP to support routine preoperative imaging of women with single-compartment prolapse, whether or not surgical treatment is contemplated. We also believe that the PICS line will improve our understanding of the pathogenesis and risks of global pelvic floor dysfunction in women by standardizing the reporting of anatomical variations of the levator ani muscle and endopelvic fascia and correlating this with supportive function.

  pad tests and, 308
  relationship with incontinence severity, 345–346
  relationship with stress continence outcomes, 346
  stress urinary incontinence, 346
  technique, 343–344
  test-retest reliability, 344
  unsuccessful burch/pubovaginal sling, 346
  UPP
    technique, 347–348
    urethral pressure profile and, 349
    urodynamic catheter size and location, 344
Valsalva maneuver
  bladder emptying, 294
  3D/4D ultrasound, 404
Vanilloid agents, 532
Vanilloid receptors, 257
Vardenafil, 528
Vascular abnormalities and hypoxia, 634
Vascular injuries, laparoscopic surgery, 1122
Vasculature
  anterior abdominal wall, 1123
  pelvic, 1081
  urethral submucosal, 200–201
Vecchietti procedure, laparoscopic, 1251
Venous thromboembolism (VTE), 708
Ventouse/vacuum delivery
  fecal incontinence and, 68
  urinary incontinence and, 68
Verapamil, 525
Vesico-bulbo-vesical micturition reflex, 248–249
Vesicoscopy
  antireflux system, 1146
  antireflux techniques, 1150–1151
  antireflux ureteric replantation, 1143
  bilateral reflux, 1146–1147
  bladder
    distension, 1148–1149
    diverticulectomy, 1147
    endometriosis, 1147–1148
    suspension, 1149
  congenital pelvic nephroureteric remnant, 1147
  distal ureteric stricture, 1146
  ectopic ureter in duplex system, 1146
  experience, 1143
  fistula repair, 1150
  foreign body, 1147–1148
  patient position, 1149
  percutaneous access, 1148–1149
  percutaneous bladder surgery, 1150
  Pfannenstiel, 1143–1144
  postoperative events, 1148
  supine retroperitoneoscopy, 1143–1145, 1150
  transperitoneal transvesical laparoscopy, 1151
  ureteric remnant postnephrectomy, 1147
  vaginal access, 1143–1144
  vesicovaginal fistula, 1144–1145

Vesico-spinal-vesical micturition reflex, 249
Vesico-spinal-vesical storage reflex, 248
Vesicoureteric reflux (VUR), 357–358
Vesicouterine fistula, presentation, 1190
Vesicouterine fistula repair (VUF)
  flap coverage, 1186–1187
  laparoscopy and robot-assisted laparoscopic techniques, 1185–1186
  open repair, 1184–1185
  outcomes, 1185
  timing of repair, 1187
Vesicouterine fistulas, 1164–1165
Vesicovaginal fistula (VVF)
  complications, 1179
  conservative management, 1175–1176
  cystoscopy, 433
  cystourethroscopy, 433
  epidemiology, 53
  etiology, 1189
  glomerulations, 435, 439
  iatrogenic cystotomy, 433
  minimally invasive techniques, 1175–1176
  obstetric, 1190–1191
  prevalence, 53
  surgical approach, 1177
  surgical repair, 1176
  timing of repair, 1176
  transabdominal approach
    conventional laparoscopy, 1183–1184
    flap coverage, 1186–1187
    open repair, 1182–1183
    outcomes, 1186
    robot-assisted laparoscopic repair, 1184–1185
    timing of repair, 1187
  transvaginal repair
    Latzko procedure, 1177
    transvaginal multilayer flap repair, 1177–1179
  ureteral pathology, 1175
  urogenital fistulae, 1163–1164
  vesical necrosis, 439
  voiding cystourethrography or plain cystograms, 1175
Vestibular bulb, 1047–1048
Vginal apex, anatomic supports, 204
Video-simulation, 87
Videourodynamics (v-UDS), 339–341, 901
  accurate analysis and critical reporting, 355
  conventional urodynamic tests, 355
  fluoroscopy, 396
  future developments, 361
  indication, 355
  limitations
    anaphylactic reaction, 361
    radiation, 361
  lower urinary tract imaging, gold standard technique, 399
  measurement, 355
  vs. pad tests, 308–309
  principles, 356–357
  urogenital fistulae, 1170
Vinpocetine, 528
Viral infections, lower urinary tract, 604
Virilization, female genitalia, 1252
Virtual reality simulators, 1086
Visceral injury, 1044
visceral nociceptors, 628
Visceral pain

  pelvic, neurobiology, 626–628
  referred, mechanisms, 628
  vs. somatic pain, 628
Visual accommodation, antimuscarinic effects, 537
Visual analog scale (VAS), 176, 881
  bothersomeness, 310
  frequency, 310
Voided volume
  healthy volunteers, 322
  uroflowmetry, 316–317, 322
Voiding
  detrusor function, 1324–1325
  dysfunction, 594–596
  function, 594–596
  interval between, 488
  neural control, 594
  phase, bladder cycle, 236
  reflexes, 248
  scheduled, 468, 471, 488 (*see also* Bladder training)
  symptoms related to, 689
  timed, 606
  urethral function, 1325
Voiding and postmicturition symptoms
  female-specific terminology report, 1329–1330
Voiding cystometry, 334–336
Voiding cystourethrography (VCUG), 392, 394, 396–400, 1205–1206
  bladder prolapse, 394
  vs. other imaging techniques, 394
  quantification of bladder neck mobility, 394–397
  urethral diverticulum, 394
Voiding diary (bladder diary)
  normative values 257
  physiotherapy assessment, 479
  stress incontinence evaluation, 888
  therapeutic use, 472–473
Voiding diary, BPS/IC, 636–637
Voiding difficulty
  after anti-incontinence surgery
    allograft slings, 903
    diagnostic evaluation, 899–900
    etiology, 898–899
    identifying risks, 899
    incidence, 898
    management, 901–907
    midurethral slings, 903, 940
  after prolapse surgery, 940
  combined with prolapse surgery, 622
  drug treatment, 296, 541
  nonneurogenic, 522
  postpartum, 675
  pregnancy, 675
  symptoms, 294–295
  treatment, 296
  uroflowmetry, 322
Voiding dysfunction (VD)
  ambulatory urodynamics, 371–372
  associations of diagnosis, 621–622
  bacterial cystitis, 649
  classification, 273–277
    expanded to include pelvic floor activity, 273–277
    by function/activity, 270–271
    by symptoms, 270–271
  CNS targets, 249
  criteria for diagnosis, 621

  definition, 1344–1345
  diagnoses, 1344–1345
  diagnosis, 621–622
  facilitating urine storage, 297
  peripheral targets, 252
  prevalence, 621
  principles, 249
  screening tests, 622–623
Voiding symptoms, IUGA/ICS definitions, 612
Voiding time, 316, 322
VR-assisted robotic surgery, 87
VR-haptic system, 87
Vulvar pruritus, 664
Vulvovaginal candidiasis (VVC), *see* Candida vulvovaginitis
V-wedge labiaplasty, labia minora, 1276–1277

Warning time
  effects of darifenacin, 519
  measurement, 519
Water, cystometry filling medium, 330
Weight loss, prevention of incontinence, 67, 474
Weight transducer uroflowmeters, 613
Wexner constipation score (grade C), 148
Wexner scores (grade C), 146–147
Whistle-tipped catheter, 503
WHO surgical safety checklist, 85
Willingness to pay assessment, 182
Wireless biofeedback devices, 484, 486
Wireless motility capsule (WMC), 734
Wolffian ducts, 218
Women’s Health Australia, 35
Women’s Health Initiative (WHI) study, 18, 531, 705
Work
  heavy lifting, 714–715, 924
  pelvic organ prolapse and, 924
Work Productivity and Activity Impairment (WPAI), 102
Work Productivity and Activity Questionnaire (WPAI), 183
World Health Organization (WHO)
  definition of health, 22, 110
  definition of quality of life, 111
  episiotomy recommendation, 1049
Wound infections, laparoscopic surgery, 1125
Wrinkle reduction surface radiofrequency therapy, 1271

X-ray imaging, lower urinary tract, 394

Yolk sac, 215–216

ZD0947, 526
Zero pressure, 326, 366
Z-plasty wedge labiaplasty, labia minora, 1276
Zuidex^{TM}, 568

Table of Contents 5
Preface 14
Editors 15
Contributors 17
VOLUME ONE 38
SECTION I: BACKGROUND ISSUES 38
1 History of Urogynecology and Female Urology 39
2 Epidemiology: United States 54
3 Epidemiology: South America 67
4 Epidemiology: Europe 75
5 Epidemiology: Australia 86
6 Epidemiology: Asia 92
7 Epidemiology of Female Pelvic Floor Dysfunction in Africa 109
8 Tackling the Stigma of Incontinence 116
9 Natural History and Prevention of Urinary Incontinence and Urogenital Prolapse 123
10 Medical Error and Patient Safety in Surgery 143
SECTION II: ROLE OF PATIENT REPORTED OUTCOME MEASURES AND HEALTH ECONOMICS 166
11 Section Introduction: The Role of Patient-Reported Outcome Measures and Health Economics 167
12 Patient-Reported Outcomes: From Development to Utilization 169
13 Patient-Reported Outcome Questionnaires to Assess Health-Related Quality of Life and Symptom Impact 181
14 Patient-Reported Outcome Questionnaires to Screen and Measure Satisfaction, Expectations, and Goal Achievement 200
15 Questionnaires to Assess Sexual Function 215
16 Questionnaires to Assess Bowel Function 226
17 International Consultation on Incontinence Modular Questionnaire 234
18 Electronic Personal Assessment Questionnaire Pelvic Floor 246
19 Questionnaires to Assess Pelvic Organ Prolapse 258
20 Economic Aspects of Urinary Incontinence 271
SECTION III: STRUCTURE AND FUNCTION OF THE LOWER URINARY AND ANORECTAL TRACTS IN WOMEN 291
21 Anatomy 292
22 Embryology of the Female Urogenital System and Clinical Applications 313
23 Physiology of Micturition 335

24 Pharmacology of the Bladder 354
25 Uropathogens and the Lower Urinary Tract 380
26 Classification of Lower Urinary Tract Dysfunction in the Female Patient 385
27 Tissue Engineering and Regenerative Medicine for the Female Genitourinary System 395
SECTION IV: DIAGNOSTIC EVALUATION OF INCONTINENCE AND UROGENITAL PROLAPSE 407
28 History and Examination 408
29 Bladder Diary and Symptom Scores 423
30 Pad Tests 431
31 Basic Urodynamic Tests: Uroflowmetry 443
32 Basic Urodynamic Tests: Filling and Voiding Cystometry 456
33 Tests of Urethral Function 471
34 Special Urodynamic Tests: Videourodynamics 492
35 Special Urodynamic Test: Ambulatory Urodynamics 504
36 Basic Neurological Evaluation and Referral 520
37 Imaging of the Upper and Lower Urinary Tract: Radiology and Ultrasound 544
38 Magnetic Resonance Imaging in Urogynecology 571
39 Endoscopy 582
40 Urinalysis 622
SECTION V: CONSERVATIVE AND MINIMALLY INVASIVE THERAPIES 628
41 The Role of the Continence Nurse 629
42 Behavioral Therapies and Management of Urinary Incontinence in Women 642
43 Physiotherapy for Urinary Incontinence 655
44 Pessaries and Devices: Nonsurgical Treatment of Pelvic Organ Prolapse and Stress Urinary Incontinence 676
45 Catheters, Pads, and Pants 686
46 Drug Treatment of Lower Urinary Tract Dysfunction in Women 708
47 Peripheral Neuromodulation 756
48 Sacral Neuromodulation in the Treatment of Female Overactive Bladder Syndrome and Nonobstructive Urinary Retention 767
49 Injectable Bulking Agents in the Treatment of Female Stress Urinary Incontinence 776
50 Use of Botulinum Toxins in the Management of Female Voiding Dysfunction 786
VOLUME TWO 797
SECTION VI: ASSOCIATED DISORDERS 797
51 The Overactive Bladder 798
52 Neurological Disorders 811
53 Nonneurogenic Voiding Dysfunction and Urinary Retention 834
54 Pathophysiological Mechanisms of Chronic Pelvic Pain 852
55 Bladder Pain Syndrome/Interstitial Cystitis 862
56 Bacterial Cystitis in Urogynecology: An Update 874
57 Vaginitis 900

58 Pregnancy and Childbirth and the Effect on the Pelvic Floor 914
59 Problems Associated with Sexual Activity 933
60 Menopause 948
61 Sports and Fitness Activities 967
62 Anal Incontinence 974
63 Constipation 990
64 Female Sexual Dysfunction 1010
65 Multidisciplinary Team 1033
66 Multidisciplinary Clinic: Urology and Urogynecology 1038
67 Multidisciplinary Clinics: Specific Considerations for Elderly Care 1044
SECTION VII: SURGERY FOR URINARY INCONTINENCE 1052
68 How and Why Incontinence Surgery Works 1053
69 Peri- and Postoperative Care 1063
70 Traditional Surgery and Other Historical Procedures for Stress Incontinence 1079
71 Retropubic Urethropexy 1113
72 Fascial Slings 1129
73 Tension-Free Vaginal Tape Procedure For Treatment of Female Urinary Stress Incontinence 1140
74 Transobturator Tape for Surgical Treatment of Stress Urinary Incontinence: Outside-In Technique 1150
75 Single-Incision Minislings 1164
76 Readjustable Slings: Safyre and Remeex 1171
77 Nonsurgical Transurethral Radio Frequency Collagen Denaturation of the Bladder Neck and Proximal Urethra for the Treatment of Stress Urinary Incontinence 1186
78 Artificial Urinary Sphincter for Treatment of Stress Urinary Incontinence in Women 1198
79 Diagnosis and Treatment of Obstruction Following Incontinence Surgery: Urethrolysis and Other Techniques 1211
80 Complications of Stress Urinary Incontinence Surgery 1225
SECTION VIII: SURGERY FOR UROGENITAL PROLAPSE 1236
81 Classification and Epidemiology of Pelvic Organ Prolapse 1237
82 Anterior Vaginal Wall Prolapse 1249
83 Enterocele 1268
84 Rectocele: Anatomic and Functional Repair 1284
85 Vaginal Approach to Fixation of Vaginal Apex 1308
86 Open Abdominal Approach to Supporting the Vaginal Apex 1329
87 Laparoscopic and Robotic Approaches to Apical and Vaginal Vault Suspension 1339
88 Uterine Prolapse 1353
89 Biological Grafts in Reconstructive Pelvic Surgery 1368
90 Synthetic Grafts in Pelvic Surgery 1377
91 Complications of Synthetic Mesh Used to Repair Pelvic Organ Prolapse 1394
92 Episiotomy and Perineal Repair 1407

93 Primary Repair of Obstetric Anal Sphincter Injuries 1417
94 Surgery for Fecal Incontinence 1431
95 Rectal Prolapse and Other Causes of Fecal Obstruction 1443
SECTION IX: LAPAROSCOPY AND ROBOTICS 1450
96 Section Introduction: The Role of Laparoscopic Surgery in Urogynecology 1451
97 Pelvic Anatomy through the Laparoscope 1452
98 Training and Accreditation in Laparoscopic and Robotic Pelvic Floor Surgery 1460
99 Laparoscopic Colposuspension and Paravaginal Repair 1466
100 Laparoscopic Sacrocolpopexy 1486
101 Laparoscopic Sacrohysteropexy 1500
102 Prevention, Recognition, and Treatment of Complications in Laparoscopic Pelvic Floor Surgery 1510
103 The Role of Robotic Surgery 1524
104 Vesicoscopy 1536
105 Cost-Effectiveness in Laparoscopic and Robotic Surgery in Urogynecology 1549
SECTION X: COMPLEX PROBLEMS 1558
106 Diagnosis of Urogenital Fistula 1559
107 Transvaginal Repair of Urogenital Fistula 1575
108 Transabdominal Vesicovaginal and Vesicouterine Fistula Repair 1588
109 Management of Obstetric Urogenital Fistula 1597
110 Urethral Diverticulum and Fistula 1617
111 Diagnosis and Management of Female Urethral Stricture Disease 1647
112 Ureteral and Bladder Reconstruction 1659
113 Gynecological Developmental Abnormalities 1677
114 Pediatric Urogynecology 1690
115 Female Genital Cosmetic Surgery: From Female Genital Cutting to Vaginal Rejuvenation 1710
116 Cosmetic Vaginal Surgery 1725
117 Urological Complications of Gynecological Surgery 1752
APPENDIX A: Standardization of Terminology 1762
APPENDIX B: The Standardization of Terminology of Lower Urinary Tract Function: Report from the Standardization Subcommittee of the International Continence Society 1768
APPENDIX C: International Urogynecological Association/International Continence Society Joint Report on the Terminology for Female Pelvic Floor Dysfunction 1784
APPENDIX D: Commentary on the 2009 IUGA/ICS Joint Report on the Terminology for Female Pelvic Floor Dysfunction 1808
APPENDIX E: Standardization of Terminology of Female Pelvic Organ Prolapse and Pelvic Floor Dysfunction 1817
APPENDIX F: Good Urodynamic Practices: Uroflowmetry, Filling Cystometry, and Pressure–Flow Studies 1829
APPENDIX G: Developing Evidence-Based Standards for Diagnosis and Management of Lower Urinary Tract or Pelvic Floor Dysfunction 1845

APPENDIX H: Standardization of Dynamic Magnetic Resonance Imaging Measurements of Pelvic Organ Prolapse: Can the PICS Line Help? 1851
Index 1854
